Ontology

Ontology asks a simple question: what is actually there before an observer names it, measures it, or compresses it into a model?

For $\mathbb{AAA}$, the answer has layers. At the bottom are absolute time, the Euclidean void, and architrinos. Above that are assemblies, causal wakes, and the Noether sea. Above that are effective fields, particles, clocks, rulers, metrics, and observer records. The main rule of this chapter is that those layers must not be mixed.

This chapter is the bedrock map. It says what exists at the substrate level, what emerges from assembly and medium behavior, and which terms must stay level-aware for the rest of the corpus to remain coherent.

Purpose and Scope

This document establishes the ontological bedrock of $\mathbb{AAA}$: what fundamentally exists, what is emergent, and what Physical Observers reconstruct from inside the system.

It defines six foundation routes:

1. **The Substrate**: absolute time, Euclidean void, and absolute timespace.
2. **The Fundamental Entity**: architrino, the point transceiver of potential-bearing causal wakes.
3. **The Physical Medium**: Noether sea, the emergent physical medium formed by coupled neutral Noether braid assemblies.
4. **The Observer Framework**: complete-state versus Physical Observer access.
5. **Terminology Discipline**: canonical level-aware terminology.
6. **Parameter Ledger**: fundamental postulates versus derived quantities.

The nine foundation chapters have distinct ownership:

Chapter	Document role
Ontology	Hub for layer assignments, postulate ownership, and navigation.
Absolute Time	Canonical owner of Postulate 1, temporal ordering, affine normalization, and delayed-only support.
Euclidean Void	Canonical owner of Postulate 2, the fixed spatial metric, and container symmetries.

Chapter	Document role
Absolute Timespace	Canonical owner of Postulate 3, the product foliation, causal-wake geometry, and the observer-metric handoff boundary.
Architrino	Canonical owner of Postulate 4, primitive identity, polarity, provenance, and point-transceiver status.
Emergence of Structure	Owner of the bottom-up assembly ladder, context-to-branch selection, and emergence claim discipline.
Absolute Time Defense	Argumentative and falsifiability companion for clock, ruler, and preferred-frame recovery.
Detecting the Absolute Frame	Owner of the complete-state rest diagnostic and tagged-wake center reconstruction.
Constructing the Absolute Frame	Owner of coordinate-frame reconstruction from nondegenerate complete-state data.

Read the substrate owners first, then Architrino and Emergence. The preferred-frame sequence is Detecting, Constructing, and Absolute Time Defense; it moves from complete-state identifiability to coordinates and then to the observer-level hiding burden.

Canonical Postulate Ownership

The Summary Postulate in each owning chapter is the single canonical wording. The shorter blocks in this hub are abridged routing statements, not competing formulations.

Postulate	Canonical owner
Postulate 1: Absolute Time	Absolute Time
Postulate 2: Euclidean Void	Euclidean Void
Postulate 3: Absolute Timespace	Absolute Timespace
Postulate 4: Architrino	Architrino

The point is not to make every later result true by definition. The point is to keep the starting inventory clean. Dynamics, assembly mappings, particle families, effective spacetime, and cosmology all depend on these foundations. If the level assignment is wrong here, the error propagates everywhere else.

The teaching order uses four levels:

Level	Plain meaning	Typical examples
Substrate ontology	What exists before observer reconstruction.	Absolute time, Euclidean void, architrino identities, intrinsic polarity, causal-wake support.
Assembly and medium behavior	What organized architrino configurations do.	Noether braids, stable branches, Noether sea density, stress, flow, and response.

Level	Plain meaning	Typical examples
Effective description	What observers can summarize as familiar physics.	Metric, field, particle, mass, charge, clock, ruler, and potential language.
Observer inference	What embedded Physical Observers can actually record.	Detector records, clock readings, coincidence windows, spectra, quantum states, and coarse histories.

This ontology also has a boundary. It states the internal bedrock of $\mathbb{AAA}$. It does not claim to explain why absolute time, the Euclidean void, the architrino identity set, c_f, or κ exist rather than not exist. Those are primitive postulates inside the present theory unless a separate meta-ontological account is supplied.

That distinction matters. Deriving particles, fields, clock behavior, and effective spacetime from architrino dynamics is one kind of explanation. Explaining why the substrate itself exists is a different kind of claim.

The same level discipline can be read through the canonical symbol map:

Level	Canonical variables or records	Owning chapters
Substrate ontology	T, Σ_T, h_{ij}, $\mathbf{X}_a(T)$, q_a, causal-wake support	Absolute Time, Euclidean Void, Absolute Timespace, Architrino
Assembly and medium behavior	assembly closure labels, including the current concrete Λ_{A1} instance, plus $\rho_{\rm NS}(\mathbf{X},T)$, $\Sigma_{\rm sea}(\mathbf{X},T)$, $\mathbf{u}_{\rm sea}(\mathbf{X},T)$	Noether Braid, A1 Dynamics, Noether sea
Effective description	$A(\mathcal{N}_{\rm sea})$, $B_{ij}(\mathcal{N}_{\rm sea})$, $u^i_{\rm sea,eff}$, $g^{\rm eff}_{\mu\nu}$, $\Phi_{\rm eff}$	Emergent Metric, Proper Time and Time Dilation, Particle Masses
Observer inference	$\Pi_{\rm obs}: S(T) \to \bar{S}(T)$, Physical Observer records $\Theta_A^{(O,W)}$, detector and measurement records	Observer Framework, Wavefunction Ontology, Measurement Ontology

Equivalently, the four levels form a tower of forgetting maps:

$$S(T) \xrightarrow{\Pi_{\rm assembly}} \mathfrak{B}(T) \xrightarrow{\Pi_{\rm eff}} \left(A, B_{ij}, g^{\rm eff}, \Phi_{\rm eff}\right) \xrightarrow{\Pi_{\rm record}} \bar{S}(T).$$

Here $\mathfrak{B}(T)$ denotes the retained assembly and branch records and $\Pi_{\rm record}$ is the final record-extraction arrow. The canonical observer projection is the composite $\Pi_{\rm obs} = \Pi_{\rm record} \circ \Pi_{\rm eff} \circ \Pi_{\rm assembly} : S(T) \to \bar{S}(T)$, refining the monolithic definition in Architrino. Pullback of retained information along the tower induces a decreasing filtration on $S(T)$. Each arrow keeps some information and discards some information. Individual provenance labels, path-history depth, inactive branch alternatives, fine assembly coordinates, medium microstate, and apparatus-inaccessible records may be lost at different stages.

A quantity is well-defined at a level only if it survives the corresponding forgetting map. A residual measures failure to survive that quotient. Examples include provenance leakage $\epsilon_{\rm prov}$, branch or record residuals $\mathcal{R}_Q$, clock-composition residuals $\Delta^{\rm comp}$, and clock-universality residuals ϵ_{univ}. This is why level discipline is not only vocabulary discipline. It decides which invariants remain meaningful after a projection.

Many projections also need regularity. A reconstruction or projection map is locally usable only where its active inverse has a declared non-degeneracy floor:

Floor	Guarded map	Failure meaning	Owner
$\kappa_{\text{hit}} > 0$	causal-root chart	fold, caustic, or root-count transition	Master Equation
$\sin\theta_{\min} > 0$	ordered-tuple frame construction	collinear or ill-conditioned basis	Constructing the Absolute Frame
$\omega_{\min} > 0$ or $\lambda_{\min}(G_a) \geq \lambda_{\min}^{\text{ctr}} > 0$	wake-center inverse	insufficient aperture or rank-deficient center fit	Detecting the Absolute Frame
$\kappa_{\text{sep}} > 0$	basin separator	unstable, riddled, or unresolved branch partition	Emergence of Structure
$\sigma_{\text{cr}} > 0$	clock/ruler handoff	rank loss or locally multivalued metric export	Absolute Time Defense

The shared theorem target is a reconstruction-regularity lemma: away from the generically codimension-1 floor-failure locus, the relevant map has controlled local inverse behavior. At the floor failure, the theory must report a residual, branch jump, or reconfiguration event rather than silently reusing a smooth chart.

Two distinctions govern the rest of this hub.

First, primitive substance is not the same as emergent matter. The architrino is primitive substance. Matter begins only when assemblies acquire mass, exclusion, persistence, and organized branch behavior.

Second, physical reality is not the same as independent material inventory. Causal wakes are physically real, finite-speed, potential-bearing causal records. They are not an extra material ingredient floating in the void. Their content is fixed by transmitter identity, polarity, and path history.

A conservative entry criterion for emergent matter status is therefore two-part. A stable assembly A must carry a nonzero closed internal causal-history energy ledger $E_{\text{internal}}(A) > 0$ as defined in Energy, and it must carry an assembly-level exclusion record protected by retained curve-configuration topology plus a branch-preserving action or energy barrier. The Euclidean void supplies no ambient topological superselection. The protected data must be carried by the assembly itself, for example by an oblate spheroidal exclusion envelope together with the ordered-frame, framed linking, or causal-writhe data needed for fermionic matter, and by a nonzero barrier $\Delta E_{\text{excl}} > 0$ against deformation through the forbidden branch. This is an entry criterion for the mass-map and exclusion programs, not a completed derivation of particle masses or spin-statistics.

The Substrate

The substrate is what $\mathbb{AAA}$ treats as fundamental. It is not what a local observer necessarily sees. It is the underlying stage and primitive inventory from which observer-level physics must be reconstructed.

Absolute Time

Absolute Time is the canonical substrate-level specification of the universal time parameter T. It defines time as a one-dimensional, continuous, oriented, non-dynamical continuum $\mathbb{R}$ with absolute event ordering, no kinematic time dilation, no relativity of simultaneity, and no reparametrization freedom beyond unit choice and origin choice: constancy of c_f and form-invariance of the receiving law pin T to its affine class.

The abridged routing statement is:

> **Abridged Postulate 1 (Absolute Time):** Time is an absolute, universal, one-dimensional continuum $\mathbb{R}$ with fixed orientation, a scale anchored by the constant primitive wake speed c_f and the receiving law, frame-independent duration, non-dynamical status, and no substrate-level time dilation or relativity of simultaneity. Dynamics occur through finite-speed causal-wake propagation (c_f) in absolute time, with all interactions routed through path history rather than instantaneous action-at-a-distance or advanced effects; worldlines are parametrized directly by T, with no reparametrization freedom beyond unit choice and origin choice.

This postulate is not a claim that embedded clocks all read the same rate. Clock slowing, synchronization offsets, and proper-time readings belong to assembly and Noether sea dynamics at the observer-accessible level.

For the argumentative case, see Absolute Time Defense. For observer-level clocks and dilation, see Proper Time and Time Dilation.

Euclidean Void

Euclidean Void is the canonical substrate-level specification of the fixed spatial container. It defines three-dimensional space as flat, homogeneous, isotropic, non-dynamical $\mathbb{R}^3$ with metric $h_{ij} = \delta_{ij}$, fixed coordinate identity, Euclidean distance, spatial operators, and Euclidean symmetry group $E(3)$.

The abridged routing statement is:

> **Abridged Postulate 2 (Euclidean Void):** Space is an absolute, static, flat, homogeneous, isotropic container $\mathbb{R}^3$ with fixed Euclidean metric $h_{ij} = \delta_{ij}$. Curvature-like observations arise

> from contents, wakes, and dynamics inside the void, not from curvature of the void itself.

This is a container claim. It does not deny that observers can reconstruct curved effective geometry. The Noether sea is physical content within the void, not the void itself. For the Noether sea branch, see Noether sea, Noether Sea Pro/Anti Coupling, and Emergent Metric.

Absolute Timespace

Absolute Timespace is the canonical product-structure specification for the background arena $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$. It owns the foliation into simultaneous Euclidean slices, the separated clock-form/spatial-metric data (dT, h), Galilean kinematic structure, product measures and spatial operators, and causal wake geometry.

The abridged routing statement is:

> **Abridged Postulate 3 (Absolute Timespace):** The background arena is the product manifold $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$, equipped with the exact substrate clock form dT and Euclidean spatial metric $h_{ij} = \delta_{ij}$, foliated by absolute-time slices Σ_T. The background is non-dynamical and non-curved; causality is ordered by T and constrained by finite wake speed c_f. The product background preserves Galilean kinematic structure, while the interaction law, by fixing the wake speed c_f relative to the void, structurally distinguishes the void rest frame.

The product notation packages the substrate clock and the spatial container. It does not introduce a non-degenerate four-dimensional metric as primitive ontology. Relativistic spacetime language enters only after medium response, clock/ruler behavior, and signal reconstruction have been derived or modeled.

For the factor-level specifications, see Absolute Time and Euclidean Void. For the observer-level metric bridge, see Emergent Metric.

The Fundamental Entity

Architrino is the canonical primitive-entity specification for $\mathbb{AAA}$. It defines the architrino as a point transceiver in absolute timespace with definite polarity, persistent identity, continuous causal-wake emission, universal wake reception, and non-creation/non-destruction at the ontological level.

The architrino is the sole primitive material substance of the theory. That does not make an isolated architrino a matter particle. Rest mass, spatial exclusion, fermionic behavior, and particle species are downstream assembly properties.

The same caution applies to exchange behavior. Fermion and boson exchange labels are assembly-level recovery targets, not inserted projector postulates. Any effective antisymmetric or symmetric exchange label must be routed through a retained assembly closure label and the ordered-frame spinor program. The current concrete braid instance is Λ_{A1}; no separate generic `NS` taxonomy is introduced.

The hard wall is the two-assembly exchange loop. An exchange of two identical braids is a loop in the configuration space of retained assembly configurations, not in the topology of the ambient void. The ambient quotient does supply a candidate loop class: for two identical centers in $\mathbb{R}^3$, the unordered coincidence-free configuration space has fundamental group $\mathbb{Z}_2$ generated by the exchange loop, the Leinaas-Myrheim/Laidlaw-DeWitt class. What the void does not supply is superselection: nothing forces a recovered effective state to transform nontrivially around that loop. The fermionic route must therefore establish two facts about the retained dynamics. The dynamically retained framed two-assembly component must not trivialize the exchange class after the allowed quotient, and the recovered effective state bundle must carry holonomy -1 around it. If either fails, whether the class dies in the retained component or the holonomy is trivial, the antisymmetric projector has not been recovered from assembly dynamics and would have to be inserted at the effective level. The generic failure mode is trivial holonomy, not a missing loop class.

The architrino's intrinsic polarity is also not the full observer-level charge record. Electric, weak, color, and particle labels are effective bookkeeping to be recovered from assembly geometry and medium response.

The emitted causal wake is not another primitive substance, but it is real. It is the source-dependent, potential-bearing causal record by which path history becomes delayed interaction.

The load-bearing ontology claim is a dependency claim: once transmitter identity, polarity, and path history are fixed, no additional freely specifiable wake substance remains. The schematic transmitter-history functional and its point-transceiver regularity boundary are owned by Architrino; the causal-root sum, Jacobian, transversality floor, and acceleration weight are owned by Master Equation. Effective field language may summarize many wake contributions, but the substrate account remains source-provenanced causal-wake history.

The abridged routing statement is:

> **Abridged Postulate 4 (Architrino):** The architrino is the sole primitive entity of $\mathbb{AAA}$: a point transceiver in absolute timespace with definite polarity, persistent identity, continuous causal-wake emission, universal wake reception, and non-creation/non-destruction at the ontological level. The set of architrino identities is fixed. Particles, effective fields, clock behavior, and emergent spacetime phenomena arise from architrino configurations, wake intersections, and assembly dynamics rather than from additional fundamental substances.

For the full primitive-entity page, see Architrino. For the receiving-law derivation, see Master Equation. For assembly emergence, see Emergence and Noether Braid.

The Physical Medium

Noether sea is the canonical medium-ontology page. It defines the Noether sea as the emergent physical medium formed by coupled neutral Noether braid assemblies occupying the Euclidean void.

This is the first step away from primitive ontology. The Noether sea is physically real content, but its variables are medium and assembly variables rather than new container geometry.

In this ontology hub, the key commitment is:

> **Medium Commitment (Noether sea):** The Noether sea is physical content inside the Euclidean void, not the void itself. It carries density, stress, energy, orientation, flow, and response properties. Effective gravity, clock and ruler behavior, signal delay/refraction, inertia, and cosmological behavior are reconstructed from Noether sea dynamics and assembly coupling, not from curvature or expansion of the void.

The routing boundary is:

- Noether sea owns medium ontology, state variables, and terminology.
- Noether Sea Pro/Anti Coupling owns pro/anti coupling hypotheses and medium assembly motifs.
- Emergent Metric owns the map from medium variables to effective metric language.
- Proper Time and Time Dilation owns clock and ruler behavior.
- Cosmology Ontology owns the cosmology-level interpretation of Noether sea evolution.

The Observer Framework

Observer Framework is the canonical page for the $\mathbb{U}_{\text{now}}$ universe-state perspective, Physical Observers, the ontic/epistemic distinction, and absolute-versus-operational simultaneity.

The complete ontic state is the absolute-time slice $\mathbb{U}_{\text{now}} \equiv S(T)$. A Physical Observer samples only a constrained record inside that state, using clocks, rulers, and signals whose behavior is itself produced by assembly and Noether sea dynamics.

In this ontology hub, the key commitment is:

> **Observer Commitment:** $\mathbb{AAA}$ distinguishes the complete ontic state on an absolute-time slice from the measurements available to embedded Physical Observers. Physical Observers are assemblies inside the Noether sea, so their clocks, rulers, synchronization procedures, and records are dynamical outputs. Effective relativity and quantum state descriptions belong to this observer-accessible layer, not to the primitive substrate itself.

There is no observer outside the ledger. A Physical Observer's records are themselves entries inside $S(T)$. Inference is therefore an internal subsystem reconstructing a coarse description from its own accessible records, not a second-level spectator reading the complete state without constraint.

Observer descriptions can be indispensable without being final ontology. Effective metric reconstruction, wave function transition, and particle records are inferential summaries of accessible interactions. They do not replace the substrate and assembly account.

Bell Nonlocality Placement

Bell-family experiments are treated as a hard observer-level correlation constraint on any deterministic completion. They are not treated as evidence by themselves for ontological randomness, backward causation, or faster-than-c_f signal transfer.

The complete state on Σ_T remains definite in the $\mathbb{U}_{\mathrm{now}}$ universe-state perspective. A Physical Observer has access only to pair records, detector settings, coincidence windows, and statistical summaries.

The no-go guardrail is strict. If measurement independence, no advanced influence, finite-speed local response, and local factorization over a complete past-state variable λ are all retained, then the Bell-local factorization is restored and Bell violations cannot be recovered. The Bell bridge must choose and declare which Bell assumption fails. A foundation page may route that burden, but it must not imply that shared provenance alone solves Bell.

The placement is therefore level-specific. If $\mathbb{AAA}$ preserves measurement independence and no-signaling at the observer level, then Bell violation must come from an explicitly nonseparable substrate response, such as a c_f-mediated coordination channel outside effective light cones with no-signaling shielding, or another declared nonseparable mechanism.

A c_f-mediated option is a substantive hierarchy claim. The primitive coordination channel must lie outside the observer photon cone, so $c_f > c_0$ after the low-energy photon speed c_0 is calibrated. Any stronger hierarchy such as $c_f \gg c_0$ must be reconciled with photon dressing, moving-assembly Lorentz closure, and clock/ruler universality. It must also evade the finite-speed hidden-influence obstruction: finite superluminal influences with $c_0 < v < \infty$ can become operationally signaling in multipartite Bell scenarios.

The observer-level compression must fail the factorizable local-response form

$$P(a, b \mid \hat{m}_A, \hat{m}_B, \lambda) = P(a \mid \hat{m}_A, \lambda)\, P(b \mid \hat{m}_B, \lambda)$$

without adding instantaneous causal influence between detectors. If instead measurement independence is relaxed, that relaxation must be stated quantitatively, and the text must not also claim exact measurement independence.

These options are mutually exclusive at the bridge level:

- **Substrate nonseparability:** retain strict measurement independence and no-signaling; Bell violation is recovered through nonfactorizable pair-provenance and apparatus-response coupling.
- **Controlled relaxation of measurement independence:** relax measurement independence in the declared substrate response variables; the relaxation must be bounded to prevent macroscopic backward causation or signaling claims.

Working selection, still provisional until the Bell derivation closes: $\mathbb{AAA}$ follows the substrate-nonseparability route. That means measurement independence and observer no-signaling are retained, while Bell nonfactorizability is carried by a live substrate-causal c_f coordination channel, gated by pair provenance. Controlled measurement-independence relaxation remains a comparison or failure route, not the active ontology-hub selection.

A mere shared-source story is not enough. If the retained provenance screens the two detector wings into independent local laws, the account has fallen back into the Bell-local class. Any shared record, including a framed pair-braid or linking invariant, is part of the complete past-state variable λ; if each wing's response remains a local function of its own setting and that record, Bell factorization returns and the correlation stays inside the Bell-local bound. The active route therefore assigns the two roles explicitly: pair provenance gates the live c_f-mediated apparatus-response coupling, and the live channel carries the nonfactorizability. During the measurement window the coupled response law must fail the product form while leaving each one-wing marginal setting-independent. Coordination outside the effective photon cone is allowed when $c_f > c_0$; faster-than-c_f influence and controllable observer signaling remain forbidden. This makes the finite-speed hidden-influence obstruction a real closure burden rather than a footnote: the route predicts either measurable degradation toward the Bell-local bound when the c_f channel cannot connect the wings during the measurement window, or an $\mathbb{AAA}$-specific derivation showing why that obstruction is evaded while preserving no-signaling. The detailed derivation and residual tests belong to Bell's Theorem and Entanglement and Nonlocality.

The routing boundary is:

- Observer Framework owns complete-state versus Physical Observer access.
- Proper Time and Time Dilation owns observer clocks, clock slowing, and $t \mapsto \tau$ extraction.
- Lorentz Kinematics owns moving-assembly deformation, clock/ruler retuning, two-way signal synchronization, and preferred-frame leakage bounds.
- Emergent Metric owns metric reconstruction from observer clocks, rulers, and signals.
- Wavefunction Ontology and Measurement Ontology own quantum-state and measurement descriptions at the observer-accessible layer.
- Bell's Theorem and Entanglement and Nonlocality own Bell-family correlation recovery, no-signaling, measurement-independence, pair-provenance closure tests, and the Bancal

finite-speed-influence no-signaling obstruction.

Terminology Discipline

Terminology discipline is controlled by the style and terminology canon, not by this hub. The relevant references are:

- Terminology Usage for level-aware usage rules and examples.
- Comparative Glossary for standard-framework to $\mathbb{AAA}$ translation.
- Mathematics Terminology for formal notation.
- Academic Style Guide for prose discipline.

This ontology hub keeps only the global rule:

> Use substrate-native terms for substrate ontology, medium terms for Noether sea contents, and effective/observer terms for emergent descriptions. Do not let `spacetime`, `field`, `charge`, `vacuum`, or `particle` silently cross levels without saying which level is being described.

Parameter Ledger

The canonical parameter accounting lives in Parameter Ledger. This ontology hub does not own tables of numerical inputs, closure targets, naturalness tests, or simulation regulators.

The ontology-level distinction is a level assignment, not a numerical claim:

- substrate commitments belong to Absolute Time, Euclidean Void, Absolute Timespace, and Architrino;
- acceleration-law parameters and regulators belong to Master Equation and the validation ledger;
- assembly radii, shielding factors, metric coefficients, and observer-level constants are closure targets, not primitive ontology.

For current open parameter status, see Parameter Ledger and Known Tensions.

Open Questions and Validation Routing

Open questions and closure burdens belong in Known Tensions, Closure Scorecard, and the relevant branch chapters. This ontology hub keeps only stable commitments.

For the current pressure ledger, see:

- Known Tensions for unresolved closure burdens.
- Parameter Ledger for open symbols and closure targets.
- Wavefunction Ontology and Measurement Ontology for quantum-ontology status.

- Cosmology Ontology for universe-history framing.

Summary

This ontology hub establishes six commitments:

1. **Substrate:** absolute time and Euclidean void form the fixed non-dynamical product background called absolute timespace.
2. **Primitive entity:** the architrino is the fixed-identity primitive point transceiver with polarity and persistent identity.
3. **Causal record:** causal wakes are real source-provenanced path-history records, not extra substances in the void.
4. **Medium:** the Noether sea is emergent physical content formed by coupled neutral Noether braid assemblies inside the Euclidean void.
5. **Observer framework:** complete-state bookkeeping is distinct from Physical Observer access.
6. **Routing discipline:** terminology, parameters, closure burdens, and open validation questions belong to their owning chapters once the topic moves beyond ontology.

All subsequent chapters build on these foundations. This hub intentionally points outward once a topic becomes dynamics, assembly structure, observer-clock extraction, terminology canon, parameter closure, or validation pressure.

Architrino

Start with the entity, not the familiar particle. In $\mathbb{AAA}$, the **architrino** is the primitive point transceiver. It continuously emits transmitter-provenanced causal wake history, receives wake intersections from the universe's wake history, including its own emitted wakes when self-hit roots exist, and responds through receiver-local acceleration. Effective equilibration appears only later, as a collective assembly response built from those received wakes.

The primitive definition also includes definite polarity, persistent identity, complete path history, and non-creation/non-destruction at the substrate level.

Architrinos live in absolute timespace: absolute time T together with the Euclidean void. They are not particles in the Standard Model sense. Standard particles, effective fields, clocks, rulers, and observer-level spacetime behavior are downstream assembly phenomena built from architrino configurations and wake dynamics.

That distinction does most of the work. A point transceiver is not a tiny electron, quark, or field quantum with familiar particle properties already attached. It is the minimal entity whose location, polarity, wake emission, wake reception, and path history can later assemble into the objects that Physical Observers call particles.

The teaching order is deliberately narrow. First fix the primitive ontology. Then separate polarity from observer-level charge bookkeeping. Then mark the boundary with dynamics and effective reconstruction. This chapter does not derive particle phenomenology; it states what must already exist before any assembly-level derivation can begin.

Core Definition

An **architrino** is the sole fundamental entity in $\mathbb{AAA}$.

Its primitive commitments are:

- A point transceiver located at position $\mathbf{X}_a(T)$ in the Euclidean void.
- Always active: it continuously emits a causal wake and continuously receives wakes according to the dynamics branch.
- Polarity-bearing: it has definite positive or negative polarity, represented in electric bookkeeping by $q_a = \pm\epsilon$.
- Persistent: it has a continuous identity-bearing worldline through absolute timespace.
- Deterministic: its detailed motion is specified by the Master Equation, with deterministic multistability possible near dynamical branch thresholds.

The architrino has no internal structure, no volume, no intrinsic spin in the classical sense, and no primitive particle-specific inertial mass. Its primitive state is its identity, position, velocity, polarity, and path-history ledger.

All larger structures arise from coordinated configurations and interactions of many architrinos. That is why the primitive definition must stay lean: if mass, spin, particle type, or field state is imported here, the later assembly derivation has already been smuggled into the premise.

Because no primitive mass is assigned to a single architrino, the primitive dynamical law is an acceleration law rather than a force law of the form $\mathbf{F} = m\mathbf{a}$. The universal coupling scale in that acceleration law is $\kappa > 0$:

$$\mathbf{a}_{i\leftarrow j} \sim \kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\mathrm{acc}} \hat{\mathbf{r}}_{ij}, \qquad W_{ij}^{\mathrm{acc}} = \frac{c_f}{|D_{t,ij}|}$$

Here $\sigma_{ij} = \mathrm{sign}(q_i q_j)$ is the polarity sign factor: $+1$ for like-polarity pairs, which repel, and -1 for unlike-polarity pairs, which attract; $r_{ij} = \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\|$ is the delayed separation evaluated at a retained causal root, where it equals $c_f(T_r - T_t)$, not the simultaneous distance; and $\hat{\mathbf{r}}_{ij}$ points from the transmitter's emission point $\mathbf{X}_j(T_t)$ toward the receiver's reception point $\mathbf{X}_i(T_r)$. $D_{t,ij} = c_f - \hat{\mathbf{r}}_{ij} \cdot \mathbf{V}_j(T_t)$ is the transmitter-side factor and $D_{r,ij} = c_f - \hat{\mathbf{r}}_{ij} \cdot \mathbf{V}_i(T_r)$ is the receiver-side factor. The acceleration weight depends only on D_t; the signed root-playback derivative $m_{ij} = D_{r,ij}/D_{t,ij}$ and root-degree data remain dynamics-level branch data in the Master Equation. The constraint conventions are: the causal constraint is length-valued, written $g_{ij} = r_{ij} - c_f(T_r - T_t)$ in the Master Equation and F_{ij} in the foundations pages, and it carries the velocity-unit transversality floor $|\partial_{T_t} g_{ij}| \geq \kappa_{\text{hit}} > 0$; when a dimensionless floor is needed, the time-normalized object is $\tilde{F}_{ij} = F_{ij}/c_f$. Then $J^t_{ij} = \partial_{T_t}\tilde{F}_{ij}$ is the transmitter-side causal-root transversality Jacobian, and $c_f J^t_{ij} = \partial_{T_t} g_{ij} = D_{t,ij}$. It is the density-of-states factor of the causal-root map, and $W^{\text{acc}}_{ij} = c_f/|D_{t,ij}|$ is the active acceleration weight. The ordinary simple-root acceleration contribution is valid away from the Whitney-fold set

$$\Sigma_{ij} = \{F_{ij} = 0,\ \partial_{T_t} F_{ij} = 0\},$$

while approaching Σ_{ij} moves the calculation into the caustic or fold-resolution chart. Using this branch denominator therefore requires the simple-root floor stated above before the schematic acceleration law is treated as an ordinary simple-root contribution rather than a catastrophe-theoretic transition.

In dimensional form κ has units

$$[\kappa] = \mathrm{L}^3\,\mathrm{T}^{-2}\,\mathrm{Q}^{-2}$$

where Q denotes the polarity unit. The coupling is recorded in the Parameter Ledger and defined by the Master Equation; any later force-like variable is effective bookkeeping after an assembly response coefficient has been introduced, not primitive architrino inertia.

This supplies a substrate universality seed: no individual architrino carries a separate inertial coefficient, so same-branch primitive response is governed by the same acceleration normalization. The mass-map and Noether sea programs must still show that assembly inertia and gravitational response preserve weak-equivalence bounds; see General Relativity and Particle Masses.

This definition is ontological, not effective. It does not assign an individual architrino a rest mass, a Standard Model particle type, or a field degree of freedom. Those descriptions enter only after architrinos form assemblies whose collective wake closure can be read by observers.

Ontological Status

Architrinos are primitive substances in this framework. They are not made of anything more basic inside $\mathbb{AAA}$.

This makes the architrino the primitive substance of the theory without making it matter in the emergent sense. In this corpus, **matter** names stable assembly-level behavior with rest mass, spatial exclusion, and fermionic organization. An individual architrino has no radius, no primitive rest mass, and no exclusion volume. It is therefore material as substrate substance, but it is not matter. Matter begins only after architrinos organize into persistent, shielded assemblies whose collective behavior exposes mass and exclusion to observers.

They are:

- **Discrete:** there is a definite ontic set of architrino identities.
- **Identifiable:** each architrino has a unique worldline.
- **Persistent:** each architrino remains the same entity through time.
- **Non-created and non-destroyed:** no fundamental process adds or removes architrinos from the ontic inventory.

Apparent association, dissociation, annihilation, production, or transmutation at the assembly level is therefore not ontic creation or destruction. It is reorganization of a fixed architrino identity set. This distinction is essential: ontology tracks the persistent inventory, while effective reaction language tracks how that inventory is repartitioned into observable assemblies.

Polarity and Electric Bookkeeping

At the architrino level, the primitive sign is **polarity**. Electric charge is the observer-facing bookkeeping that becomes useful after architrino signs are counted inside assemblies.

For calculations that need continuity with electric-charge bookkeeping, each architrino carries an effective signed unit

$$q_a = \sigma_a \epsilon, \qquad \sigma_a \in \{-1, +1\}$$

The observer-level electron-charge benchmark is then

$$|e| = 6\epsilon$$

The two polarity names are:

- **Electrino:** negative-polarity architrino, with bookkeeping label $q_a = -\epsilon$.
- **Positrino:** positive-polarity architrino, with bookkeeping label $q_a = +\epsilon$.

Like polarities repel; unlike polarities attract in the universal interaction law. At the assembly level, electric charge is the coarse bookkeeping summary of the signed architrino inventory. For example, quark and lepton electric charges are built from integer counts of ϵ units in stable assembly patterns rather than from a separate primitive charge substance.

This relocation keeps both sides of the inherited word `charge`. The effective charge table remains real at the observer level, but its substrate basis is polarity inventory, not a separate charge substance attached to a miniature Standard Model particle.

The normalization $|e| = 6\epsilon$ is currently an input parameter and a high-priority explanatory target. In this convention, the architrino polarity unit is primitive for bookkeeping, and the observed electron or positron charge is a six-unit assembly-level multiple. The general structural target is a protected six-unit polarity inventory: six sign-carrying architrinos or six retained polarity slots whose signed sum supplies observer-level charge bookkeeping. This parent target does not yet decide whether the six units are internal to the Noether braid, externally coupled to it, embedded in its retained path-history, or realized by a non-axial coupled branch.

The axial-layer model is one charged-fermion realization of that parent target. In that model, the six-unit inventory appears as a closed six-polar-site branch record: three polar dyads in a branch-defined axial frame, with each polar site occupied by one axial architrino of sign $\pm\epsilon$. The dyads use persistent indices $a \in \{1, 2, 3\}$; those identities do not impose an ordering by radius or another derived property. The protected-site version of the axial target asks for a finite site-stabilizer action G_{ax} on the Noether braid framing such that

$$|G_{\mathrm{ax}}\text{-orbit}| = 6,$$

with each orbit site carrying a fixed polarity sign. If assembly closure retains exactly that six-unit inventory, the allowed observer-level charge table follows as a finite signed inventory result. Deriving why a charged-fermion Noether braid supplies six protected axial polar sites, or whether a more general non-axial six-unit carrier is required, belongs to Quantum Number Mapping and Gauge Structure Emergence, not to the primitive definition of an architrino.

Provenance and Persistence

The stronger ontological claim is not merely that architrinos move through time. It is that each architrino persists as the same entity through time.

Let $\mathcal{A}$ denote the ontic set of architrino identities. The foundational claim is that $\mathcal{A}$ is fixed. Architrinos may move, bind, unbind, exchange partners, enter a subsystem, or leave a subsystem, but they are not fundamentally created or destroyed by the dynamics. This is a primitive inventory postulate, not an inference from observer-level conservation laws.

This gives $\mathbb{AAA}$ a built-in provenance ledger. At the substrate level, it is not enough to say that an equivalent unit appears later. The sharper question is which architrino appears later, where it came from, and through which path history it arrived.

Provenance is therefore stronger than coarse conservation:

- Conservation says that an inventory is preserved.
- Provenance says which exact entities realize that preserved inventory.

Many effective conservation rules can be read as summaries of this deeper identity continuity. Signed electric-charge conservation, for example, is preservation of the signed architrino inventory under rearrangement. The effective law is what an observer can track; provenance is the substrate claim about which persistent architrinos make that tracking possible.

Provenance does not replace Noether reasoning. Energy conservation still depends on time-translation invariance and on the interaction law. Momentum and angular momentum still depend on spatial translation and rotation symmetry. Provenance is the ontological basis that makes microscopic conservation statements sharp; symmetry supplies the dynamical conservation theorems.

Observer-level indistinguishability is therefore a quotient, not erasure of substrate identity. Let

$$\Pi_{\mathrm{obs}} : S(T) \to \bar{S}(T)$$

denote the projection from the complete provenance-bearing state to the variables exposed to Physical Observers. For any permutation π of same-polarity architrinos inside an observationally unresolved class, observer-accessible quantities must satisfy

$$\|\mathcal{O}(S) - \mathcal{O}(\pi S)\| \le \epsilon_{\mathrm{prov}}$$

This is only the provenance-leakage closure. It says that inaccessible architrino labels do not leak into observer-accessible quantities beyond the residual ϵ_{prov}. Fermionic and bosonic exchange statistics require the stronger projector residuals owned by Fermi-Dirac and Bose-Einstein Statistics. The coarse leakage residual and the fine exchange-sign carrier are different objects: ϵ_{prov} bounds label leakage through Π_{obs}, while the substrate carrier for an exchange sign must live in the joint framed-braid class, including protected rows such as $Lk = \mathrm{Wr} + \mathrm{Tw}$ when those rows are part of the branch certificate; see Absolute Time. Exact architrino identities remain present in $\mathbb{U}_{\mathrm{now}}$; ordinary particle indistinguishability begins with the leakage bound and then depends on the separate exchange-statistics closure after the Physical Observer projection and effective assembly-state extraction are specified.

Non-Creation and Non-Destruction

Architrino non-creation and non-destruction is a foundational postulate:

> No architrino enters or leaves the ontic inventory of $\mathbb{AAA}$ through a fundamental creation or destruction event. Every assembly-level change is a repartitioning or reorganization of persistent architrinos.

This statement is narrower and more precise than saying architrinos are “eternal.” Non-creation and non-destruction states the internal ontology of the theory. It does not need the broader metaphysical claim that the modeled world has no external initialization, no outer boundary condition, or no implementation substrate.

If a discussion becomes meta-theoretic, the careful wording is that architrinos have no known beginning or ending within the modeled dynamics.

Point-Transceiver Status

An architrino is a point transceiver: it emits and receives continuously.

The emitted structure is a potential-bearing **causal wake**. The wake is physically real: it propagates at the primitive causal-wake speed c_f, the field propagation speed relative to the Euclidean-void rest frame; carries transmitter provenance; and is received through later causal intersections.

The wake is not an independent substance. It has no freely specifiable state apart from the transmitter architrino's path history. At the effective level, many such wake contributions may be summarized as a field, but the substrate term remains causal wake.

Schematically, if the transmitter history has time domain I_a, the wake emitted by architrino a is a transmitter-history functional

$$\mathcal{W}_a(\mathbf{X},T)=\int_{\{T_t\in I_a:\,T_t<T\}} q_a\,K(\mathbf{X},T;\mathbf{X}_a(T_t),T_t)\;dT_t,\qquad \operatorname{supp}K\subseteq\{\|\mathbf{X}-\mathbf{X}_a(T_t)\|=c_f(T-T_t)\}$$

The kernel K is only a schematic placeholder here; the exact causal-root sets, transmitter-side factors, transmitter-side acceleration weights, kernels, and regularization belong to the dynamics chapter. The ontology claim is the dependency claim: after the transmitter identity, polarity, and path history are fixed, there is no second material inventory or autonomous field state left to specify.

Point-transceiver causal-delay theories carry a known pathology class. Classical point-charge electrodynamics develops divergent self-energy at zero radius, runaway solution branches, and pre-acceleration in Abraham-Lorentz-Dirac-type reductions. This chapter does not solve those issues by naming the architrino primitive. It routes them to the dynamics layer: coincidence handling, self-hit admissibility, regularized or weak-limit kernels, Jacobian/transversality floors, and energy-momentum accounting must remove or quarantine those pathology channels in the branch being used.

A retained point-transceiver branch is admissible as an ordinary ontology branch only if its regularized self-energy and self-acceleration contributions remain finite under the declared regulator removal $\eta\to 0$ or weak limit, with the active causal roots still protected by a transversality floor such as $\kappa_{\mathrm{hit}}>0$. The two singular loci are not the same: the coincidence stratum $\{r_{ij}=0\}$ is a spatial point-kernel problem, while the caustic stratum $\{\partial_{T_t}F_{ij}=0\}$ is a causal-root fold problem. The former requires the declared spatial or weak-limit regularization; the latter requires a fold-resolution chart and the active-root floor. If finite self-response or simple-root transversality fails, the branch is not an ordinary point-transceiver case; it must be rejected, moved to a caustic or regularized chart, or quarantined as a pathology channel in the dynamics chapter.

Ontologically, the causal wake is a **dynamical geometry**: a transmitter-provenanced interaction structure generated by the path history of the transmitter architrino. It is not a material ether or hidden fluid in the Euclidean void. Distinct wakes superpose perfectly and do not scatter, bind, fragment, or interact with one another as substances.

This linearity is a statement about wake superposition, not about the receiver worldline. A wake can act on any architrino, including its own transmitter, and that receiver response makes the dynamics nonlinear. The entire substrate-level content of a wake is therefore computable from the historical trajectory of the transmitter architrino that emitted it.

Constant-Time Emission Measure (postulate)

The emission is uniform in absolute time. Each architrino deposits its causal wake at a constant rate in T, with constant per-wavefront amplitude, independent of the transmitter's state of motion: successive causal surfaces leave the transmitter at equal increments of absolute time, and no wavefront is preferentially weighted by the transmitter's velocity or acceleration.

> **Constant-time emission measure.** The emission measure along a transmitter worldline is dT_t — Lebesgue measure in absolute time — with a motion-independent per-wavefront amplitude. This is a postulate of the transceiver, not a derived result.

This postulate is the canonical home of the emission rule used throughout the theory. It is what makes moving-transmitter effects purely *geometric*: because emission cadence is constant in T, all velocity dependence in the received pattern comes from the transmitter changing position between equally spaced emission instants, which is what produces the transmitter-side factor $D_t = c_f - \hat{\mathbf{r}} \cdot \mathbf{V}_t$ and the acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$ in the Master Equation. It is also one of the two declared conditionalities of the narrowed master-equation proposal (the other being the assumed K_0 kernel scaffold); the master-equation chapter consumes this measure by reference rather than restating it as an independent rule.

This page fixes the ontological commitments:

- Emission is continuous, not pulse-like.
- Emission is uniform in absolute time (constant-time emission measure dT_t, motion-independent amplitude).
- Emission has transmitter provenance tied to architrino identity and emission time.
- Wake propagation is finite-speed in absolute time.
- Reception is universal across architrinos.
- Emitted wake history supplies provenance for later dynamics.

This chapter stops before the exact acceleration law. Exact causal wake surfaces, density representations, causal emission-time roots, transmitter-side factors, transmitter-side acceleration weights, inverse-square kernels, and regularization belong in Master Equation.

Worldlines and Path History

Each architrino traces a worldline

$$\mathbf{X}_a : I_a \subseteq \mathbb{R} \to \mathbb{R}^3, \qquad T \mapsto \mathbf{X}_a(T)$$

where I_a is an interval of absolute time. It may equal $\mathbb{R}$, or it may be bounded by the domain of a realized cosmological solution. The worldline lies inside the product background

$$\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$$

The worldline is at least absolutely continuous so that

$$\mathbf{V}_a(T) = \frac{d\mathbf{X}_a}{dT}$$

exists almost everywhere and is piecewise continuous in regular regimes.

Because architrinos are point entities, multiple architrinos may occupy the same spatial coordinate at the same absolute time without volume exclusion. Collision regularization and received-hit kernels belong to the dynamics layer.

The complete path history of an architrino matters to its identity ledger. This is stronger than an observer reconstruction of a trajectory: the path history is part of the substrate bookkeeping required by delayed causal dynamics. The law that converts path history into acceleration belongs in Master Equation.

Wake History Boundary

An architrino has an emitted-wake history: the record of causal wakes sourced by that same persistent entity at earlier emission times.

This is an ontology statement about transmitter identity and path-history provenance. It is not the delay-root law. When a calculation needs wake-surface notation, causal emission-time sets, branch counts, or received acceleration, use Master Equation.

Reception Rule Boundary

The ontology only states that every architrino receives wake contributions according to one universal law. This is a universality claim about the primitive receiver, not a claim that all effective assemblies respond in the same coarse-grained way.

It does not define the acceleration kernel, causal emission-time set, transmitter-side factor, transmitter-side acceleration weight, root topology, or branch-resolved acceleration. Those are dynamical commitments, not primitive-entity ontology. The canonical dynamics are in Master Equation.

Dynamics and Regime Boundary

This page does not own wake regimes, self-hit activation, maximum-curvature binaries, or Noether braid stability mechanisms. Those are behavioral and assembly-level dynamics, not primitive-entity definitions. The chapter names those topics only to keep the reader from importing them back into the definition of a single architrino.

The canonical homes are:

- Master Equation for causal hits, delay roots, transmitter-side factors, transmitter-side acceleration weights, received acceleration, and branch topology.
- Binary Dynamics for wake-speed regimes, partner hit versus self-hit behavior, spiral contraction, and maximum-curvature binary analysis.
- A1 Dynamics for coupled indexed-binary speed regimes, alignment behavior, and assembly-stability mechanisms.
- Noether Braid for the assembly-level Noether braid architecture built from those dynamics.

Determinism and Multistability

$\mathbb{AAA}$ is deterministic in its laws. Given the complete architrino identity set, positions, velocities, polarities, and relevant path-history ledger on a slice, subsequent evolution is fixed by the dynamical law stated in Master Equation.

Determinism does not imply practical predictability. The dynamics are nonlinear and non-Markovian. Near threshold regimes, multiple stable attractors can coexist; the realized branch is selected by the exact microstate. This is deterministic multistability, not ontic randomness and not a probability postulate added at the primitive level.

Absolute Rest Case

The preferred rest frame is defined first by the propagation law: primitive causal wakes expand isotropically at speed c_f in the Euclidean-void rest frame. A stationary architrino is a sufficient diagnostic exposer of that frame, not the definition of the frame itself.

A stationary architrino, with

$$\mathbf{V}_a = \mathbf{0}$$

emits a concentric wake stream centered on one fixed point of the Euclidean void. This state is physically distinct from nonzero motion, where wake centers trace a path and the wake stream becomes non-concentric.

Over a diagnostic interval I, the relevant complete-state object is the transmitter-tagged center curve

$$Z_a(I) = \{\mathbf{Z}_a(s) : s \in I\}, \qquad \mathbf{Z}_a(s) = \mathbf{X}_a(s),$$

where $\mathbf{Z}_a(s)$ is the center of the wake isochron emitted at time s.
Rest is the zero-diameter case, $\operatorname{diam} Z_a(I) = 0$, so the center record is effectively a single point. Self-hit is a different condition: the same worldline must re-enter one of its own forward causal isochrons. That is a root-existence condition on the curved center history, not a rest diagnostic and not a speed test by itself.

The existence of a stationary architrino is sufficient for choosing a material origin and for exposing concentric stationary-transmitter wakes, but it is not necessary for defining the preferred rest frame. If no architrino is stationary over a diagnostic interval, complete-state reconstruction may still recover the rest-frame structure from transmitter-tagged wake centers. This is a substrate-level diagnostic, not by itself an operational measurement procedure. Whether physical observers can detect that frame is a separate emergent-observer question addressed by Detecting the Absolute Frame, Lorentz Kinematics, and Proper Time and Time Dilation.

Boundary With Assemblies and Effective Particles

An architrino is not a Standard Model particle. It is the primitive constituent from which particle-like assemblies are built. The distinction is a level distinction, not a competing particle classification.

The boundary is:

- **Architrino:** primitive point transceiver with polarity and persistent identity.
- **Wake:** causal interaction structure emitted by architrino motion.
- **Dynamics regime:** behavior of wake intersections, self-history, root multiplicity, and delay-geometry stability.
- **Assembly:** localized bound configuration of architrinos and their wake closure.
- **Effective particle:** observer-level particle description of a stable or transient assembly.
- **Effective field:** coarse-grained continuum description of many wake contributions.

This boundary prevents a point-charge ontology from being imported prematurely. The primitive object is the architrino as a polarity-bearing transceiver. Electric charge, particle type, inertial mass, spin, and field behavior are downstream descriptions of assembly and wake organization.

Inference runs from stable observer records back toward this substrate account; it does not make the observer-level categories fundamental.

Summary Postulate

> **Postulate 4 (Architrino):** The architrino is the sole primitive entity of $\mathbb{AAA}$: a point transceiver in absolute timespace with definite polarity, persistent identity, continuous causal-wake emission, universal wake reception, and non-creation/non-destruction at the ontological level. The set of architrino identities is fixed. All particles, effective fields, clock behavior, and emergent spacetime phenomena arise from architrino configurations, wake intersections, and assembly dynamics rather than from additional fundamental substances.

Absolute Time

This chapter defines absolute time in $\mathbb{AAA}$ at the substrate level. It says what the time parameter T is, how it orders events, how causal wakes use it, and why observer proper time is a derived clock readout rather than a second fundamental time.

The companion chapter Absolute Time Defense gives the argumentative case for this choice. This chapter does the more basic job: it states the postulate and the mathematical structure used by the later dynamics.

The safest way to read the chapter is to keep three uses of time separate. Absolute time is the substrate ordering parameter. Causal-wake timing is how that ordering becomes active in interactions. Clock time is a physical assembly readout extracted from repeatable cycles. The later spacetime chapters can compare those readouts with relativistic proper time, but they do not add a second ontological clock.

Core Concept

Absolute time is the one universal ordering parameter. It is **one-dimensional, continuous, and oriented**, and it advances uniformly and independently of space, matter, energy, or any physical process. In substrate ontology, it is **non-dynamical**: time does not curve, dilate, accelerate, or respond to forces.

Physical clocks are different. A clock is an assembly with repeatable internal cycles. The clock can speed up or slow down as an assembly, but the cycles are compared against the absolute parameter; they do not generate it.

The word **uniformly** is a dynamical normalization statement, not an extra clock substance on the bare line. Before units and laws are declared, the oriented time line admits affine relabelings $T \mapsto aT + b$ with $a > 0$. The origin b remains conventional. The scale a is fixed only after the dynamics are declared: the primitive wake speed c_f is constant in the Euclidean-void rest frame, all worldlines use the same parameter T, and the master equation keeps its receiving law form.

A rescaling of T is therefore a unit change involving T_0, L_0, c_f, and the coupling normalizations. It is not a second physical freedom to choose a different flow of time. Constancy of c_f together with form-invariance of the receiving law pins T to its affine class; a smooth nonlinear reclock $T \mapsto \phi(T)$ would introduce time-dependent propagation and derivative factors, so $\mathrm{Diff}^+(\mathbb{R})$ is not a substrate symmetry.

After that scale fixing, the remaining freedom is only translation by b. The background time line is therefore best understood as a principal homogeneous space for $(\mathbb{R}, +)$: it has a global orientation and duration scale, but no marked origin. This makes the conventional status of $T = 0$ precise without weakening the physical status of the affine scale chosen by the receiving law.

Time Implementation Ladder

Ordinary language uses the word “time” for several different things. $\mathbb{AAA}$ separates those things so the reader does not confuse the substrate parameter with clocks or observations:

1. **Substrate ordering:** Absolute time T orders universe states. It is not directly measured by a physical clock and has no natural origin; its affine scale is fixed only after the causal-wake law and unit convention are declared.
2. **Causal-wake implementation:** Architrino worldlines and emissions make the ordering physically operative. A transmitter event at emission time T_t contributes at a receiver time T_r only when the causal wake support satisfies

$$r_{ij}(T_r, T_t) = c_f(T_r - T_t),$$

where $r_{ij}(T_r, T_t) = \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\|$ is the receiver-transmitter separation. In this layer, temporal separation and Euclidean distance become a receiver-local interaction condition.
3. **Assembly clock readout:** Physical clock time is an assembly-level phase extraction. A stable binary or Noether braid branch supplies repeatable internal cycles, and observer clock time is the count of those cycles relative to a reference branch, not another substrate parameter. In the notation of Proper Time and Time Dilation, with $\varphi_{\mathcal{A}}$ the counted clock phase and $\Omega_{\mathcal{A}}^{(0)}$ its rest-branch reference rate,

$$d\tau_{\mathcal{A}} = \frac{d\varphi_{\mathcal{A}}}{\Omega_{\mathcal{A}}^{(0)}}.$$

Motion through the Euclidean void and coupling to the Noether sea can retune the internal cycle, so derived clock time changes even though absolute time does not.

This ladder preserves the useful intuition that cycles make clocks while preventing cycles from being confused with time itself. A moving assembly may trace a helical history through absolute timespace, and its internal cycle may slow or speed relative to T; the substrate ordering parameter remains the same line.

It also prevents a second confusion. Absolute simultaneity does not mean an observer can read the whole simultaneous universe state. It means there is a fact of the matter about the ordering parameter. What an observer can reconstruct is limited by assembly clocks, causal wakes, signal transport, and Noether sea coupling.

Mathematical Description

Mathematically, time is the real number line:

$$\mathbb{R}$$

A specific instant is a point $T \in \mathbb{R}$.

The same orientation can be encoded by the exact **clock 1-form**:

$$dT$$

on the oriented time line. This 1-form is closed and exact, and its level sets define simultaneity slices when combined with space in the product manifold $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$.

The notation keeps the levels apart. The symbol τ is reserved for derived observer proper time. Emission times use T_t, and causal delay is written $\Delta_{ij} = T - T_t$ rather than by reusing the proper-time symbol.

The substrate structure is absolute time together with the Euclidean void, formally the absolute timespace $\mathcal{M}$. Effective spacetime geometry and proper time are later observer-level reconstructions from assembly dynamics, clock behavior, and Noether sea response. They are not additional time coordinates at the ontological level.

Dimensionalization

The equations are usually written in nondimensional form. Choose a reference timescale $T_0 > 0$ such that physical time $\hat{T}$ is given by:

$$\hat{T} = T_0 \, T$$

where T is dimensionless.

Positions require the corresponding length scale. Choose $L_0 > 0$ and write

$$\hat{\mathbf{X}} = L_0 \mathbf{X}, \qquad \hat{T} = T_0 T, \qquad c_f = \frac{\hat{c}_f T_0}{L_0}$$

Here hatted quantities are dimensional and unhatted quantities are nondimensional. With this convention, the nondimensional causal-root condition keeps the same form,

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f (T_r - T_t)$$

while the dimensional condition is

$$\|\hat{\mathbf{X}}_i(\hat{T}_r) - \hat{\mathbf{X}}_j(\hat{T}_t)\| = \hat{c}_f (\hat{T}_r - \hat{T}_t)$$

Choosing T_0 fixes the affine scale of T for the declared model. Setting $c_f = 1$ is the special unit convention $L_0/T_0 = \hat{c}_f$; keeping c_f explicit leaves the physical anchor visible.

Symbolic derivations may retain c_f when its dependence matters, but every new numerical instantiation, fixture, simulation, tolerance, and worked numerical example uses normalized wake-speed units with $c_f = 1$. A provenance-bound legacy artifact recorded with another value must be rerun at $c_f = 1$ before it supports a current conclusion.

> **Plain language:** We pick a standard unit of duration, such as one second or one maximum-curvature binary orbit time, and measure all times as pure numbers of that unit, keeping equations dimensionally clean.

Duration and Linear Advancement

Once the affine scale is fixed by the declared dynamical normalization, duration is simple. The **duration** between two instants T_1 and T_2 is the absolute difference:

$$\Delta T = |T_2 - T_1|$$

The corresponding physical duration is:

$$\Delta \hat{T} = T_0 \, \Delta T$$

This duration rule is **invariant under time translation**. It is the same for all observers, regardless of their position or state of motion.

> **Plain language:** The gap between any two moments is always given by subtraction; there is no acceleration or deceleration of time itself.

Time Orientation and Causal Ordering

We endow $\mathbb{R}$ with a **global orientation**:

- **Future** corresponds to increasing T.

- **Past** corresponds to decreasing T.

The set of all instants is **totally ordered**: for any two instants T_1 and T_2, exactly one of the following holds:

$$T_1 < T_2, \quad T_1 = T_2, \quad \text{or} \quad T_1 > T_2$$

Temporal ordering: Event A temporally precedes event B if and only if $T_A < T_B$. This ordering is absolute and observer-independent.

Causal influence is stricter than temporal precedence. Event A can influence event B only when $T_A < T_B$ and event B lies on the finite-speed causal wake support emitted from A. Being earlier is necessary; being on the received wake support is the additional physical condition.

Remark on the Thermodynamic Arrow of Time: The background time manifold $\mathbb{R}$ is symmetric under time reversal $T \mapsto -T$ as a bare oriented line. The declared interaction law is not time-symmetric in that same sense: causal wakes contribute only from emission times $T_t < T$, and the theory excludes advanced or instantaneous interaction terms.

The causal arrow is therefore a law-level feature of the master-equation support convention. Thermodynamic, biological, and cosmological arrows are emergent finite-window properties built on that oriented dynamics, initial and boundary conditions, and the records retained by a finite observer. This differs from time-symmetric absorber formulations, where past- and future-supported solutions are treated as part of one law. The law-level asymmetry also carries a recovery burden of the same family as preferred-frame leakage: effective observer-level dynamics must recover microreversibility and detailed-balance behavior in the validated equilibrium and weak-interaction regimes up to known T-violation bounds, with the derivation owned by the theory-bridge layer.

The entropy arrow is therefore a finite-window statement, not a definition of time itself. A valid entropy claim must declare its preparation measure, coarse-graining, observer-accessible window, boundary flux, and any record-change residual. Projection can discard path-history, boundary-wake, or apparatus information and thereby create an increasing retained entropy even when the complete dynamics remain deterministic. The full definitions, data-processing argument, boundary-flux balance, and chart-change residual $\mathcal{R}_Q$ are owned by Entropy. Their load-bearing conclusion here is simple: entropy diagnoses an emergent arrow inside a stated physical and inferential window; it does not supply the absolute ordering parameter T.

Absolute and Universal Nature

The time coordinate T is **absolute and universal**:

- The duration ΔT between any two events is **the same for all observers**, regardless of their position, velocity, or state of motion.

- **No relativity of simultaneity:** Two events with equal T-coordinates are simultaneous for all observers in an objective, frame-independent sense.
- **No time dilation at the kinematic level:** The advancement of the background parameter is not affected by motion or observer-level gravitational conditions.

Any observed slowing of clocks for moving or bound assemblies is not a change in the background time flow. It is a change in how those assemblies' internal dynamics map onto the absolute time parameter. Proper time is therefore an inferred clock readout in the observer sector, not a second substrate time. See Proper Time and Time Dilation.

> **Implication:** In contrast to special relativity, simultaneity is an **objective, frame-independent property** in $\mathbb{AAA}$.

No Absolute Origin and Completeness

The choice of $T = 0$ is **arbitrary and purely conventional.** It serves only as a reference point. The timeline extends infinitely into:

- The **past**: $T \to -\infty$
- The **future**: $T \to +\infty$

As a manifold, $\mathbb{R}$ is:

- **Connected**: no gaps.
- **Complete**: complete as a metric space under the duration distance $|T_2 - T_1|$, with no edges or boundaries.
- **Without endpoints.**

This is a statement about the background time manifold used by the fundamental dynamics. It is not by itself a solved cosmological boundary condition. A particular cosmological solution may occupy all of $\mathbb{R}$ or a dynamically selected interval, depending on its boundary data. Modeling the time factor as $\mathbb{R}$ prevents artificial endpoints in the substrate parameter; it does not prove that every realized universe history has no initialization, cutoff, or external selection condition.

Symmetries of Absolute Time

The fundamental kinematic symmetry of absolute time is the **additive group**:

$$(\mathbb{R}, +)$$

of **time translations.** This acts on time via:

$$T \mapsto T + T_{\text{shift}}, \quad T_{\text{shift}} \in \mathbb{R}$$

This symmetry expresses the principle that **the laws of physics are time-translation invariant**: the same admissible state and path-history data, translated by a constant amount in T, obey the same dynamical law.

The larger group of smooth orientation-preserving time relabelings is not a symmetry of the substrate law. Once the constant wake speed and receiving-law normalization are fixed, nonlinear time reparametrizations change the causal-root spacing, transmitter-side factors, and receiver-side factors rather than merely changing units.

Connection to Conservation Laws: Time-translation invariance is the kinematic basis for **energy conservation** when the relevant dynamics admit an energy or action formulation. In this chapter, the point is structural: the background clock supplies a fixed parameter against which such conservation statements can be formulated.

At the level of the background structure, time is symmetric under **time reversal**:

$$T \mapsto -T$$

This is a **mathematical symmetry** of the manifold $\mathbb{R}$, not automatically a symmetry of the declared dynamics. The master equation chooses future as increasing T by summing only over causal-root rows with $T_t < T$. A reflected history would solve a different future-supported law unless the causal-support convention were changed. The **causal orientation** is therefore part of the dynamics' support rule; it is not curvature, force, or internal structure of the time background itself.

Role of Time in Dynamics

Time serves as a **universal, non-dynamical parameter** for all worldlines, causal wakes, and observer-level effective laws. It is:

- The independent variable in all equations of motion.
- The basis for defining velocities ($d\mathbf{X}/dT$) and accelerations ($d^2\mathbf{X}/dT^2$).
- A passive parameter, not an active participant in forces or curvature.

Crucial constraint: There is **no freedom to choose alternative fundamental time parameters** along a worldline. There is no proper time at the substrate level; all worldlines are parametrized directly by the absolute T. This ensures that all dynamical evolution can be tracked consistently against a single, universal clock.

A **worldline** of an architrino or assembly is a map:

$$\mathbf{X} : I \subset \mathbb{R} \to \mathbb{R}^3, \quad T \mapsto \mathbf{X}(T)$$

where I is an interval and T is **strictly increasing** with respect to the time orientation.

Key property: Worldlines are **graphs over T**: each worldline is a map $T \mapsto \mathbf{X}(T)$ on its interval, so there is no admissible parametrization in which T decreases, and closed timelike curves and backward segments are excluded by construction. Branching, when it occurs, is **deterministic multistability in the dynamics** (multiple coexisting attractors), not a splitting of the time parameter itself.

Causality and Finite Propagation Speed

Causal Ordering: Event A can influence event B **only if $T_B > T_A$**. This is a necessary condition, not a sufficient one.

Finite Propagation Speed: All physical interactions are mediated by causal wakes that propagate at a **finite speed c_f**, the wake speed used by the master equation.

The foundation stack keeps the relevant speed symbols distinct:

Symbol	Meaning	Status
c_f	Primitive causal-wake propagation speed relative to the Euclidean void	fundamental
$c_\gamma(\mathcal{N}_{\mathrm{sea}}, \hat{\mathbf{k}})$	Photon-channel speed in a Noether sea state and direction	derived
c_{eff}	Effective signal or clock-channel speed for a specified dressed branch	derived/contextual
$c_\star$	Local comparison speed used in a declared clock, ruler, or signal branch	branch-dependent
c_0	Measured low-energy invariant light speed in weak homogeneous conditions	empirical calibration and dressing-flow fixed-point target

These symbols must not be identified unless the local regime and derivation have been stated.

Path-History Interactions: If transmitter j emits from $\mathbf{X}_j(T_t)$ and receiver i is at $\mathbf{X}_i(T_r)$, the contributing emission times are the delayed roots

$$\mathcal{C}_{ij}(T_r) = \{\, T_t < T_r : \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t) \,\}$$

Only emission times in $\mathcal{C}_{ij}(T_r)$ contribute to the receiver at reception time T_r. Earlier events that miss this root condition do not contribute through this channel. In dimensional variables, the same condition is written with hatted times and positions using the corresponding dimensional value of c_f.

Equivalently, define the root function

$$F_{ij}(T_r, T_t) = \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| - c_f(T_r - T_t), \qquad T_t < T_r$$

Then $\mathcal{C}_{ij}(T_r) = \{\, T_t < T_r : F_{ij}(T_r, T_t) = 0 \,\}$. The same set covers ordinary partner hits when $i \neq j$ and self-hits when $i = j$; no separate self-hit law is needed. A simple-root branch chart requires

$$|\partial_{T_t} F_{ij}(T_r, T_t)| = |c_f - \hat{\mathbf{r}}_{ij}(T_r, T_t) \cdot \mathbf{V}_j(T_t)| \geq \kappa_{\text{hit}} > 0$$

where

$$\mathbf{r}_{ij}(T_r, T_t) = \mathbf{X}_i(T_r) - \mathbf{X}_j(T_t), \qquad \hat{\mathbf{r}}_{ij} = \frac{\mathbf{r}_{ij}}{\|\mathbf{r}_{ij}\|}$$

Failure of this transversality floor marks a caustic-like or degenerate wake-root regime. It must be routed to branch-chart or regularization analysis rather than treated as an ordinary force perturbation.

For self-hits, the shared root function does not erase the additional geometry carried by transmitter identity. When $i = j$, a root means the same worldline γ_i re-enters its own forward causal isochron. In general this is a curvature, torsion, and return-geometry condition on γ_i, not a speed test by itself. A super-field-speed segment is a regime warning for possible self-hit roots, but the accepted branch is still defined by same-transmitter root existence together with the transversality floor and the retained transmitter-side acceleration weight.

The symbol $\kappa_{\text{hit}} > 0$ is not a universal coupling constant and not the regularization width η. It denotes a declared positive lower bound for one retained branch chart, certificate, or regularized model after the units, root labels, endpoint convention, and memory window have been fixed. Concrete branch packets may report the same condition as a certified Jacobian floor such as J_0 or ν_J. The existence of a positive floor is part of simple-root admissibility; its numerical value belongs to the branch-chart or validation record, not to the universal parameter ledger. It is not a coordinate parameter and cannot be removed by relabeling the same history.

Topologically, a generic loss of this floor is a codimension-one fold of the causal-root manifold: two simple roots can merge into one degenerate root, or a simple root can be born at a caustic boundary. The floor is therefore not merely an analytic small-denominator guard. It certifies that the branch count and causal-root topology are stable on the retained chart; when it fails, the event must be treated as a root bifurcation, reconnection, or chart transition.

The corresponding root caustic set for a pair of histories is

$$\Sigma_{ij} = \{(T_r, T_t) : F_{ij}(T_r, T_t) = 0,\ \partial_{T_t} F_{ij}(T_r, T_t) = 0\}$$

On a generic one-parameter branch this is a Whitney fold, or A_2 singularity, of the root map $T_t \mapsto F_{ij}(T, T_t)$. Higher events such as a cusp, where $\partial^2_{T_t} F_{ij} = 0$ also holds, are codimension-two alarms for branch-pair creation, annihilation, or merger of fold events. In simulation language, fold contact is the first warning that the Jacobian floor has failed; cusp contact is a stronger warning that the local branch-count catalogue itself is changing.

This is one instance of a broader foundation-stack discipline: **non-degeneracy floors** convert exact failure sets into graded admissibility certificates. The root Jacobian floor here, the basin-separatrix floor in Emergence, and the basis-conditioning floor in Constructing the Absolute Frame serve the same role for different objects. They are certificate margins attached to declared charts, not universal constants.

The interaction law is built entirely from path-history contributions at emission times $T_t < T_r$ that satisfy the causal-root condition; $\mathbb{AAA}$ contains no advanced or instantaneous interaction terms. This delayed-only support condition is a law-level causal asymmetry, not merely an initial-condition effect.

There are **no instantaneous actions-at-a-distance** and **no advanced potentials**.

This gives the postulate a hard failure wall. Postulate 1 fails if any accepted substrate-level interaction requires support from $T_t > T$, instantaneous coupling at spatial separation, or a clock-rate field that enters the receiving law as an independent substrate variable rather than as a derived assembly readout. Observer-level proper time, clock dilation, and effective metric lapse may still be recovered, but they cannot be promoted into a second fundamental time parameter without replacing the postulate.

Path History and Non-Markovian Memory

A critical feature of $\mathbb{AAA}$ is that **all interactions are mediated by path history**. The present receiver does not respond to an instantaneous distant object. It responds to the cumulative causal wake surfaces that reach it from prior emission events.

At time T, an architrino at position $\mathbf{X}(T)$ receives wake contributions where its worldline intersects **causal wake surfaces** emitted at all past times $T_t < T$; through the Master Equation, those received wakes determine receiver-local acceleration rather than a primitive force. This gives rise to **non-Markovian memory effects**, including the self-hit regime where an architrino interacts with its own past emissions.

Because T is universal and absolute, the past (all $T_t < T$) is unambiguous, and the theory can sum or integrate over admissible delayed contributions. This allows for a mechanistic model of interaction without invoking action-at-a-distance, while still permitting **deterministic multistability** at self-hit thresholds.

Provenance and Identity Through Time

Each architrino carries a unique **provenance** record tied to its worldline history. That provenance is strictly monotone in T: exchanging records is not a mere relabeling but an operation that changes the physical history of the participating entities. Any bookkeeping, conservation statement, or coarse-graining must explicitly state when provenance has been suppressed or when identical-looking exchanges are being treated at the effective level.

Consequently, an exact global flip or permutation of architrinos is not a substrate symmetry unless it preserves the full path-history and causal-wake record. Schematically, if a universe state is written as

$$\mathbb{U}_{\text{now}} \equiv S(T) = \{(\mathbf{X}_i(T), \mathbf{V}_i(T), q_i, H_i(T))\}_i$$

where $H_i(T)$ denotes the path-history and provenance record carried by architrino i, then a proposed exchange is exact only when it preserves the instantaneous data and the corresponding $H_i(T)$ records. Generic architrinos are therefore not interchangeable at the ontic level even when finite observers can treat their exposed properties as effectively identical.

For same-polarity exchange and downstream fermionic-statistics claims, the history record must be read jointly, not as a set of independent single-worldline ledgers. A braid can preserve endpoint data while changing the relative framing or linking class of the exchanged worldlines. Exact exchange therefore requires preservation of the joint path-history record, including relative framing, linking, and any protected framed self-linking row such as $Lk = \mathrm{Wr} + \mathrm{Tw}$ when that row is part of the branch certificate. If the joint framed or linking class changes, the exchange is a different substrate branch, not a hidden exact permutation symmetry.

Equivalently, exact exchange acts on connected components of the configuration space of framed worldline strands, not merely on the symmetric group of endpoint labels. A same-polarity permutation is exact only in the identity-component stabilizer of the joint framed-braid data. Provenance leakage is therefore expected whenever an exchange path crosses between components of framed-braid space, even if a finite observer cannot resolve the endpoint-preserving difference.

The architrino-specific identity claim is developed further in Architrino.

Geodesics and the Absence of Temporal Dynamics

In $\mathbb{AAA}$, time itself has no internal structure or dynamics. It does not encode forces, curvature, or acceleration of any kind.

- The **flow of time** is trivial: the parameter advances uniformly, and there is no geodesic equation to solve because no metric or connection is declared on the bare time line.
- All **accelerations** (and any assembly-level effective forces) arise from:
  - **Causal wakes** acting within the fixed Euclidean void.
  - **Self-interaction** of extended assemblies, such as the self-hit regime of binaries.

They do **not** arise from any curvature or dynamics of the time coordinate itself.

Comparison to General Relativity: In GR, time is part of a dynamical spacetime manifold that curves in response to stress-energy. Here, time is **fixed and non-dynamical**. Any observer-level clock dilation, lapse effect, or effective metric curvature observed in experiments must emerge from assembly dynamics, causal wakes, and Noether sea response within this fixed temporal framework. The comparison does not deny relativistic phenomenology; it assigns that phenomenology to an effective recovery layer rather than to fundamental time.

Distinction from Relativistic Time

Feature	Absolute Time ($\mathbb{AAA}$)	Relativistic Time
Manifold	$\mathbb{R}$ (1D, separate from space)	Part of 4D spacetime with Lorentzian metric
Universality	Universal, frame-independent clock	Relative; different observers measure different intervals
Simultaneity	Absolute and global	Relative; depends on observer's frame
Duration	Frame-independent	Frame-dependent; proper time varies with velocity and gravity
Dilation	None at kinematic level	Yes; $d\tau = \sqrt{1 - v^2/c^2}\, dt_{\mathrm{eff}}$
Mixing with Space	No; time and space strictly separate	Yes; Lorentz boosts mix t_{eff} and x^i_{eff}
Causal Structure	Defined by temporal ordering plus finite propagation speed c_f	Encoded in the metric via lightcones
Background Dynamics	Non-dynamical	Dynamical; Einstein's equations

Summary Postulate

> **Postulate 1 (Absolute Time):** Time is an **absolute, universal, one-dimensional continuum** $\mathbb{R}$, with a fixed orientation (future = increasing T) and a dynamical scale anchored by the constant primitive wake speed c_f and the time-translation-invariant master equation. Duration between events is **frame-independent**. The time coordinate is **non-dynamical** and does not encode forces or curvature. All dynamics occur via finite-speed wake propagation (c_f) in absolute time, with all interactions via path history; there is no instantaneous action-at-a-distance and no advanced interaction term. Worldlines are parametrized directly by T with no fundamental reparametrization freedom beyond unit choice and origin choice. Any thermodynamic arrow, observer-clock dilation, or relativistic proper-time effect is an emergent property of assemblies, causal wakes, and effective observer reconstruction, not a feature of the background T parameter itself.

Euclidean Void

Start with the thing that does not change. The Euclidean void is the fixed spatial container in $\mathbb{AAA}$. It supplies location, distance, volume, and spatial derivatives. It does not supply matter, curvature, expansion, memory, or dynamical response.

The main separation is the whole point of this chapter. The Euclidean void is the container. The Noether sea is physical content inside the container. Effective spacetime is the observer-level geometry reconstructed from assemblies, wakes, clocks, rulers, and signals. This chapter defines the first layer and keeps it from being confused with the other two.

The order is deliberately simple. First fix the geometry. Then explain how coordinates and event identity work in that geometry. Then mark the boundary where the story leaves the void and becomes medium dynamics, effective metric closure, or observational inference.

This page is also a guardrail for cosmology and gravity language. If a later chapter speaks about expansion, curvature, lensing, or clock redshift, the first question is not “what did space do?” The first question is which contents, transport histories, clocks, rulers, or observer reconstructions changed inside the fixed Euclidean void.

Core Concept

The Euclidean void is three-dimensional, continuous, flat, and non-dynamical. It is the arena in which architrinos move and interact. It does not curve, expand, contract, or respond to matter.

That statement is stronger than a coordinate convenience. Curvature-like behavior in $\mathbb{AAA}$ is recovered from assembly and medium dynamics inside the fixed background. It is not assigned to the background itself.

Space is **homogeneous** and **isotropic**:

- Homogeneous: every location is equivalent.
- Isotropic: every direction is equivalent.

These are claims about the container only. They are not claims that the material contents are evenly distributed. A dense region, a galaxy, or a disturbed Noether sea cell can break the symmetry locally as content. The void underneath it remains homogeneous and isotropic.

This is why cosmological expansion, light bending, orbital precession, and other curvature-like observations must be recovered as dynamics of the Noether sea and assemblies within the void. They are not metric expansion or curvature of the void itself.

Manifold and Metric

The mathematical model is ordinary three-dimensional Euclidean space:

$$\mathbb{R}^3$$

A location is represented by a point

$$\mathbf{X} = (X, Y, Z) \in \mathbb{R}^3$$

or in index notation by X^i where $i \in \{1, 2, 3\}$.

The metric is fixed:

$$h_{ij} = \delta_{ij}$$

where δ_{ij} is the Kronecker delta.

The spatial line element is therefore

$$d\ell^2 = h_{ij}\, dX^i dX^j = dX^2 + dY^2 + dZ^2$$

The distance between two points $\mathbf{p}$ and $\mathbf{q}$ is

$$d(\mathbf{p}, \mathbf{q}) = \sqrt{(X_p - X_q)^2 + (Y_p - Y_q)^2 + (Z_p - Z_q)^2}$$

For fixed void points, this distance does not change with time. Equivalently, with

$$D_h(\mathbf{p}, \mathbf{q}) = \sqrt{h_{ij}(p^i - q^i)(p^j - q^j)}$$

the substrate condition is

$$\partial_T h_{ij} = 0, \qquad R^i{}_{jkl}(h) = 0, \qquad \frac{d}{dT} D_h(\mathbf{p}, \mathbf{q}) = 0$$

The consequence is immediate: a cosmological scale variable cannot be a time-dependent scale factor multiplying the void metric. It must be an effective summary of medium state, transport history, or observer records.

This gives a clean accounting identity for later effective geometry:

$$\mathcal{R}^{\text{eff}}[g^{\text{eff}}] = \mathcal{R}^{\text{eff}}[\mathcal{N}_{\text{sea}}, O, \text{clock/ruler/signal response}] + 0_{\text{void}}.$$

The void contribution is exactly zero. Effective curvature, effective expansion, and effective anisotropy may still be recovered from Noether sea state, assembly clock/ruler response, signal transport, and observer reconstruction. They just cannot be charged to the Euclidean container.

The zero term is also a topology-and-bundle statement. Because the void is $\mathbb{R}^3$, it is contractible and parallelizable; its oriented orthonormal frame bundle is globally trivial,

$$F(\mathbb{R}^3) \cong \mathbb{R}^3 \times SO(3),$$

and the unoriented orthonormal bundle (fiber $O(3)$) and full frame bundle (fiber $GL(3)$) are likewise trivial over $\mathbb{R}^3$.
The flat Levi-Civita connection therefore has trivial holonomy. The container has no ambient bundle curvature, monodromy, or topological obstruction that can secretly supply effective curvature or an assembly label.

> **Plain language:** The void is the ordinary three-dimensional space of rulers and straight-line distance. What changes is the content moving through it, not the space itself.

Flat Geometry and Topology

Formally, the Euclidean void is the Riemannian manifold $(\mathbb{R}^3, h)$ with flat metric $h_{ij} = \delta_{ij}$.

Its curvature tensors vanish identically:

- Riemann curvature tensor: $R^i{}_{jkl} = 0$.
- Ricci tensor: $R_{ij} = 0$.
- Scalar curvature: $R = 0$.

The Levi-Civita connection ∇ is compatible with the metric,

$$\nabla h = 0$$

and is torsion-free. In Cartesian coordinates, all Christoffel symbols vanish:

$$\Gamma^i{}_{jk} = 0$$

For the declared flat Levi-Civita connection, the geodesic equation in Cartesian coordinates becomes

$$\frac{d^2 X^i}{ds^2} = 0,$$

with s Euclidean arclength, so its solutions are straight lines.

Topologically, the void stays $\mathbb{R}^3$: contractible, simply connected, and without substrate-level topology change. The interesting topology is not in the container. It is in architrino worldlines and assembly configurations inside the container.

Consequently, topological protection in $\mathbb{AAA}$ is not supplied by nontrivial cycles or torsion in the ambient container. Linking, framing, and assembly topological charge labels are invariants of worldline and braid configurations inside a trivial ambient space. Their protection must come from branch-preserving deformation barriers, causal-root folds, collision or transversality floors, and finite action or energy gaps.

Canonical Coordinates and Event Identity

Coordinates are names for fixed substrate locations. The void itself does not come with painted axes or a built-in origin. Once a chart is chosen for calculation, the canonical spatial chart is a fixed Cartesian coordinate system

$$\mathcal{C} = \{X, Y, Z\}$$

on the Euclidean void.

This differs from General Relativity. In GR, coordinates may function as gauge labels under diffeomorphism invariance. In $\mathbb{AAA}$, once a Cartesian chart has been declared, it names fixed spatial locations in the substrate. The chart is still just a representation for components and simulation addresses; it is not an extra ontological ingredient. Coordinate points do not move, curve, or stretch.

This gives a plain rule for spatial identity:

- The point (X_0, Y_0, Z_0) is the same spatial location at every absolute time T.
- The events (T_1, X_0, Y_0, Z_0) and (T_2, X_0, Y_0, Z_0) occur at the same spatial location at two different instants.
- Local Noether sea density, architrino occupancy, and assembly configuration may change there without changing the identity of the underlying void point.

Fixed identity matters whenever a calculation needs provenance. Self-hit diagnostics, path-history bookkeeping, and simulations must know where a wake was emitted and where it is later received.

For a received wake contribution, the provenance record keeps the transmitter identity, emission time, emission location, receiver identity, reception time, and reception location:

$$(j, T_t, \mathbf{X}_j(T_t), i, T_r, \mathbf{X}_i(T_r))$$

The causal-root condition is then

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\|_h = c_f(T_r - T_t)$$

This condition is invariant under Euclidean translations and rotations of the chosen chart. The chart may be changed for calculation, but relabeling does not move the underlying void point where the emission occurred.

Curvilinear Coordinates

Cartesian coordinates are the natural default, but flat Euclidean geometry can be written in other coordinates when a problem calls for them.

In spherical coordinates (r, θ, ϕ) with $r \geq 0$, $\theta \in [0, \pi]$, and $\phi \in [0, 2\pi)$,

$$h = dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta \, d\phi^2$$

with components

$$h_{ij} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2 \sin^2\theta \end{pmatrix}$$

In cylindrical coordinates (ρ, ϕ, z),

$$h = d\rho^2 + \rho^2 d\phi^2 + dz^2, \qquad h_{ij} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \rho^2 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

The metric components look different in these coordinates, but the geometry has not changed. Curvature is coordinate-invariant, and

$$R^i{}_{jkl} = 0$$

in every coordinate system.

Index Notation and Tensor Operations

Use Cartesian core indices $i, j, k \in \{1, 2, 3\}$ for spatial components. In these coordinates, the Euclidean metric and its inverse are

$$h_{ij} = \delta_{ij}, \qquad h^{ij} = \delta^{ij}$$

Raising and lowering indices then changes notation but not the component value:

$$v_i = h_{ij} v^j = \delta_{ij} v^j = v^i, \qquad v^i = h^{ij} v_j = \delta^{ij} v_j = v_i$$

The dot product and norm are

$$\mathbf{u} \cdot \mathbf{v} = h_{ij} u^i v^j = u^1 v^1 + u^2 v^2 + u^3 v^3$$

and

$$\|\mathbf{v}\|^2 = h_{ij} v^i v^j = (v^1)^2 + (v^2)^2 + (v^3)^2$$

The spatial volume element in Cartesian coordinates is

$$dV = \sqrt{\det h}\, d^3X = dX\, dY\, dZ$$

Surface elements pick up the usual Jacobian factors when parametrized, for example $dA = r^2 \sin\theta\, d\theta\, d\phi$ on a constant-r sphere.

Spatial Differential Operators

Because the metric is Euclidean, the tensor formulas specialize to the familiar vector-calculus operators.

The gradient of a scalar field is

$$\nabla f = \left(\frac{\partial f}{\partial X}, \frac{\partial f}{\partial Y}, \frac{\partial f}{\partial Z}\right) = h^{ij}\partial_i f\, \mathbf{e}_j$$

The divergence of a vector field is given by the invariant formula

$$\nabla \cdot \mathbf{v} = \frac{1}{\sqrt{\det h}}\partial_i \left(\sqrt{\det h}\, v^i\right)$$

In Cartesian coordinates $\sqrt{\det h} = 1$, so this reduces to

$$\nabla \cdot \mathbf{v} = \partial_i v^i = \partial_{X^1} v^1 + \partial_{X^2} v^2 + \partial_{X^3} v^3$$

The scalar Laplacian in Cartesian coordinates is

$$\Delta f = \nabla^2 f = h^{ij}\partial_i\partial_j f = \partial^2_{X^1} f + \partial^2_{X^2} f + \partial^2_{X^3} f$$

In curvilinear coordinates on the same flat geometry, the invariant scalar Laplacian is

$$\Delta f = \frac{1}{\sqrt{\det h}}\partial_i \left(\sqrt{\det h}\, h^{ij}\partial_j f\right)$$

The tensor expressions are the invariant statements. The component formulas change with the chosen chart.

Homogeneity, Isotropy, and the Euclidean Group

The symmetry group of the Euclidean void is the full Euclidean group:

$$E(3) = \mathbb{R}^3 \rtimes O(3)$$

This combines:

- Spatial translations: $\mathbf{X} \mapsto \mathbf{X} + \mathbf{a}$.

- Spatial rotations: $\mathbf{X} \mapsto R\mathbf{X}$, with $R \in SO(3)$.
- Spatial reflections: $\mathbf{X} \mapsto M\mathbf{X}$, with $M \in O(3) \setminus SO(3)$.

Any element $g = (R, \mathbf{a}) \in E(3)$ with $R \in O(3)$ acts on a point $\mathbf{X}$ as

$$g \cdot \mathbf{X} = R\mathbf{X} + \mathbf{a}$$

The metric is invariant under all such transformations:

$$g^* h = h$$

Homogeneity and isotropy give the container-level consequences:

- Laws of physics are identical at any two void locations.
- There is no center or edge of space.
- No direction is preferred by the substrate.
- Translation symmetry supplies the kinematic basis for momentum conservation when the delayed action and wake-ledger channels preserve the same symmetry.
- Rotation symmetry supplies the kinematic basis for angular momentum conservation when the delayed action and wake-ledger channels preserve the same symmetry.

Reflections are container symmetries, and the primitive wake law is parity-even: causal isochrons are spheres and the received acceleration follows $\hat{\mathbf{r}}_{ij}/r_{ij}^2$. This parity-evenness is proved for the declared causal kernel in B1 Symmetry. Chirality bookkeeping such as writhe and linking signs is therefore conventional at the container level, and physical parity violation must be recovered as assembly and branch-level selection; see Gauge Structure Emergence.

Any preferred-frame effect, anisotropy, or effective Lorentz behavior must therefore come from dynamics, Noether sea response, or observer construction. It cannot come from an anisotropy of the Euclidean void.

Geodesics and Dynamics

Here the important separation is between a straight path in the container and a curved path caused by dynamics. A geodesic of the Euclidean void is a straight spatial path in the fixed metric. It is not an observer-level spacetime geodesic.

In the absence of causal-root hits, motion in the Euclidean void follows straight-line, constant-velocity paths:

$$\mathbf{X}(T) = \mathbf{X}_0 + \mathbf{V}_0 T$$

Only physical interactions can bend a trajectory. A curved path in the void is not the same thing as curvature of the void:

- A circular orbit is a curved path in flat space.
- A forced trajectory is a dynamical effect.
- The void remains flat even when trajectories curve within it.

Thus deviations from straight-line motion arise from causal wakes, self-interaction, assembly structure, and medium response. They do not arise from spatial curvature.

Substrate acceleration terms must also carry provenance. A deviation from straight motion is admissible only when it is sourced by a causal-wake contribution, a self-hit contribution, an assembly interaction, or Noether sea response. A transverse or velocity-dependent term with no wake or medium provenance is either a coordinate artifact of a non-inertial chart or not a substrate acceleration in the ontology.

Forbidden Transformations

Allowed spatial isometries are exactly the transformations that preserve the Euclidean spatial metric:

- Spatial translations.
- Spatial rotations.
- Spatial reflections.

At the product-background level, absolute timespace may also be described in coordinate systems related by time translations or Galilean boosts that preserve the foliation by constant-T slices. Those transformations describe the product structure. They are not spatial isometries of one void slice. On a fixed slice Σ_{T_*}, a Galilean boost reduces to the translation $\mathbf{X} \mapsto \mathbf{X} + \mathbf{V}_0 T_*$; its boost content appears only when different slices are compared. The wake equation still selects the preferred rest frame in which c_f is isotropic, and Absolute Timespace carries the corresponding dynamical non-invariance under boosted coordinates.

Forbidden as substrate symmetries:

- Non-isometric scalings or shears that change distances or angles.
- Lorentz boosts as fundamental transformations of the void.
- Transformations that mix spatial coordinates with absolute time as though the product background were a single relativistic metric.
- Any operation that introduces a preferred direction at the substrate level.

Galilean coordinate behavior belongs to the absolute-timespace product structure. Lorentz behavior remains a closure target for moving assemblies, clocks, rulers, and signals. Neither Lorentz boosts nor effective metric transformations are fundamental symmetries of the Euclidean void itself.

Boundary With the Noether Sea

The boundary with the Noether sea is an ontology boundary. The Euclidean void is not the Noether sea. Neither one is effective spacetime.

Keep the layers separate:

1. **Euclidean void:** fixed spatial container $\mathbb{R}^3$ with metric $h_{ij} = \delta_{ij}$.
2. **Noether sea:** physical content occupying the void, built from coupled neutral braids.
3. **Architrino occupancy:** local presence or absence of point entities and assemblies at a given coordinate location.
4. **Effective spacetime:** observer-level geometry reconstructed from how clocks, rulers, and signals behave in the Noether sea.

At any time T, a coordinate point may be occupied by an architrino, traversed by a wake, located inside a Noether sea cell, or empty of local architrino content. Those are different content states at the same location. None changes the identity or metric of the underlying void point.

This gives a direct no-expanding-void criterion for cosmology. After an observer chart is declared, effective cosmology variables such as $a_{\rm eff}(t_{\rm eff})$, $H_{\rm eff}(t_{\rm eff})$, redshift, and CMB temperature summaries are admissible only as functions of Noether sea state, transport history, and observer clock comparison:

$$a_{\rm eff}(t_{\rm eff}) = \mathcal{A}[\mathcal{N}_{\rm sea}(T), O(t_{\rm eff})]$$

Here $\mathcal{N}_{\rm sea}(T)$ denotes the relevant Noether sea state variables, and $O(t_{\rm eff})$ denotes observer records and calibration data in the effective chart. The formula is a schematic inference map into the observer-level metric, not a new substrate law.

It yields a scalar global scale factor only when the retained Noether sea record and observer family are statistically homogeneous and isotropic over the declared averaging cell. Without that condition, the honest output is a local or tensorial effective metric summary such as $g^{\rm eff}_{\mu\nu}(x^i_{\rm eff}, t_{\rm eff})$, or an anisotropic scale response $a_{{\rm eff},ij}(x^i_{\rm eff}, t_{\rm eff})$, not a single FRW-style $a_{\rm eff}(t_{\rm eff})$.

When a tensorial scale response is retained, the scalar FRW projection is the trace

$$a_0(x^i_{\rm eff}, t_{\rm eff}) = \frac{1}{3} h^{ij} a_{{\rm eff},ij}(x^i_{\rm eff}, t_{\rm eff}), \qquad a_{\langle ij\rangle} = a_{{\rm eff},ij} - a_0 h_{ij}.$$

The scalar scale-factor summary is admissible only in a sector where the trace-free obstruction $a_{\langle ij\rangle}$ is below the declared isotropy tolerance. The same obstruction appears as ruler anisotropy in response tensors such as B_{ij} and in Hughes-Drever-style orientational residuals; it is a medium-and-assembly response question, not a hidden anisotropy of the void.

These effective variables must not be interpreted as

$$h_{ij}(T) = a_{\text{eff}}^2(t_{\text{eff}})\delta_{ij}$$

for the Euclidean void. The substrate spatial metric remains $h_{ij} = \delta_{ij}$, flat and unchanging. Any effective cosmological expansion factor belongs to observer-level metric reconstruction.

The no-expanding-void commitment creates a specific observational burden. Any medium-and-observer redshift mechanism must still recover the tested expansion signatures normally carried by an FRW scale factor: the Tolman surface-brightness scaling $B_{\text{obs}} \propto (1+z)^{-4}$ after the declared distance map is applied, supernova light-curve time dilation $\Delta t_{\text{obs}} \approx (1+z)\Delta t_{\text{emit}}$, and CMB temperature-redshift scaling $T_{\text{CMB}}(z) \approx T_0(1+z)$ in the appropriate thermal record.

The mechanism filter is transport rather than loss. Redshift must retune the signal clock rate through Noether sea transport, clock/ruler response, or both. Operationally, an admissible transport redshift is a phase-clock reparametrization of the received signal together with the matching distance and intensity bookkeeping. It is not merely attenuation of amplitude or untracked energy loss. Pure propagation loss can lower received energy, but it does not supply the observed time-dilation or thermal scaling rows. A fixed-void model that supplies redshift only by generic scattering loss, phase degradation, or photon fatigue falls into the excluded tired-light class.

The cosmology branch owns the positive recovery: Cosmology Ontology defines the shared fixed-void variables, Expansion Mechanism carries the redshift and distance tests, and CMB carries the temperature and spectrum tests.

Plenum of Potential

The Euclidean void is strictly empty of material substance. It is not a material ether, not a quantum foam, and not a hidden continuum with internal state variables. Its points do not store energy, density, curvature, stress, or memory.

Still, a coordinate location in the full universe should not be treated as relationally empty. Architrinos continuously emit expanding causal isochrons, so a location may lie on many geometrical wakes from historical architrino motion. These wakes do not fill the void as material contents. They form the delayed relational ledger through which later architrino intersections can be computed.

For a point $(\mathbf{X}, T)$, define the wake-support index set

$$\mathcal{P}(\mathbf{X}, T) = \{(a, T_t) : T_t < T,\ \|\mathbf{X} - \mathbf{X}_a(T_t)\|_h = c_f(T - T_t)\}.$$

This set records source identities and emission times whose causal isochrons pass through the point. It is a provenance index set, not a field. It has no independent state variables, stress, density, energy, or equation of motion.

Equivalently, $\mathcal{P}(\mathbf{X}, T)$ is the receiver-side fiber of the tagged-emission map before the received wake terms are summed into an untagged potential. The receiver-centered exhaustion problem is therefore a summability question over this fiber: the weighted counting measure on $\mathcal{P}(\mathbf{X}, T)$ must converge after the transmitter-side acceleration weights, inverse-square distance factors, and transmitter-side transversality floors are applied. Convergence of the Noether sea background is not a new property of the void. It is a condition on the population of provenance labels and their wake weights.

In this precise sense, the void is a **Plenum of Potential**: materially empty, but relationally available to causal-wake history. The phrase is explanatory rather than ontological. It does not add a new substance between the Euclidean void and the Noether sea, and it does not create a fourth layer alongside void, medium, and effective spacetime. It names the fact that an empty coordinate location can still lie within the superposed causal-wake history of the architrino population. Noether sea density and response variables belong to $\mathcal{N}_{\text{sea}}$; $\mathcal{P}(\mathbf{X}, T)$ names only the wake-history provenance labels available at that point.

For the Noether sea ontology, see Noether sea. For Noether braid assembly hypotheses, see Noether Sea Pro/Anti Coupling. For the metric bridge, see Emergent Metric. For cosmological translation, see Cosmology Ontology.

Distinction From Curved Space

The comparison with curved space preserves the operational success of curved-spacetime descriptions while relocating their status. In $\mathbb{AAA}$, curvature-like behavior is an effective metric or refractive-gravity reconstruction. It is not a property of the Euclidean void.

Feature	Euclidean Void ($\mathbb{AAA}$)	Curved Space / GR Geometry
Geometry	Flat Euclidean, $R = 0$ everywhere	Curved pseudo-Riemannian geometry
Metric	Fixed $h_{ij} = \delta_{ij}$ in Cartesian coordinates	Dynamical $g_{\mu\nu}$
Spatial points	Permanent substrate locations	Coordinate identity may be gauge-dependent
Curvature source	None; the void does not respond	Stress-energy sources curvature
Expansion	No expansion of the void	Metric scale factor may expand
Gravity	Emergent from assembly and Noether sea dynamics	Geometric curvature of spacetime

The phrase `curved space` should not be used for the fundamental ontology. Use `effective metric`, `effective spacetime`, or `refractive gravity` when describing observer-level curvature-like behavior.

Summary Postulate

Postulate 2 fails if an accepted result requires the substrate container itself to carry a dynamical curvature, expansion, contraction, or anisotropy row after contributions from matter content, wake transport, Noether sea response, and observer reconstruction have been exhausted. An effective curved metric may remain a valid observer description; promoting that metric response to the Euclidean void would replace this postulate.

> **Postulate 2 (Euclidean Void):** Three-dimensional space is the Euclidean void: an absolute, static, flat container $\mathbb{R}^3$ equipped with fixed metric $h_{ij} = \delta_{ij}$. It is homogeneous, isotropic, non-dynamical, and does not curve, expand, contract, or respond to matter and energy. All spatial displacements, distances, volumes, and spatial differential operators are defined by the fixed Euclidean metric. Curvature-like observations, effective scale histories, and observer-level redshift summaries arise from trajectories, assemblies, wakes, and Noether sea response within the void, not from curvature or expansion of the void itself.

Absolute Timespace

This chapter specifies the fixed background in which the microscopic dynamics run. In $\mathbb{AAA}$, **absolute timespace** means the product of one universal time line and one fixed Euclidean 3-space. The chapter defines that product background $\mathbb{R} \times \mathbb{R}^3$, its global foliation into simultaneous Euclidean slices, the Newton-Cartan data used to keep time and space separate, and the causal wake geometry used by the microscopic dynamics.

Absolute timespace is not relativistic spacetime. It is the formal product of Absolute Time and the Euclidean Void. Effective spacetime geometry is reconstructed later from assembly and Noether sea dynamics; it is not the substrate itself.

Core Concept

Absolute timespace is the formal, non-dynamical product background for all physical phenomena. It is the direct product of absolute time and the Euclidean void. That product forms a **foliated structure**: each leaf is a complete instantaneous Euclidean 3-space indexed by the universal time parameter T.

In $\mathbb{AAA}$:

- Time and space are logically and mathematically separate at the kinematic level.
- There is absolute simultaneity: all events with the same T belong to the same simultaneity slice.
- There is no fundamental 4D Lorentzian metric mixing temporal and spatial dimensions.
- The background is non-dynamical: it does not respond to matter, energy, assemblies, or the Noether sea.

This separation fixes the chapter's sequence: first name the substrate datum, then identify the effective or inferential layer that reads it. The Euclidean void and absolute time are ontology. Clocks, rulers, metric tensors, and relativistic symmetries are treated as recovered behavior of assemblies and the Noether sea; their detailed laws are closure targets when the derivation is not supplied locally.

All curvature, expansion, clock dilation, and relativistic behavior must be recovered as effective descriptions of assemblies and Noether sea response within this fixed background.

Product Manifold

The absolute timespace background is the Cartesian product

$$\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$$

with coordinates

$$(T, \mathbf{X}) = (T, X, Y, Z)$$

Each point in $\mathcal{M}$ represents an event: a fixed location $\mathbf{X}$ in the Euclidean void at a definite instant T.

The two factors have different ontological roles:

- $\mathbb{R}$ supplies the universal time parameter and total event ordering.
- $\mathbb{R}^3$ supplies the fixed Euclidean spatial container and spatial metric.

The product structure is fundamental. It is not an approximation to a deeper 4D curved metric.

Foliation and Simultaneity Slices

Each instant $T = T_*$ defines a global simultaneity slice

$$\Sigma_{T_*} = \{T_*\} \times \mathbb{R}^3 \cong \mathbb{R}^3$$

Every event $(T, \mathbf{X})$ belongs to exactly one slice Σ_T. This foliation is absolute and frame-independent at the substrate level.

An object or assembly traces a worldline through the product background:

$$\gamma : I \subset \mathbb{R} \to \mathcal{M}, \qquad T \mapsto (T, \mathbf{X}(T))$$

Worldlines are graphs over T: there is no admissible parametrization in which T decreases, so closed timelike curves and backward-time propagation are excluded by construction, and there is no fundamental reparametrization freedom that replaces the absolute time parameter.

> **Plain language:** Absolute timespace is a stack of Euclidean 3-spaces, one for each value of T. A worldline passes through one slice at each instant.

On a fixed slice, the canonical universe-now notation is

$$\mathbb{U}_{\text{now}} \equiv S(T)$$

This denotes the complete ontic universe state on Σ_T: architrino positions, velocities, polarities, path-history and provenance bookkeeping, and self-hit history needed for deterministic evolution. It is not an observer's measurement record. Observer reconstructions sample or coarse-grain this state through assemblies and Noether sea coupling, which prevents absolute simultaneity from being confused with operationally synchronized clocks.

The same distinction blocks a common relativity confusion. A substrate slice Σ_T is a real element of the ontology, but it is not an observer-readable global present. Physical Observers recover simultaneity through clock phases, ruler records, photon channels, and local Noether sea state; those channels may hide the preferred frame well enough to reproduce special-relativistic no-global-present behavior. Cosmological records such as the CMB rest frame can supply an approximate effective foliation, but that foliation is an inferred observer chart, not the substrate slice itself.

Because the master equation is path-history dependent, this complete state is not merely an instantaneous Markov list of positions and velocities. A precise slice-state schematic is

$$S(T) = \big(X(T), H_T, \mathcal{N}_{\text{sea}}(T, \cdot), \mathcal{B}_T\big)$$

Here $X(T)$ contains instantaneous architrino and assembly data, H_T is the required path-history and provenance ledger, $\mathcal{N}_{\text{sea}}$ is the local Noether sea state record, and $\mathcal{B}_T$ records the active branch chart or regularization data. Determinism applies to this complete history state, not to a history-free instantaneous projection.

Newton-Cartan Data

The background geometry is encoded by a pair of structures rather than by a single non-degenerate 4D metric. One structure keeps time ordered; the other measures distances inside each slice.

The substrate clock 1-form is the exact form

$$dT$$

This 1-form is closed, exact, and nowhere vanishing on $\mathcal{M}$. Its level sets are the simultaneity slices Σ_T. The symbol τ is reserved for derived observer proper time; emission times use T_t, and causal delay is written $\Delta_{ij} = T - T_t$.

The spatial metric on each slice is

$$h = dX^2 + dY^2 + dZ^2$$

with Cartesian components

$$h_{ij} = \delta_{ij}$$

The metric h acts only on spatial vectors tangent to Σ_T. Time and space are therefore encoded separately by (dT, h).

A flat, torsion-free connection ∇ satisfies

$$\nabla dT = 0, \qquad \nabla h = 0$$

These compatibility equations do not determine ∇ by themselves in ordinary Newton-Cartan geometry. The same (dT, h) admits torsion-free compatible connections whose coefficients represent rotating-frame or accelerating-frame inertial terms. In $\mathbb{AAA}$ the connection is therefore a dynamically completed piece of substrate data: (dT, h) supply the foliation and spatial metric, and the interaction law selects the rest frame in which the finite causal-wake speed c_f is isotropic. In the corresponding global Cartesian rest coordinates, the selected connection has

$$\Gamma^{\lambda}_{\mu\nu} = 0$$

Covariant derivatives then reduce to ordinary partial derivatives, and spatial geodesics within each slice are straight lines. Nonzero coefficients introduced by rotating or accelerating coordinates are non-inertial descriptions of the same fixed substrate, not background curvature.

More geometrically, the compatible-connection freedom is an affine gauge freedom. Relative to a chosen flat rest connection, the rotational part of the Newton-Cartan freedom is modeled by rotation-valued 1-forms,

$$\Omega^1(\mathcal{M}) \otimes \mathfrak{so}(3)$$

with the corresponding boost or acceleration terms supplying the usual non-inertial chart data. Thus the family of compatible descriptions is a torsor over the inertial-gauge data, while the wake law selects the unique flat representative in the c_f-isotropic frame. Rotating-frame Christoffel symbols are therefore pure-gauge representatives of that same flat ∇; their Riemann curvature remains zero.

Non-Inertial Coordinate Terms

A rotating coordinate chart can make ordinary motion acquire extra coordinate terms. If $\mathbf{X} = R(T)\mathbf{X}'$ with angular velocity $\boldsymbol{\Omega}$, then the Cartesian-rest-frame acceleration decomposes as

$$\mathbf{A} = R(T)\left[\mathbf{A}' + 2\boldsymbol{\Omega} \times \mathbf{V}' + \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{X}') + \frac{d\boldsymbol{\Omega}}{dT} \times \mathbf{X}'\right]$$

The terms proportional to $2\boldsymbol{\Omega} \times \mathbf{V}'$, $\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{X}')$, and $(d\boldsymbol{\Omega}/dT) \times \mathbf{X}'$ are coordinate descriptions on absolute timespace. They do not add curvature to the Euclidean void, and they do not introduce a substrate magnetic field. Their value is diagnostic: they show how transverse-looking observer equations can arise from a choice of non-inertial chart while the underlying substrate remains $\mathbb{R} \times \mathbb{R}^3$ with the selected flat connection in the Euclidean-void rest frame.

The provenance no-go is strict. A transverse velocity-dependent term produced only by a rotating or accelerating coordinate chart carries no transmitter identity, emission time, causal-root label, or wake-energy ledger entry. It therefore cannot source a physical wake-mediated interaction or an emergent magnetic channel. A genuine transverse interaction must be traced to causal-wake provenance in the Master Equation or to an explicitly derived observer-level reduction of such provenance, not to inertial-coordinate algebra alone.

Equivalently, let $\mathcal{P}[\mathcal{T}]$ denote the provenance payload of a candidate acceleration term $\mathcal{T}$: transmitter identity, emission time, causal-root label, and energy or wake-history row when those data exist. Pure inertial-coordinate terms satisfy

$$\mathcal{P}[\mathcal{T}_{\text{inertial}}] = \varnothing$$

A physical wake-mediated transverse term must instead satisfy $\mathcal{P}[\mathcal{T}] \neq \varnothing$ after reduction to the retained branch record. This separates connection-gauge content from the image of the causal-wake provenance map.

No Fundamental 4D Metric

$\mathbb{AAA}$ does **not** define a fundamental non-degenerate 4D metric $g_{\mu\nu}$ on $\mathcal{M}$.

This means:

- There is no fundamental 4D interval mixing dT and $d\mathbf{X}$.
- There are no fundamental Lorentz boosts that rotate time into space.
- Proper time is not a substrate interval.
- Effective metric language belongs to observer-level spacetime reconstruction.

The specified Newton-Cartan substrate data (dT, h, ∇) encode the substrate kinematics: absolute temporal ordering, Euclidean spatial geometry, and the selected Euclidean-void rest-frame connection. Effective metric language enters only after clocks, rulers, and signal channels are reconstructed from assemblies and Noether sea response.

Measurement and Geometry

Spatial distance within a simultaneity slice is

$$d_{\text{spatial}}(\mathbf{X}_1, \mathbf{X}_2) = \sqrt{\delta_{ij}(X_1^i - X_2^i)(X_1^j - X_2^j)}$$

Temporal duration between events is

$$\Delta T = |T_2 - T_1|$$

Spatial arc length along a path $\mathbf{X}(T)$ from T_1 to T_2 is

$$L[\mathbf{X}; T_1, T_2] = \int_{T_1}^{T_2} \|\mathbf{V}(T)\| \, dT = \int_{T_1}^{T_2} \sqrt{\left(\frac{dX}{dT}\right)^2 + \left(\frac{dY}{dT}\right)^2 + \left(\frac{dZ}{dT}\right)^2} \, dT$$

A relativistic 4D arc length such as

$$s = \int \sqrt{|g_{\mu\nu} \, dx^\mu dx^\nu|}$$

with the sign of the integrand fixed by the declared signature convention, is a standard comparison form, not a substrate-level object in $\mathbb{AAA}$.

Velocity, Acceleration, and Momentum

Spatial velocity is the 3-vector

$$\mathbf{V}(T) = \frac{d\mathbf{X}}{dT}$$

Speed is

$$\|\mathbf{V}\|$$

Acceleration is

$$\mathbf{A}(T) = \frac{d\mathbf{V}}{dT} = \frac{d^2\mathbf{X}}{dT^2}$$

At the observer level, the usual low-velocity bookkeeping forms are

$$\mathbf{p} = m\mathbf{V}, \qquad K = \frac{1}{2}m\|\mathbf{V}\|^2$$

Here m is an effective assembly-response coefficient, not substrate data; its derivation and possible anisotropy are stated below.

Causal-root hits produce accelerations in the Euclidean void. Time supplies the universal evolution parameter; it does not supply curvature, acceleration, or clock dilation by itself.

The same distinction applies to momentum and inertia: the kinematic variables live on the substrate, while the coefficients that make them measurable are effective assembly responses.

The scalar m in the low-velocity observer formula is not a primitive rigid-body constant of the substrate. A rigid-body inertia tensor is a useful foil: in ordinary mechanics it maps a fixed body's angular velocity to angular momentum after a mass distribution has already been supplied. In $\mathbb{AAA}$, the corresponding observer-level inertial response must be derived from the assembly's closed internal causal-history ledger, shielding state, coupling to the Noether sea, and orientation.

For a coarse-grained assembly A, the local linear response may be written as a pair of response maps

$$\delta p_i = \mathcal{M}^{\mathrm{resp}}_{ij}(A; \mathcal{H}_A, \mathcal{S}_A, \mathcal{N}_{\mathrm{sea}}|_A, R_A)\,\delta V^j, \qquad \delta J_i = \mathcal{I}^{\mathrm{resp}}_{ij}(A; \mathcal{H}_A, \mathcal{S}_A, \mathcal{N}_{\mathrm{sea}}|_A, R_A)\,\delta\Omega^j$$

Here $\mathcal{H}_A$ denotes the closed internal path-history and causal-root ledger of the assembly, $\mathcal{S}_A$ its shielding state, $\mathcal{N}_{\mathrm{sea}}|_A$ the local Noether sea state sampled by the assembly, and $R_A \in SO(3)$ its orientation relative to the Euclidean-void rest frame. The ordinary scalar mass relation is recovered only in an isotropic observer branch where $\mathcal{M}^{\mathrm{resp}}_{ij} \to m\,\delta_{ij}$ over the probed directions.

The isotropy of $\mathcal{M}^{\mathrm{resp}}_{ij}$ is an assembly-geometry claim, not an unexplained smallness assumption. If the symmetry group of the retained trajectory bundle and closed causal-history ledger has no preferred axis on the probed scale, the tensor response can reduce to $m\delta_{ij}$. If the branch retains an axial layer, six-site axial frame, or other framed orientation data, the leading correction is a quadrupole-like orientational residual in $\mathcal{M}^{\mathrm{resp}}_{ij}$ unless shielding and averaging cancel it. The branch-level carrier can be represented by a symmetric trace-free framing tensor

$$Q_A^{ij} = \left\langle \hat{n}^i \hat{n}^j - \frac{1}{3} h^{ij} \right\rangle_A^{\mathrm{frame}}$$

where the average is taken over the retained framed trajectory bundle or declared axial frame of the assembly. The Hughes-Drever row below is therefore a direct constraint on residual orientational symmetry breaking in the assembly framing.

Framing-Quadrupole Economy Theorem Target

One branch certificate bounding $\|Q_A\|$ should control all three leading $\ell = 2$ preferred-axis projections:

1. the matter-sector Hughes-Drever residual ϵ_M^{HD};
2. the clock-orientation residual Δ^{ori};

3. the ruler or metric-handoff anisotropy carried by the trace-free part of B_{ij}.

This target does not prove that any row vanishes. It requires the three projections to descend from the same retained framing tensor rather than from independently fitted anisotropies. The limit $Q_A = 0$ marks a retained framed trajectory bundle with no preferred quadrupole axis at the tested scale.

The isotropic limit is not merely a simplifying convention. Hughes-Drever-type clock-comparison tests constrain orientation-dependent matter-sector response, so the residual attached to $\mathcal{M}_{ij}^{\mathrm{resp}}$ must be declared alongside clock and photon anisotropy bounds. A representative matter-anisotropy row should track a projected residual such as

$$\epsilon_M^{\mathrm{HD}} = \sup_{\hat{\mathbf{n}}} \left| \frac{\hat{n}^i \left(\mathcal{M}_{ij}^{\mathrm{resp}} - m\delta_{ij}\right) \hat{n}^j}{m} \right|$$

after mapping the assembly response onto the tested matter-sector coefficients. The benchmark is not a single universal number: SME translations are species- and coefficient-dependent, with Hughes-Drever and clock-comparison rows reaching roughly the 10^{-27}-class matter-anisotropy scale or stronger in several spin-coupling channels. Passing the scalar-mass limit therefore means driving the projected matter response below the declared Hughes-Drever/clock-comparison row, not only asserting isotropy in prose.

Galilean Kinematic Structure

The product background admits the usual Galilean kinematic transformations that preserve the absolute foliation and the spatial metric on each slice.

Time translation:

$$T' = T + T_0, \qquad \mathbf{X}' = \mathbf{X}$$

Spatial translation:

$$T' = T, \qquad \mathbf{X}' = \mathbf{X} + \mathbf{X}_0$$

Rotation:

$$T' = T, \qquad \mathbf{X}' = R\mathbf{X}, \qquad R \in SO(3)$$

Galilean boost:

$$T' = T, \qquad \mathbf{X}' = \mathbf{X} + \mathbf{V}_0 T$$

The transformation preserves simultaneity slices because $T' = T$ up to a constant shift.

The Galilean group may be summarized as a semidirect product combining time translations, spatial Euclidean transformations, and velocity boosts. This is a kinematic statement about the product background.

Preferred Rest Frame from the Wake Law

Although Galilean boosts preserve the product foliation kinematically, the interaction law selects a preferred rest frame: the frame in which the wake speed c_f is isotropic. This selects the rest structure for the dynamics, not a pre-labeled spatial origin or built-in axis orientation.

The distinction is visible directly in the root equation. Under a Galilean coordinate change $\mathbf{X}' = \mathbf{X} - \mathbf{U}T$, the same primitive wake condition becomes

$$\left\|\mathbf{X}_i'(T) - \mathbf{X}_j'(T_t) + \mathbf{U}(T - T_t)\right\| = c_f(T - T_t), \qquad T_t < T$$

Thus boosts preserve the product foliation and are allowed coordinate descriptions, but they do not preserve the same isotropic wake-law form unless $\mathbf{U} = \mathbf{0}$ relative to the Euclidean-void rest frame. Galilean boosts are therefore kinematic coordinate transformations of the background, not dynamical symmetries of the primitive wake law.

This preferred frame is not curvature of the background. It is a structural consequence of the wake law: finite-speed causal wake propagation fixes c_f relative to the void, and Noether sea and assembly dynamics build on that distinguished frame.

The observer-level task is therefore not to remove the absolute frame from the ontology. The task is to derive how physical clocks, rulers, and signals hide preferred-frame leakage to the required experimental precision. See Lorentz Kinematics and Proper Time and Time Dilation.

Speed Convention

The foundation stack keeps primitive, channel, branch, and calibrated speeds distinct:

Symbol	Meaning	Status
c_f	Primitive causal-wake propagation speed relative to the Euclidean void	fundamental
$c_\gamma(\mathcal{N}_{\mathrm{sea}}, \hat{\mathbf{k}})$	Photon-channel speed in a Noether sea state and direction	derived
c_{eff}	Effective signal or clock-channel speed for a specified dressed branch	derived/contextual
$c_\star$	Local comparison speed used in a declared clock, ruler, or signal branch	branch-dependent
c_0	Measured low-energy invariant light speed in weak homogeneous conditions	empirical calibration and dressing-flow fixed-point target

The symbols c_f, c_γ, c_{eff}, $c_\star$, and c_0 must not be identified unless the local document states the regime and derivation. In particular, c_f belongs to primitive causal-root equations, while c_0 belongs to weak homogeneous observer calibration.

Causal Wake Geometry

Causality is defined by absolute temporal ordering plus finite wake propagation speed.

Three related objects must be kept separate: temporal order, the filled reachability region, and actual causal-wake support. The Master Equation uses the last of these, not the whole filled region.

For two events

$$A = (T_A, \mathbf{X}_A), \qquad B = (T_B, \mathbf{X}_B)$$

event A can causally precede B only if

$$T_A < T_B$$

A wake emitted at $(T_t, \mathbf{X}_{\text{em}})$ reaches points on the causal wake surface

$$\|\mathbf{X} - \mathbf{X}_{\text{em}}\| = c_f(T - T_t), \qquad T > T_t$$

The filled causal future of that emission is

$$\{(T, \mathbf{X}) : T \geq T_t,\ \|\mathbf{X} - \mathbf{X}_{\text{em}}\| \leq c_f(T - T_t)\}$$

The equality surface is an expanding causal isochron: at each later T it appears as a spatial sphere in the Euclidean void, not as a fundamental light cone of a Lorentzian metric. The filled region records causal order and finite-speed reachability, but it is not the support of a single emitted wake. In the exact Master Equation, a receiver is acted on only at boundary roots satisfying the equality condition above. With a mollifier, support is a narrow neighborhood of that boundary and is interpreted in the weak limit.

For transmitter j and receiver i, the canonical root function is

$$F_{ij}(T_r, T_t) = \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| - c_f(T_r - T_t), \qquad T_t < T_r$$

with active causal-root set

$$\mathcal{C}_{ij}(T_r) = \{\, T_t < T_r : F_{ij}(T_r, T_t) = 0 \,\}$$

The same notation covers partner hits ($i \neq j$) and self-hits ($i = j$). Simple-root branch charts require the transversality floor

$$|\partial_{T_t} F_{ij}(T_r, T_t)| = |c_f - \hat{\mathbf{r}}_{ij}(T_r, T_t) \cdot \mathbf{V}_j(T_t)| \geq \kappa_{\mathrm{hit}} > 0$$

where

$$\mathbf{r}_{ij}(T_r, T_t) = \mathbf{X}_i(T_r) - \mathbf{X}_j(T_t), \qquad \hat{\mathbf{r}}_{ij} = \frac{\mathbf{r}_{ij}}{\|\mathbf{r}_{ij}\|}$$

Failure of this floor marks a caustic-like or degenerate wake-root regime; it is a branch-chart failure condition, not an ordinary small perturbation.

On a smooth retained branch $T_t = T_{t,\ell}(T_r)$, differentiating $F_{ij}(T_r, T_{t,\ell}(T_r)) = 0$ gives the receiver-side factor

$$\frac{dT_{t,\ell}}{dT_r} = \frac{c_f - \hat{\mathbf{r}}_{ij}(T_r, T_{t,\ell}) \cdot \mathbf{V}_i(T_r)}{c_f - \hat{\mathbf{r}}_{ij}(T_r, T_{t,\ell}) \cdot \mathbf{V}_j(T_{t,\ell})}$$

This identity is not a new coupling constant. It distinguishes the transmitter-side causal-root Jacobian from the rate at which a moving receiver path samples the same emitted causal wake sequence. A stationary receiver in the Euclidean-void rest frame sets the numerator to c_f; radial receiver motion changes the receiver-side action or wake-history rate and must be recorded when a proof uses accumulated action rather than only an event-local acceleration contribution.

The status of κ_{hit} is fixed in Absolute Time: it is a declared branch-chart or certificate lower bound, not a universal coupling constant, coordinate parameter, or regularization width.

The causal wake geometry does not forbid a point architrino from having $\|\mathbf{v}\| > c_f$. It forbids backward-time influence. This separates kinematic freedom from dynamical stability: the Euclidean substrate places no kinematic speed limit on a point architrino, but that freedom does not imply that an assembly can be carried through the same regime intact.

In observer-level wave language, causality is often diagnosed by front velocity rather than group or phase velocity. The substrate statement is sharper: the causal front is the first nonzero causal-wake support in absolute time. Observer-level group-speed, phase-speed, or packet-reshaping effects cannot override the support condition above; they are summaries of how an already causal wake record is sampled by assemblies.

For standard-matter assemblies, the observer-level relativistic speed limit is a closure result of assembly structure and channel dressing, usually expressed with the declared local comparison speed $c_\star$ and with c_0 in the weak homogeneous observer branch. This statement is effective, not ontological: it constrains the recovered observer branch rather than the admissible velocities of individual architrinos.

At the primitive branch level, as constituent architrino speeds approach the wake-speed threshold c_f, the constituents increasingly outrun the potential interactions that normally maintain internal closure. The leading side of the assembly encounters a strongly asymmetric wake ledger while trailing structure remains tied to older path-history contributions. The result is severe mechanical deformation rather than a substrate-level prohibition.

A useful theorem-target diagnostic for this deformation is the sign-resolved active-root ledger of an assembly branch over a return cycle. Split the retained simple roots by Jacobian sign into counts $N_+(A)$ and $N_-(A)$, and record the pair together with the active-root Euler characteristic

$$\chi_{\text{root}}(A) = N_+(A) - N_-(A) = \sum_{i,j\in A} \sum_{T_t \in \mathcal{C}_{ij}} \operatorname{sgn}(\partial_{T_t} F_{ij})$$

with the sums taken over the retained self-hit and partner-hit rows on the branch chart. The two components detect different failure channels. Generic fold events create or annihilate root pairs of opposite Jacobian sign, so they change the unsigned count $N = N_+ + N_-$ by ± 2 while leaving χ_{root} invariant; this is the fold-pair surgery conservation recorded in Master Equation and Noether Braid Topological Charge. A near-threshold fold cascade therefore appears as jumps in (N_+, N_-), while a jump in $\chi_{\text{root}}(A)$ signals a root crossing the chart or memory boundary, a pair-set change, or a degeneracy outside the generic fold class. A structural-integrity failure near the wake-speed threshold should appear in this sign-resolved ledger rather than as a smooth kinematic slowing of the substrate background. This is a diagnostic target for Theorem G, not a proof that every branch fails at the same value of $\|\mathbf{v}\|$.

This structural-integrity claim is the central Lorentz-closure theorem target for this chapter and is restated as Theorem G in Lorentz Kinematics. It must prove more than the qualitative statement that assemblies fail mechanically near c_f. A successful recovered observer branch must show that the matter-assembly limiting speed, Noether sea dressed clock/ruler speed, photon-channel speed, and weak-homogeneous calibration speed collapse to one common limit:

$$c_{\text{mat}}^{\text{lim}} = c_{\text{eff}} = c_\gamma = c_0 \left[1 + O(\epsilon_{\text{LV}})\right]$$

The same weak-field constitutive record must also keep the gravitational-wave tensor-channel speed tied to the photon channel within the multi-messenger residual recorded in the constraint ledger. It must also recover the three effective boost rows missing from the substrate symmetry group, so the seven substrate conservation rows extend to the ten-row observer-level Lorentz structure within the same ϵ_{LV} budget.
It must also show that approach to this limit yields Lorentzian kinematics rather than an arbitrary deformation law:

$$\frac{R_\parallel}{R_\perp} = \frac{1}{\gamma_0(v_{\mathrm{eff}})} + O(\epsilon_{\mathrm{LV}}), \qquad \frac{d\tau}{dt_{\mathrm{eff}}} = \frac{1}{\gamma_0(v_{\mathrm{eff}})} + O(\epsilon_{\mathrm{LV}}), \qquad \gamma_0(v_{\mathrm{eff}}) = \left(1 - \frac{v_{\mathrm{eff}}^2}{c_0^2}\right)^{-1/2}$$

The proposed mechanism is one structural claim, not four independent coincidences. Matter transport, clock/ruler retiming, photon transport, and weak-homogeneous calibration must all be projections of the same causal-root ledger through the same Noether sea dressing map in the tested branch. The Lorentz shape is the same claim expressed in deformation variables: near the wake-speed threshold, the leading longitudinal-versus-transverse asymmetry of a closed return cycle must generate the same $\gamma_0(v_{\mathrm{eff}})$ in envelope shape and phase rate. A sharper formulation is that the translating branch's closed-cycle geometry should factor through one deformation family on its orbit moduli,

$$\mathcal{D}(v_{\mathrm{eff}}) = \exp(\varphi_{\mathrm{eff}} K), \qquad \tanh \varphi_{\mathrm{eff}} = \frac{v_{\mathrm{eff}}}{c_0},$$

with a single generator K producing both the envelope ratio and the clock-phase rate at the tested order; the rapidity parameter φ_{eff} matches the observer-level convention in Special Relativity and the Noether Braid and makes the one-parameter family additive if the branch composes boosts. If the longitudinal envelope response and the phase-rate response require independent generators, the branch has not recovered Lorentzian shape even if one scalar speed limit happens to match. The proof burden is to derive these relations from that shared ledger, dressing, and assembly deformation law. The theorem target fails if stable matter classes acquire composition-dependent limiting speeds, if c_γ remains independently dressed from matter transport in the weak homogeneous branch, or if the leading deformation is non-Lorentzian after the c_0 calibration is fixed. The observer "speed of light" limit for macroscopic assemblies is therefore a structural integrity barrier only after this common-limit and Lorentz-shape closure is satisfied.

Coordinates and Forbidden Transformations

Allowed substrate coordinates preserve the product structure:

- T remains the absolute time parameter.
- Spatial coordinates may be Cartesian or curvilinear coordinates on Σ_T.
- Spatial coordinate changes may rewrite h_{ij} but do not curve the Euclidean void.

Forbidden at the substrate level:

- Lorentz boosts as fundamental time-space rotations.
- Transformations of the form $T' = T + f(\mathbf{X})$ with nonconstant f.
- Any operation that destroys the foliation into constant-T slices.
- Any transformation that treats effective metric behavior as the fundamental background.

These exclusions preserve the distinction between absolute timespace and emergent spacetime.

Measures and Operators

The absolute time measure is

$$dT$$

The spatial volume element on a slice is

$$dV = dX\, dY\, dZ$$

The product measure is

$$d\mathcal{V} = dT\, dX\, dY\, dZ = dT\, dV$$

The spatial gradient is

$$\nabla f = \left(\frac{\partial f}{\partial X}, \frac{\partial f}{\partial Y}, \frac{\partial f}{\partial Z}\right)$$

The spatial Laplacian is

$$\Delta f = \partial_X^2 f + \partial_Y^2 f + \partial_Z^2 f = \delta^{ij}\partial_i\partial_j f$$

The temporal derivative is

$$\frac{\partial}{\partial T}$$

All dynamical equations should make clear which derivatives are temporal, which are spatial, and when a calculation is using an effective metric approximation rather than substrate geometry.

Regularity and Boundary Conditions

For well-posed dynamics on absolute timespace:

- Worldlines are absolutely continuous with piecewise continuous velocities.
- Any alternate parametrization $T(s)$ is strictly increasing.
- Source configurations are locally finite or represented by integrable measures.
- Regularized wake surfaces should preserve total polarity and converge to the intended causal-wake limit as the regulator is removed.

- Solutions should decay suitably at spatial infinity unless an incoming condition is explicitly imposed.

Receiver-Centered Exhaustion Lemma

Infinite source families must supply a declared summation or continuum prescription under which the many-source wake sum converges. For each receiver event (i, T_r), choose an increasing receiver-centered exhaustion of retained transmitter events and take the limit in that order. In the simplest radial form the condition is

$$\lim_{R\to\infty} \sum_{\substack{j,\, T_t\in\mathcal{C}_{ij}(T_r)\\ \|\mathbf{X}_j(T_t)-\mathbf{X}_i(T_r)\|<R}} \mathbf{A}_{ij}(T_r;T_t)$$

with any neutrality, screening, principal-value, or mean-field subtraction rule stated before the limit is used. The exhaustion is over retained emission events, that is (j, T_t) root pairs, not over sources: a super-wake-speed transmitter history can contribute several active roots entering the ball at different R, and the refinement-independence requirement applies to that event-level ordering.

This is an admissibility lemma for branches and continuum reductions: the branch is well-defined only when the receiver-centered limit exists under the declared subtraction or screening rule, and allowed refinements of the exhaustion do not change the resulting local acceleration. Inverse-square surface dilution alone is not enough in three spatial dimensions because the number of sources in a radial layer grows like $r^2\,dr$. The lemma supplies the convergence condition used by emergence arguments to justify effective locality and metastable assembly behavior.

There is one important homogeneous case where the lemma becomes a theorem rather than a bare admissibility requirement. Its scope is a background-sea result: it guarantees convergence for a statistically neutral far population under the stated mixing assumptions, not for every coherent assembly embedded in that population. Suppose the far population is statistically homogeneous, isotropic, locally neutral, and vector-mixing, with correlation length ℓ for the cell acceleration fluctuations. The required mixing is a condition on the vector sum, not only on scalar polarity neutrality; schematically, after subtracting the local neutral mean,

$$|\mathbb{E}[\delta\mathbf{a}_{\text{cell}}(\mathbf{r})\cdot\delta\mathbf{a}_{\text{cell}}(\mathbf{r}')]| \le C\, e^{-\|\mathbf{r}-\mathbf{r}'\|/\ell}$$

or a comparable summable vector-correlation bound. Partition space outside a fixed local ball into receiver-centered shells of thickness comparable to ℓ, and group sources into neutral cells of diameter $O(\ell)$. Let S_n be the vector acceleration contribution from shell n after subtracting the local neutral mean. A shell at radius $r_n \sim n\ell$ contains $N_n = O(n^2)$ effectively independent cells, so signed fluctuations scale like $\sqrt{N_n} = O(n)$ while each cell contribution carries the inverse-square factor $O(r_n^{-2}) = O(n^{-2})$. Hence

$$\mathbb{E}\|S_n\|^2 = O(n^{-2})$$

under the declared mixing bound, and therefore

$$\sum_{n=1}^{\infty} \mathbb{E}\|S_n\|^2 < \infty$$

The shell series converges in L^2 and almost surely by the standard square-summable fluctuation criterion. Thus a homogeneous locally neutral Noether sea record supplies a convergent receiver-centered exhaustion under these assumptions. This result does not prove convergence for arbitrary inhomogeneous or coherent far populations. A coherent far dipole texture, long-range orientational correlation, or anisotropic source family can defeat vector cancellation even when scalar polarity neutrality holds. Every coherent assembly, anisotropic source family, or long-range correlated medium feature on top of the background must supply its own shielding, screening, finite active horizon, or explicit subtraction prescription before its many-source wake sum is treated as closed.

These assumptions are not additional ontology. They are the analytic conditions needed for the master equation and simulation approximations to be well-defined on the product background.

Relation to Relativistic Spacetime

Relativistic spacetime remains the correct comparison target for recovered observer laws, but this chapter does not treat it as substrate ontology. The table therefore compares a fixed product background with a downstream effective description.

Feature	Absolute Timespace	Relativistic Spacetime
Manifold	$\mathbb{R} \times \mathbb{R}^3$	Four-dimensional spacetime manifold
Time	Universal parameter	Coordinate dimension or proper-time relation
Spatial geometry	Fixed Euclidean slices	Part of a dynamical metric
Metric	Separate (dT, h) data	Non-degenerate $g_{\mu\nu}$
Simultaneity	Absolute global foliation	Observer/frame dependent
Causality	Absolute order plus finite wake speed	Effective metric light cones
Gravity	Emergent from assembly and Noether sea dynamics	Spacetime curvature
Expansion	No expansion of the void	Metric expansion possible

The effective metric used in GR-style recovery is a downstream constitutive object. It must be derived from clocks, rulers, signal transport, and Noether sea response. The local handoff is an observer-level clock-and-ruler relation of the form

$$d\tau^2 = A^2(\mathcal{N}_{\rm sea})\, dt_{\rm eff}^2 - \frac{1}{c_0^2} B_{ij}(\mathcal{N}_{\rm sea}) \left(dx^i_{\rm eff} - u^i_{\rm sea,eff} dt_{\rm eff}\right) \left(dx^j_{\rm eff} - u^j_{\rm sea,eff} dt_{\rm eff}\right)$$

with $A > 0$ and B_{ij} symmetric positive definite. Equivalently, defining $ds^2_{\rm eff} = -c_0^2 d\tau^2$ and $x^0_{\rm eff} = c_0 t_{\rm eff}$ gives the component export

$$g^{\rm eff}_{00} = -A^2 + \frac{1}{c_0^2} B_{ij} u^i_{\rm sea,eff} u^j_{\rm sea,eff}, \qquad g^{\rm eff}_{0i} = -\frac{1}{c_0} B_{ij} u^j_{\rm sea,eff}, \qquad g^{\rm eff}_{ij} = B_{ij}$$

This is the same observer-level ADM/Cartan map stated in Emergent Metric. This equation is not substrate geometry; it is the required metric handoff from Noether sea state and Physical Observer assemblies into effective spacetime language.

Role in $\mathbb{AAA}$

Absolute timespace is the formal product background in which all architrino dynamics unfold:

- Architrino worldlines are curves $(T, \mathbf{X}(T))$ in $\mathcal{M}$.
- Causal wakes are emitted at earlier events and intersect receivers at later events.
- Path history is well-defined because the past is the set of all events with smaller T.
- Assembly motion, clock behavior, and effective spacetime geometry are built on this substrate but are not identical with it.
- Proper time is a functional of physical observer dynamics, not a fundamental interval of $\mathcal{M}$.

Summary Postulate

Postulate 3 fails if any accepted substrate-level interaction requires breaking the constant-T foliation, for example through a substrate time coordinate of the form $T' = T + f(\mathbf{X})$, or requires a fundamental nondegenerate four-metric. Effective clock synchronization, proper time, and metric reconstruction may mix observer coordinates after recovery; they cannot replace the substrate product structure without replacing this postulate.

> **Postulate 3 (Absolute Timespace):** The background arena for all physics is the product manifold $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$, equipped with the exact substrate clock form dT and Euclidean spatial metric $h_{ij} = \delta_{ij}$. This defines a global foliation into simultaneous Euclidean slices indexed by universal time. The background is non-dynamical and non-curved. Causality is defined by absolute temporal ordering and finite wake speed c_f. The product background preserves Galilean kinematic structure, while the interaction law, by fixing the wake speed c_f relative to the void, structurally distinguishes the void rest frame. Effective Lorentz behavior, gravity, lensing, clock dilation, and cosmological expansion are recovery targets: when the

> assembly and Noether sea closure programs succeed, they are emergent descriptions within absolute timespace, not properties of the background itself.

Absolute Time Defense

This chapter states why absolute time is the theory's fundamental evolution parameter. The key distinction is simple but load-bearing: absolute time is the variable used by the master equation; a simultaneity slice is the complete substrate state at one value of that variable; proper time is the derived readout of a physical clock assembly.

The teaching sequence is deliberately layered. First comes the ontological claim about absolute time and the Euclidean void. Then comes the dynamical claim about universe-state evolution on those simultaneity slices. Only after those claims are fixed does the chapter introduce proper time, clock-rate extraction, and relativistic observer inferences. It is the argumentative companion to Ontology, Proper Time and Time Dilation, and Lorentz Kinematics.

The Case for Absolute Time (T)

1. **Fundamental evolution parameter**: Absolute time T is the unique evolution parameter of the master equation.
2. **Product substrate**: The kinematic background is the product manifold $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$ with clock projection $\pi_T : \mathcal{M} \to \mathbb{R}$.
3. **Unique foliation**: The simultaneity slice at fixed T_* is the level set

$$\Sigma_{T_*} = \pi_T^{-1}(\{T_*\}) = \{T_*\} \times \mathbb{R}^3$$

4. **Substrate clock form**: The substrate clock form dT is exact, closed, and nowhere vanishing as the pullback from the $\mathbb{R}$ factor. Together with the chosen orientation of increasing T, it fixes the tangent planes to the slices Σ_T; foliation ambiguity is absent at the substrate level rather than removed by coordinate gauge.
5. **Derived clock time**: Proper time τ is not fundamental; it is a derived functional of Noether braid internal phase dynamics.

The list separates what exists at the substrate level from what embedded observers can read. Absolute time, the Euclidean void, and the slices Σ_T are substrate commitments. Proper time, clock synchronization, and relativistic simultaneity judgments are effective readouts produced by assemblies embedded in the Noether sea. The defense of absolute time therefore does not deny observed clock dilation; it relocates clock dilation from fundamental temporal ontology to derived assembly dynamics.

A useful comparison with relativistic block-universe arguments is the distinction between absolute time, the substrate-level simultaneity slice, and the observer-readable present.

Absolute time T is fundamental. The complete slice $\mathbb{U}_{\text{now}} \equiv S(T)$ is substrate-level: it is the full universe state at one value of T, not a clock reading available to embedded observers. Special relativity correctly removes any observer-accessible global three-space: a Physical Observer cannot synchronize distant records into one public present without using clocks, rulers, and signal conventions that must themselves satisfy Lorentz tests. The observer-facing obligation is therefore to show why attempts to read the absolute foliation through matter clocks, photon synchronization, CMB rest-frame comparison, or gravitational channels collapse to an effective Lorentz or metric reconstruction with preferred-frame leakage below the declared bounds.

A cosmological frame such as the CMB rest frame can be a useful effective foliation for data reduction, but it is not absolute time itself and does not expose the substrate clock form. It supplies a large-scale observer record only after photon transport, source evolution, and receiver cadence are modeled; it cannot by itself license an exact observer-readable global present.

Absolute Time, Global Foliation, and Proper Time

Absolute time T and universe state

- The $\mathbb{U}_{\text{now}}$ perspective indexes the exact microstate as $S(T)$ on each slice Σ_T.
- On each Σ_T, the spatial metric is Euclidean: $h_{ij} = \delta_{ij}$.
- Absolute time is substrate structure, not a coordinate gauge choice.

At this level, $\mathbb{U}_{\text{now}} \equiv S(T)$ is not an observer's reconstruction of events. It is the complete ontic universe state on a simultaneity slice, including constituent positions, velocities, polarities, path-history data, and any branch information required by the delayed dynamics. Observers infer only a coarse-grained portion of this state through clocks, rulers, signals, and records.

Because the master equation is path-history dependent, the complete state on a slice is not merely an instantaneous Markov projection. The precise schematic form is

$$S(T) = \big(X(T), H_T, \mathcal{N}_{\text{sea}}(T, \cdot), \mathcal{B}_T\big)$$

where $X(T)$ contains instantaneous architrino and assembly data, H_T is the path-history and provenance ledger, $\mathcal{N}_{\text{sea}}$ is the retained Noether sea state, and $\mathcal{B}_T$ records the active branch chart or regularization data. Determinism applies to this complete history state, not to a history-free slice projection.

The branch-chart entry is not an observer bookkeeping choice imported into the substrate. $\mathcal{B}_T$ is ontic only insofar as it records which attractor basin, active causal-root labels, and regularization regime the deterministic history H_T actually occupies. A different analyst may choose different coordinates for describing that branch, but cannot choose a different occupied basin without changing $S(T)$ itself.

Deterministic evolution and basin selection

- The delay-differential master equation is deterministic: where the declared branch chart or regularization makes the evolution well posed, a fully specified $\mathbb{U}_{\text{now}} \equiv S(T_*)$, including the required path-history and provenance ledger, generates a unique trajectory $S(T)$ for $T > T_*$.
- Apparent branching is multistability, not stochastic evolution: near separatrices, infinitesimal perturbations in initial microstate direct trajectories into different attractor basins.
- Therefore the correct statement is basin selection under deterministic flow, not a "distribution of allowed configurations" from one exact state.

This is a claim about the exact substrate flow, not about practical prediction. A finite observer may lack the path-history resolution needed to know which basin the system occupies, but that ignorance is inferential. It does not convert a single exact state into many simultaneous ontic futures.

Proper time τ for physical observers

Physical clocks are Noether braid assemblies. Their ticks are internal limit-cycle phase advances, so the primary definition is phase extraction, not an arbitrary scalar fit:

$$d\tau_{\mathcal{A}} = \frac{d\varphi_{\mathcal{A}}}{\Omega_{\mathcal{A}}^{(0)}}, \qquad \frac{d\tau_{\mathcal{A}}}{dt_{\text{eff}}} = \frac{\Omega_{\mathcal{A}}\left(\mathbf{w}, \mathcal{N}_{\text{sea}}, R_{\mathcal{A}}, H_{\mathcal{A}}\right)}{\Omega_{\mathcal{A}}^{(0)}}$$

Here $\varphi_{\mathcal{A}}$ is the declared clock phase, $\Omega_{\mathcal{A}}^{(0)}$ is its rest-branch reference rate, $R_{\mathcal{A}}$ is the clock assembly orientation and geometry record, and $H_{\mathcal{A}}$ is the relevant path-history ledger. Both $\Omega_{\mathcal{A}}$ and $\Omega_{\mathcal{A}}^{(0)}$ are phase rates per unit effective time t_{eff}, so the ratio is dimensionless. The velocity relative to the local Noether sea flow in the observer-level bookkeeping map is

$$w_{\mathcal{A}}^{i} = \frac{dx_{\mathcal{A},\text{eff}}^{i}}{dt_{\text{eff}}} - u_{\text{sea,eff}}^{i}$$

for the clock worldline $x_{\mathcal{A},\text{eff}}^{i}(t_{\text{eff}})$.

This phase extraction is admissible only on a clock branch whose internal return map retains a hyperbolic attracting limit cycle with a unique rotation number. In plain terms, the assembly must keep returning to the same countable cycle before it can function as a clock. More explicitly, let $P_{\mathcal{A}}$ be the Poincare return map on the retained clock branch and let $\tilde{P}_{\mathcal{A}}$ be a lift of its action on the invariant phase circle. The clock rotation number is

$$\rho_{\mathcal{A}} = \lim_{n\to\infty} \frac{\tilde{P}_{\mathcal{A}}^{n}(\theta) - \theta}{n} \mod 1$$

defined mod 1 through the choice of lift. When $P_{\mathcal{A}}$ restricted to the retained clock circle is an orientation-preserving homeomorphism, this limit exists and is independent of θ; that invertibility is the real hypothesis. If the restriction is only degree-one and non-invertible, the rotation set can be an interval rather than a point, and clock validity requires it to collapse to a point. The clock-validity domain is the parameter region where $P_{\mathcal{A}}$ restricted to the clock circle is topologically conjugate to a rigid rotation, or reduces to a unique normally hyperbolic periodic orbit with a well-defined phase advance. In that regime $\varphi_{\mathcal{A}}$ can be chosen continuously and $\Omega_{\mathcal{A}}$ is a branch observable. If the moving or dressed branch loses normal hyperbolicity through a saddle-node of cycles, torus breakdown, quasiperiodic transition, loss of return-map invertibility with an open rotation interval, or collapse of the cycle-stability floor, then a single rotation number no longer exists and $d\tau_{\mathcal{A}}$ is undefined for that branch. That event is a clock-failure mode, not a new proper-time law; in simulation it appears as a Floquet or Lyapunov-spectrum sign change in the transverse clock-cycle directions.

In the Noether-braid clock class, this is the observer-side use of the candidate and certified braid distinction. A physical clock is an admitted branch whose retained record returns under the delayed return map, modulo only true neutral symmetries, with a positive non-symmetry Floquet margin. Its declared clock phase $\varphi_{\mathcal{A}}$ is the rotation coordinate of that relative periodic orbit. Thus the clock-validity certificate can be written schematically as

$$\mathcal{R}_{\text{cert}}(\mathcal{A}) \leq \epsilon_{\text{cert}}, \qquad \Delta^{\perp}_{\text{Floquet}}(\mathcal{A}) > 0.$$

The certificate condition is open: a normally hyperbolic phase-locked cycle with positive Floquet margin persists under small perturbations of the dressing and retained record, which is why certified clocks are robust standards rather than fine-tuned branches. Loss of this certificate is the clock instance of branch de-certification: the phase coordinate ceases to be single-valued, and $d\tau_{\mathcal{A}}$ is not exported.

The same condition has a memory-boundary form. A valid clock branch must replay the retained path-history window over one return, so that the memory-corrected symplectic flux has no secular remainder:

$$\oint_{\text{return}} \omega_{\text{mem},\partial[-h,0]} = O(\epsilon_\omega).$$

This is the clock-sector reading of the branch-symplectic-promotion condition in Effective Lagrangian. A branch that leaks energy, symplectic area, or wake momentum through the memory boundary per cycle may still be a transient oscillator, but it is not a stable proper-time standard because its rotation number drifts.

The full local Noether sea state is the retained state record $\mathcal{N}_{\text{sea}}$, for example

$$\mathcal{N}_{\text{sea}} = \left(\rho_{\text{NS}}, n, u^i_{\text{sea}}, Q^{\text{sea}}_{ij}, \sigma^{\text{sea}}_{ij}, \nabla\rho_{\text{NS}}, \ldots\right)$$

The scalar $\chi_{\mathrm{sea}}(\mathbf{X},T) \equiv c_f/c_{\mathrm{eff}}(\mathbf{X},T)$ is only the Noether sea delay factor extracted for a specified channel. It is not the full Noether sea state.

A broad constitutive expression $d\tau = F(\cdots)dt_{\mathrm{eff}}$ may still be used as a schematic summary after the clock channel has been declared, but the closure target is the extracted phase functional above. Proper time is not a free scalar function assigned independently of assembly dynamics.

The integral clock-frequency form is

$$\tau(t_{\mathrm{eff},1}) - \tau(t_{\mathrm{eff},0}) = \int_{t_{\mathrm{eff},0}}^{t_{\mathrm{eff},1}} \frac{\omega_{\mathrm{clk}}(t_{\mathrm{eff}})}{\omega_0}\, dt_{\mathrm{eff}}$$

where $\omega_{\mathrm{clk}}(t_{\mathrm{eff}})$ is the phase rate extracted from the declared Noether braid clock channel and ω_0 is its rest-branch reference frequency; this is the integral form of the same phase extraction, with $\omega_{\mathrm{clk}} = \Omega_{\mathcal{A}}$ and $\omega_0 = \Omega_{\mathcal{A}}^{(0)}$ on the declared branch. The dependencies hidden in ω_{clk} are the local causal-root ledger, the relevant path-history data, and the same Noether sea state variables used by the clock/ruler metric handoff.

This definition avoids assigning proper time as an independent scalar, but it does not by itself prove relativity-compatible clock behavior. The non-circular closure statement is stronger: after phase extraction, all admitted low-energy clock and ruler assemblies in a tested comparison class must reduce to the same observer-level clock/ruler map. Equivalently, for each clock assembly $\mathcal{A}$,

$$A_{\mathcal{A}} = A + \delta A_{\mathcal{A}}, \qquad B_{ij}^{(\mathcal{A})} = B_{ij} + \delta B_{ij}^{(\mathcal{A})}$$

with the assembly-dependent remainders bounded by the clock-comparison, composition, and Lorentz-test rows below. The residual universality condition can be written schematically as

$$\epsilon_{\mathrm{univ}} \equiv \sup_{\mathcal{A},\mathcal{B}} \max \left(\left| \frac{A_{\mathcal{A}}}{A_{\mathcal{B}}} - 1 \right|, \frac{\left\| B^{(\mathcal{A})} - B^{(\mathcal{B})} \right\|}{\left\| B^{(\mathcal{B})} \right\|} \right)$$

with ϵ_{univ} forced below the relevant residual ceilings for the comparison being made. The proposed mechanism is primitive-wake commonality: atomic, nuclear, and mechanical clocks are all architrino assemblies whose stable translating branches are solved from the same causal-wake law, causal-root ledger grammar, and Noether sea state. A moving branch should therefore deform its closed return cycles, clock periods, and ruler scales together rather than receiving separate Lorentz factors by definition.

A useful sufficient-condition target is connected-moduli dressing. Let $\mathfrak{M}_{\mathrm{clk}}$ denote the retained moduli component for the admitted low-energy clock and ruler branches in a comparison class, and let Φ_λ be the Noether sea dressing flow on that component. If all admitted clock branches lie in one connected component of $\mathfrak{M}_{\rm clk}$, and if the generator $D_{\rm dress}$ of Φ_λ preserves the topological branch labels carried by the causal-root ledger and framing data, then clock universality reduces to the failure of dressing and branch-label transport to commute:

$$\epsilon_{\rm univ} = O\left(\sup_{\mathcal{A}\in\mathfrak{M}_{\rm clk}} \|[D_{\rm dress}, D_{\rm br}]_{\mathcal{A}}\|\right) + O(\epsilon_{\rm chart})$$

Here $D_{\rm br}$ denotes transport along the retained branch-label flow and $\epsilon_{\rm chart}$ collects declared chart and regularization remainders. This is not yet a proof of universality; it states the topological route by which a single dressing map could move every admitted clock and ruler branch together.

This is the clock-side analogue of the mass-map universality residual $\mathcal{R}_\alpha$ in Energy. Both are flatness conditions over the connected component of realized assembly moduli: $\epsilon_{\rm univ}$ tests whether clock and ruler functionals (A, B_{ij}) are transported together, while $\mathcal{R}_\alpha$ tests whether the exposed inertial coefficient is transported together. If compared species lie in one connected dressed certified-braid component, the two residuals should be controlled by the same holonomy and chart remainders. If they lie in disconnected assembly topological charge sectors, composition-dependent clock leakage and mass-map non-universality can become one inter-class obstruction rather than two unrelated failures.

The dressing caveat is essential. The simple common-wake argument works only after the Noether sea dressing map descends to a shared clock/ruler channel. If one apparatus samples $c_\star = c_{\rm eff}^{(1)}$ and another samples a different dressed channel $c_\star = c_{\rm eff}^{(2)}$ without a common reduction to the same A and B_{ij}, the mismatch is not hidden by the definition of τ. It appears as $\Delta_{\mathcal{A}}^{\rm comp}$, $\Delta_{\mathcal{A}}^{\rm ori}$, or $\Delta_{\mathcal{A}}^{\rm PF}$ and must be carried as a failure pressure on the Lorentz-closure program. The clock universality row is therefore one component of the structural-integrity common-limit closure in Lorentz Kinematics, not a standalone proper-time definition.

The low-energy Lorentz-closure target for a declared clock branch has the form

$$\frac{d\tau_{\mathcal{A}}}{dt_{\rm eff}} = A(\mathcal{N}_{\rm sea})\sqrt{1 - \frac{B_{ij}(\mathcal{N}_{\rm sea})w^i w^j}{c_0^2}}\,\left[1 + \Delta_{\mathcal{A}}^{\rm ori} + \Delta_{\mathcal{A}}^{\rm comp} + \Delta_{\mathcal{A}}^{\rm PF} + O(w^4/c_0^4)\right]$$

The residuals record orientation leakage, composition dependence, and preferred-frame leakage. They must be bounded by clock-comparison and Lorentz-test rows rather than hidden inside the constitutive function. The leading orientation row should be read as the trace-free quadrupole of the clock branch's framed trajectory bundle, not as an independent nuisance. If $Q_{\mathcal{A}}^{ij}$ is the symmetric trace-free framing tensor

$$Q_{\mathcal{A}}^{ij} = \left\langle \hat{n}^i\hat{n}^j - \frac{1}{3}h^{ij}\right\rangle_{\mathcal{A}}^{\rm frame}$$

then the lowest anisotropic clock response has the schematic form

$$\Delta_{\mathcal{A}}^{\mathrm{ori}}(\hat{\mathbf{n}})=\lambda_{\mathcal{A}} Q_{\mathcal{A}}^{ij}\left(\hat{n}_i\hat{n}_j-\frac{1}{3}h_{ij}\right)+O_{\ell\geq 4}$$

The same $Q_{\mathcal{A}}^{ij}$ is the matter-response source constrained by Hughes-Drever-type anisotropy tests, so the clock orientation row and the inertial-response anisotropy row are two exports of one branch certificate.

For Noether braid candidates, Noether Braid Configuration Space supplies the corresponding geometric order parameter. The theorem target is sharper than near-orthogonality alone: $|D_{\mathrm{plane}}|\to 1$ suppresses the non-orthogonal-frame part of the trace-free framing quadrupole $Q_{\mathcal{A}}^{ij}$, while small total $\|Q_{\mathcal{A}}\|$ also requires near-degenerate retained spectral weights, shielding, or branch averaging in the same frame extraction. If those conditions close for a clock assembly, the strict orientation row, Hughes-Drever matter anisotropy, scalar-mass anisotropy, and translating-loop Lorentz period anisotropy become different projections of one $\ell=2$ framing-isotropy condition rather than separately tuned residuals.

The residual budget is not symmetric. The defense is most exposed in the composition channel: $\Delta_{\mathcal{A}}^{\mathrm{comp}}$ is the residual that can survive if two stable clock species sample inequivalent dressed c_{eff} channels even after each has an internally consistent phase definition. The common-channel reduction must therefore prove that atomic, nuclear, mechanical, and material clock/ruler assemblies descend to the same A and B_{ij} in the tested regime, or else carry the mismatch as a failed universality row. Once that reduction holds, $\Delta_{\mathcal{A}}^{\mathrm{ori}}$ and $\Delta_{\mathcal{A}}^{\mathrm{PF}}$ become branch-geometry and medium-drift leakage rows bounded by the orientation, two-way anisotropy, and PPN tests below.

The composition row has a topological floor when clock species live in disconnected dressed components. Let $\mathfrak{M}_{\mathrm{clk}}^{(a)}$ and $\mathfrak{M}_{\mathrm{clk}}^{(b)}$ be the retained moduli components containing two compared clock species. If there is a continuous dressing path between them that preserves the certified-braid certificate and the relevant assembly topological charge data, then $\Delta_{\mathcal{A}}^{\mathrm{comp}}$ is bounded by the holonomy and chart error along that path. If every such path crosses a phase-lock jump, root-fold sector change, $D_{\mathrm{plane}}=0$ frame wall, or memory-boundary failure, then the composition residual has an irreducible inter-component floor. The defense fails in that case unless the compared species are removed from the same clock-universality class.

Equivalence-principle differential acceleration is a separate observer-level residual. For two test assemblies A and B falling toward a source S, use the Eötvös row owned by General Relativity:

$$\eta_{AB}^{S}=\frac{2(a_A^S-a_B^S)}{a_A^S+a_B^S}$$

The MICROSCOPE experiment platinum/titanium result supplies a 10^{-15}-class benchmark for this free-fall row, not for $\Delta_{\mathcal{A}}^{\text{comp}}$. The two residuals may be linked only after a formal cross-map derives both the gravitational/inertial response and the clock/ruler maps (A, B_{ij}) from the same retained assembly and Noether sea record.

These scales are experimental requirements and bookkeeping ceilings, not framework-predicted amplitudes by themselves:

Residual	Meaning	Required low-energy ceiling	Framework-predicted scale
$\Delta_{\mathcal{A}}^{\text{ori}}$	Orientation leakage in clock/ruler response	typically 10^{-16}–10^{-18}, with the strictest resonator rows at the 10^{-18} scale	Must be computed from branch-chart, hierarchy, dressing, and regularization residuals; no value is predicted by the phase definition alone.
$\Delta_{\mathcal{A}}^{\text{comp}}$	Composition dependence across atomic, nuclear, mechanical, or material clock/ruler assemblies	bounded by the declared composition-sensitive clock-comparison row for the selected species and channel; no universal equivalence-principle ceiling is assigned	Must descend from a common A and B_{ij} after dressing; channel-dependent c_{eff} maps contribute directly to this residual.
η_{AB}^{S}	Composition-dependent differential acceleration of test assemblies A and B toward source S	bounded by the declared equivalence-principle instrument and material pair; MICROSCOPE supplies a 10^{-15}-class platinum/titanium benchmark	Must descend from the effective gravitational and inertial response maps. It constrains $\Delta_{\mathcal{A}}^{\text{comp}}$ only after the formal cross-map stated above is derived.
$\Delta_{\mathcal{A}}^{\text{PF}}$	Preferred-frame leakage from the Euclidean-void rest frame into observer observables	projected into the two-way anisotropy and PPN rows below unless a sharper channel-specific bound is declared	Must be traced to named branch-chart, medium-drift, or dressing terms rather than fitted as an independent nuisance.

Required emergent limits:

- Speed convention: c_f is the primitive wake speed used inside delayed-root equations. Observer-level clock limits use the declared channel speed $c_\star$ from the transverse causal budget lemma: $c_\star = c_{\text{eff}}(\mathbf{X}, t)$ for Noether sea dressed clocks and rulers, with $c_0 \equiv c_{\text{eff}}(\infty)$ in the weak homogeneous comparison. In this sense c_0 is the deformation-invariant fixed point of the dressing flow as $\mathcal{N}_{\text{sea}}$ approaches the homogeneous neutral background, not a second primitive speed. Set $c_\star = c_f$ only for a primitive branch chart, or after deriving that a specific internal limit-cycle branch is governed directly by the undressed wake speed.
- Homogeneous medium, low velocities:

$$\frac{d\tau_{\mathcal{A}}}{dt_{\text{eff}}} \approx \sqrt{1 - \|\mathbf{w}\|^2 / c_\star^2}, \qquad c_\star = c_0 \text{ in the weak homogeneous observer branch}$$

In the weak homogeneous sea-rest branch, $u_{\text{sea}}^i = 0$, so $\mathbf{w} = \mathbf{v}$.

- Weak field, low velocities, after the clock-channel potential has been matched to the Newtonian benchmark:

$$\Phi_{\text{eff}} = \Phi_N + O(\Phi_N^2/c_0^2), \qquad \frac{d\tau_{\mathcal{A}}}{dt_{\text{eff}}} \approx \sqrt{1 + 2\Phi_{\text{eff}}/c_0^2 - \|\mathbf{w}\|^2/c_0^2}$$

Here Φ_N is the conventional negative Newtonian potential. If a positive PPN potential $U_N \geq 0$ is used, set

$$\Phi_N = -U_N$$

so the first-order clock expansion reads

$$\frac{d\tau_{\mathcal{A}}}{dt_{\text{eff}}} \approx 1 + \frac{\Phi_N}{c_0^2} - \frac{\|\mathbf{w}\|^2}{2c_0^2} = 1 - \frac{U_N}{c_0^2} - \frac{\|\mathbf{w}\|^2}{2c_0^2}$$

Speed convention table

Symbol	Meaning	Status
c_f	Primitive causal-wake propagation speed relative to the Euclidean void	fundamental
$c_\gamma(\mathcal{N}_{\text{sea}}, \hat{\mathbf{k}})$	Photon-channel speed in a Noether sea state and direction	derived
c_{eff}	Effective signal or clock-channel speed for a specified dressed branch	derived/contextual
$c_\star$	Local comparison speed used in a declared clock, ruler, or signal branch	branch-dependent
c_0	Measured low-energy invariant light speed in weak homogeneous conditions	empirical calibration and dressing-flow fixed-point target

These symbols must not be identified unless the local regime and derivation have been stated.

Preferred-frame leakage closure

The operational two-way photon-speed diagnostic is

$$c_{2w}(\hat{\mathbf{n}}) = \frac{2L}{T_+(\hat{\mathbf{n}}) + T_-(\hat{\mathbf{n}})}$$

In ordinary low-energy conditions its anisotropy must fit

$$\frac{c_{2w}(\hat{\mathbf{n}}) - c_0}{c_0} = \zeta_0 + \zeta_{ij}^{\text{TF}} \left(\hat{n}^i \hat{n}^j - \frac{1}{3}\delta^{ij} \right) + \cdots$$

with the trace-free anisotropy below the current hard-wall row in the constraint ledger, presently of order $|\zeta_{ij}^{\text{TF}}| \lesssim 10^{-17}$ and, for the strictest cavity rows, at the 10^{-18} scale. The PPN export must also pass the componentwise bound vector

$$(|\gamma_{\rm PPN}-1|,|\beta_{\rm PPN}-1|,|\alpha_1|,|\alpha_2|,|\alpha_3|)\leq\left(2.3\times10^{-5},8\times10^{-5},4\times10^{-5},2\times10^{-9},4\times10^{-20}\right)$$

Any screening mechanism must be included before exporting the observer-level PPN and Lorentz-test coefficients. The exported coefficients themselves must pass the ledger bounds. Preferred-frame hiding is therefore a numerical closure condition, not a prose reassurance.

The trace-free coefficient $\zeta_{ij}^{\rm TF}$ is the photon-channel projection of the Noether sea framing quadrupole. It is parallel to, but not identical with, the matter framing tensor $Q_{\mathcal{A}}^{ij}$ above: matter leakage tests the retained assembly framing, while photon and PPN leakage test the sea-response framing sampled by the signal channel. Translation and rotation invariance forbid leading $\ell=1$ preferred-axis leakage in the homogeneous rest branch, so the first dangerous rows are $\ell=2$ trace-free projections. The preferred-frame budget is therefore a collection of framing-isotropy conditions on matter assemblies and on the Noether sea response, with the two-way photon row measuring the sea-side quadrupole.

Effective metric handoff

The clock/ruler handoff to effective metric language can be written locally as

$$d\tau^2=A^2(\mathcal{N}_{\rm sea})\,dt_{\rm eff}^2-\frac{1}{c_0^2}B_{ij}(\mathcal{N}_{\rm sea})\left(dx_{\rm eff}^i-u_{\rm sea,eff}^i dt_{\rm eff}\right)\left(dx_{\rm eff}^j-u_{\rm sea,eff}^j dt_{\rm eff}\right)$$

The metric handoff is admissible only on branches where

$$A>0,\qquad B_{ij}=B_{ji},\qquad B_{ij}\xi^i\xi^j>0\quad\text{for }\xi\neq0$$

These inequalities have a physical meaning. $A>0$ says the declared clock phase remains monotone in absolute time, so the branch still supplies a usable clock. Positive-definite B_{ij} says the local ruler/signal compliance remains an ordinary spatial quadratic form, so one observer-level light cone can be exported from the branch. The handoff fails when a stable clock limit cycle is lost, when a separator or branch-chart transition makes the causal-root ledger discontinuous, when a Jacobian floor collapses, or when a strong-field channel becomes dispersive, birefringent, or multi-valued enough that no single B_{ij} represents the local response. In those regimes the effective metric description is suspended and the analysis must return to finite branch data, as in Lorentz Kinematics and the strong-field continuation criteria in Singularity Resolution.

Equivalently, the metric handoff is a local-invertibility claim. Let the reduced clock/ruler branch map be written schematically as

$$\Psi_{\rm cr}:(\mathcal{B}_t,H_t,\mathcal{N}_{\rm sea})\longmapsto(A,B_{ij}).$$

On a regular branch, $\Psi_{\rm cr}$ has the fixed rank needed to export one clock rate and one positive spatial quadratic response. The failure set is the branch-fold locus

$$\mathfrak{F}_{\rm cr} = \{\operatorname{rank} D\Psi_{\rm cr} < \operatorname{rank}_{\rm reg}\}$$

The conditioning face of the same admissibility condition is a singular-value floor:

$$\sigma_{\min}\left(D\Psi_{\rm cr}\big|_{\rm reg}\right) \geq \sigma_{\rm cr} > 0.$$

The inequalities $A > 0$ and $B_{ij} \succ 0$ are the positivity face of this condition, while the rank and singular-value bounds are the local-invertibility face. A branch can therefore fail metric export either by losing clock/ruler positivity or by becoming so ill-conditioned that the effective metric is locally multivalued under small retained-record perturbations.

For a generic finite-dimensional retained branch chart, the regular clock/ruler region is the open complement of a stratified failure set. Its top stratum is expected to be codimension one: a fold hypersurface across which $\Psi_{\rm cr}$ loses local invertibility and the metric handoff must be suspended. Higher-codimension strata correspond to cusp, multiple-fold, or simultaneous clock/ruler degeneracies. The preceding list gives coordinate descriptions of the same loss of one-to-one branch structure. This is the clock/ruler version of the fold and non-degeneracy-floor discipline used for causal-root charts in Master Equation.

Define the Lorentzian observer metric by

$$ds^2_{\rm eff} = -c_0^2 d\tau^2$$

With $x^0_{\rm eff} = c_0 t_{\rm eff}$, the exported components are

$$g^{\rm eff}_{00} = -A^2 + \frac{1}{c_0^2} B_{ij} u^i_{\rm sea,eff} u^j_{\rm sea,eff}$$

$$g^{\rm eff}_{0i} = -\frac{1}{c_0} B_{ij} u^j_{\rm sea,eff}$$

and

$$g^{\rm eff}_{ij} = B_{ij}$$

Photon-channel closure then reads the null condition of this observer-level quadratic form, with c_γ derived from the same Noether sea state rather than assigned independently:

$$\frac{dx^i_{\rm eff}}{dt_{\rm eff}} = u^i_{\rm sea,eff} + c^{\rm rel}_\gamma(\hat{\mathbf{k}})\hat{k}^i$$

$$c_\gamma^{\mathrm{rel}}(\hat{\mathbf{k}}) = \frac{c_0 A}{\sqrt{B_{ij}\hat{k}^i\hat{k}^j}}$$

The weak homogeneous branch requires $A \to 1$, $B_{ij} \to \delta_{ij}$, and $u^i_{\mathrm{sea,eff}} \to 0$.

The same-record rule is stricter than using one symbol $\mathcal{N}_{\mathrm{sea}}$ in several equations. The clock/ruler map must consume the same Noether sea response record that supplies G_{eff} in the gravity inventory, c_{eff} in the matter limiting-speed and mass-shell rows, and c_γ in the photon channel:

$$\Theta_{\mathrm{sea}} \longmapsto (A,\, B_{ij},\, G_{\mathrm{eff}},\, c_{\mathrm{eff}},\, c_\gamma)\,.$$

If these projections require separate sea records or independently tuned response tensors, the effective metric is fitted rather than derived. The closure burden is therefore one sea-constitutive object with clock, ruler, gravity, matter-speed, and photon projections, not a separate clock-sector construction.

Key point

Relativity of simultaneity and time dilation are emergent observer-level effects of assembly dynamics. The $\mathbb{U}_{\mathrm{now}}$ formalism evolves in absolute time T; proper time τ is a derived clock functional. The closure burden is therefore not to remove the preferred foliation, but to derive clock, ruler, and signal behavior that bounds preferred-frame leakage to the required precision in the effective observer sector.

The converse is a hard falsifiability wall. The defense fails if $\Delta^{\mathrm{comp}}_{\mathcal{A}}$ cannot be driven to the declared clock-comparison ceiling by a common-channel reduction. A sharp topological obstruction is disconnected clock moduli: if physically realized clock species occupy different deformation classes of the Noether braid atlas and no shared dressing path identifies their A and B_{ij} maps, then the composition residual is irreducible rather than a small correction. The defense also fails if a stable low-energy clock or ruler species retains orientation or preferred-frame leakage after branch-chart, dressing, and regularization terms have been accounted for, with residuals exceeding the relevant cavity or two-way anisotropy row, in particular at the 10^{-18} scale for the strictest resonator comparisons. Such leakage would not be an alternate interpretation of proper time; it would be a failed Lorentz-closure branch.

Detecting the Absolute Frame

This chapter asks how the theory can identify absolute rest without first painting a coordinate grid onto the Euclidean void. The answer is a complete-state diagnostic: in $\mathbb{AAA}$, the preferred frame is encoded in the transmitter-tagged geometry of causal wakes available to complete-state bookkeeping.

Overview

This chapter answers the question that must be settled before any coordinate construction can begin: can the architrino framework identify **absolute rest** from its own physics, without assuming a pre-labeled grid? The answer in this framework is yes, but the answer belongs first to the $\mathbb{U}_{\text{now}}$ universe-state perspective. The complete-state diagnostic is the **concentricity of transmitter-tagged causal isochron centers**. A stationary architrino is sufficient to expose that diagnostic, but the preferred rest frame itself is defined by the propagation law: it is the frame in which primitive causal wakes expand isotropically at c_f.

This argument sits between Euclidean Void, which states the underlying substrate, and Constructing the Absolute Frame, which turns the preferred-rest diagnostic into a usable coordinate frame. Its operational shielding claims also connect directly to Absolute Time Defense and Lorentz Kinematics.

The important separation is transmitter-tagged geometry versus summed observation. Complete-state bookkeeping can ask where each causal isochron was emitted. A physical apparatus normally receives only a combined record after propagation, coupling, clocking, and Noether sea dressing. The preferred frame can be real in the first sense without becoming an easy observable in the second.

The Fundamental Challenge

The architrino theory posits the **Euclidean void** and **absolute time** as the fundamental substrate. These are ontological commitments, not coordinate labels. Unlike a laboratory bench with meter sticks and clocks, the void has no inherent origin, no painted grid lines, no axis arrows, and no universal clock reading “now = 0.”

This presents an apparent paradox:

- We claim architrinos have **definite positions $\mathbf{X}(T)$** and **definite velocities $\mathbf{V}(T)$** in the Euclidean void as indexed by absolute time.
- Yet the Euclidean void is **translationally and rotationally invariant**: the physics is identical at any location, any orientation, and any moment.
- How can the theory internally distinguish absolute rest ($\mathbf{V} = \mathbf{0}$) from absolute motion ($\mathbf{V} \neq \mathbf{0}$) without reference coordinates?

This is not merely a philosophical puzzle. It is a **practical requirement** for the theory’s internal consistency. If the theory cannot, even in principle, extract a preferred rest condition from intrinsic physics, then claims about absolute velocity lack complete-state content and become only an imposed coordinate convention.

Detecting Absolute Rest: The Causal Wake Diagnostic

The Key Physical Mechanism

The diagnostic rests on the theory's **finite wake-speed** postulate: architrino-emitted causal wakes propagate at speed c_f **relative to the Euclidean void**, not relative to the source's subsequent motion. This postulate structurally distinguishes the void rest frame, making it available to complete-state reconstruction through purely geometric relationships.

The idea is easiest to see by following the centers of emitted wake surfaces. A stationary transmitter keeps emitting from the same void point. A moving transmitter leaves a sequence of distinct emission centers behind it. The center pattern, not an external grid label, carries the rest diagnostic.

The Nature of Causal Wakes

Each architrino continuously emits potential-bearing structure as **expanding causal isochrons**. A single emission at time T_t produces a causal wake surface expanding at speed c_f from the emission point. This is not a discrete shell or particle; it is a **potential-bearing distribution** supported on the emitted wake surface. At any given absolute time T, with $\Delta T = T - T_t$, that emitted isochron has radius $r = c_f \Delta T$ centered on the point where it was emitted.

The crucial point is that this expanding causal isochron carries transmitter-tagged information about the **absolute location** where the architrino was when it emitted that portion of the potential-bearing wake. The isochron does not follow where the architrino goes afterward. It continues expanding from its emission point in the Euclidean void.

The Concentricity Test

Consider a $\mathbb{U}_{\text{now}}$ universe-state perspective with access to complete microdynamics that can track:

1. The complete path history of any architrino,
2. The transmitter identity and provenance of each emitted causal isochron,
3. The geometric centers of all emitted and expanding causal wake surfaces,
4. The absolute emission times associated with those wake surfaces.

The Diagnostic Signature: An architrino at **absolute rest** ($\mathbf{V} = \mathbf{0}$) exhibits a unique geometric property. It remains at the **exact center** of every transmitter-tagged expanding causal isochron it has ever emitted during the rest interval.

The Physical Basis:

- At time T_t, the architrino emits potential from position $\mathbf{X}_{\text{em}}$, creating a causal isochron.
- This causal isochron expands at speed c_f relative to the void, centered on $\mathbf{X}_{\text{em}}$.

- If the architrino is stationary, at later time $T_1 = T_t + \Delta T$, it remains at $\mathbf{X}_{\text{em}}$.
- The causal isochron has expanded to radius $r = c_f \Delta T$, but its center remains $\mathbf{X}_{\text{em}}$.
- All successive emissions create perfectly **concentric causal isochrons**: nested potential distributions sharing a common geometric center.

If the architrino moves:

- At T_t, emission occurs at $\mathbf{X}_{\text{em}}$.
- On a uniform segment, at T_1 the architrino has displaced to $\mathbf{X}_1 = \mathbf{X}_{\text{em}} + \mathbf{V}\Delta T$.
- The first causal isochron remains centered on $\mathbf{X}_{\text{em}}$ with radius $c_f \Delta T$.
- Subsequent causal isochrons are centered on displaced positions along the trajectory.
- The emitted centers are **non-coincident**; the transmitter-tagged wake stream is **non-concentric**.
- The architrino lies closer to the expanding wake front in its direction of motion, producing the geometric asymmetry that later appears as Doppler-like structure at the observer level.

The difference between these two cases is the whole diagnostic. Rest means one repeated center. Uniform motion means a straight center sequence. Accelerated motion means a curved center history.

The Complete-State Diagnostic Procedure

Step 1: Track the transmitter-tagged geometric centers of all expanding causal isochrons emitted by a target architrino over a diagnostic interval.

Step 2: Test for spatial coincidence of these centers.

Result:

- **All centers coincident** means $\mathbf{V}_{\text{abs}} = \mathbf{0}$ on that interval (absolute rest).
- **Centers form a trajectory** means $\mathbf{V}_{\text{abs}} \neq \mathbf{0}$; for a uniform segment, the displacement vector $\Delta\mathbf{X}$ per unit time ΔT yields the absolute velocity: $\mathbf{V}_{\text{abs}} = \Delta\mathbf{X}/\Delta T$.

This is definitionally a complete-state test. It assumes the individual transmitter identity, emission time, and isochron support are already available in the provenance-bearing state. A physical apparatus receiving only the summed potential cannot recover the transmitter-tagged centers by a clever superposition-resolving operation unless it already has access to the very provenance data the diagnostic assumes.

That limitation is not a weakness of the ontology. It marks the difference between complete-state reconstruction and what embedded Physical Observers can infer after provenance has been erased into a summed received record.

Wake-center theorem: Let a transmitter-tagged causal isochron emitted by transmitter a at time T_t and inspected at time $T > T_t$ have emission center $\mathbf{Z}_a(T_t) = \mathbf{X}_a(T_t)$ and support

$$W_a(T_t; T) = \{\mathbf{Y} \in \Sigma_T : \|\mathbf{Y} - \mathbf{Z}_a(T_t)\| = c_f(T - T_t)\}$$

In Euclidean three-space, a nondegenerate isochron support of this form has a unique center. Therefore, if $W_a(T_t; T)$ is known as a transmitter-tagged support, its emission center $\mathbf{Z}_a(T_t)$ is geometrically reconstructible without first assigning coordinates to the void.

Equivalently, Euclidean geometry gives a bijection between nondegenerate metric spheres and center-radius pairs:

$$W_a(T_t; T) \longleftrightarrow (\mathbf{Z}_a(T_t),\, c_f(T - T_t))$$

for full spherical supports. In a finite sampled reconstruction, a clean nondegeneracy certificate is supplied by four support points $\mathbf{Y}_0, \ldots, \mathbf{Y}_3$ whose displacement Gram determinant is bounded away from zero:

$$\Delta_{\text{sph}} = \det\left[(\mathbf{Y}_\alpha - \mathbf{Y}_0) \cdot (\mathbf{Y}_\beta - \mathbf{Y}_0)\right]_{\alpha,\beta=1}^{3} > 0$$

with a declared numerical floor in simulation. This is the same determinant family as the volume test used in Constructing the Absolute Frame: when the sampled support collapses toward a line, plane, or tiny aperture, the inverse center fit is no longer a stable complete-state reconstruction. If the radius $c_f(T - T_t)$ is already supplied, three non-collinear points plus a side convention can reduce the data requirement, but the four-point certificate is the safer branch-independent test.

For a full spherical support, uniqueness is exact. A finite reconstruction usually sees only a partial support $U_a(T_t; T) \subset W_a(T_t; T)$, so the inverse-center problem needs its own conditioning floor. Let

$$\omega_a(T_t; T) = \text{area}_{S^2}\left\{\frac{\mathbf{Y} - \mathbf{Z}_a(T_t)}{\|\mathbf{Y} - \mathbf{Z}_a(T_t)\|} : \mathbf{Y} \in U_a(T_t; T)\right\}$$

The reconstructed center is admissible only when

$$\omega_a(T_t; T) \geq \omega_{\min} > 0$$

on the declared support window. Below that solid-angle floor, the center may remain formally unique in the full-support idealization while the finite inverse problem becomes ill-conditioned.

The solid-angle floor is a practical proxy for a smallest-eigenvalue floor in the sphere-fit Jacobian. For sampled directions $\hat{\mathbf{n}}_k = (\mathbf{Y}_k - \mathbf{Z})/\|\mathbf{Y}_k - \mathbf{Z}\|$ with positive weights w_k, define the direction design matrix

$$G_a = \sum_k w_k\, \hat{\mathbf{n}}_k \hat{\mathbf{n}}_k^T$$

The finite-aperture inverse is accepted only when $\lambda_{\min}(G_a) \geq \lambda_{\min}^{\mathrm{ctr}} > 0$ on the reconstruction window, or when an equivalent continuous-support bound is supplied. A direction cloud concentrated in a small cap or nearly planar arc is rank-deficient in the same way that a near-collinear tuple is rank-deficient in frame construction. Thus $\omega_{\min}$, the basis floor $\sin\theta_{\min}$, separatrix regularity, and the causal-root transversality floor κ_{hit} are all instances of one non-degeneracy requirement: the retained reconstruction map must have a bounded local inverse on the chart being used.

For a target architrino a and emission interval I, define the transmitter-tagged center set

$$Z_a(I) = \{\mathbf{Z}_a(T_t) : T_t \in I\}$$

and its Euclidean diameter

$$D_a(I) = \sup_{T_t, T_t' \in I} \|\mathbf{Z}_a(T_t) - \mathbf{Z}_a(T_t')\|$$

Equivalently,

$$D_a(I) = \operatorname{diam} Z_a(I)$$

With exact complete-state access and transmitter-independent propagation at c_f, $D_a(I) = 0$ if and only if $\mathbf{Z}_a(T_t)$ is constant on I, so the transmitter is at absolute rest almost everywhere on that interval. For uniform motion over a duration ΔT_I, $D_a(I) = \|\mathbf{V}_a\|\Delta T_I$. This is a **coordinate-free** geometric diagnostic. It does not compare position to some external grid. It checks an **intrinsic relational property**: whether the transmitter-tagged centers of emitted causal isochrons occupy the same point in the Euclidean void.

The velocity readout in the uniform case assumes $\mathbf{Z}_a(T_t) = \mathbf{Z}_0 + \mathbf{V}_a(T_t - T_0)$ on the interval. For accelerated or curved transmitter histories, $D_a(I)$ measures only the chord-span of the center curve and cannot determine the velocity history by itself. The faithful complete-state object is the full center curve $T_t \mapsto \mathbf{Z}_a(T_t)$, including its tangent, curvature, and torsion where those derivatives exist; that curve is the geometric record the self-hit ledger later samples.

The resulting diagnostic hierarchy is a hierarchy of derivative data on the same center curve. Absolute rest is the zeroth-order condition that $Z_a(I)$ has zero diameter, equivalently $\mathbf{Z}_a(T_t)$ is constant on the interval. Uniform absolute motion is the first-order condition $d\mathbf{Z}_a/dT_t = \mathbf{V}_0$ with vanishing curvature on the interval. Self-hit eligibility is a higher-order and global condition: curvature, torsion, recurrence, or super-field-speed history must bring the source into the forward isochron foliation generated by its own past centers. The Frenet framing is useful on regular curve segments, but the self-hit condition itself is the causal-root condition below, not merely a local curvature scalar.

If no architrino is stationary over the diagnostic interval, complete-state reconstruction may still recover the preferred rest-frame structure from the centers of transmitter-tagged wake isochrons. A coordinate origin can then be chosen conventionally from any reconstructed emission center at a chosen time. The stationary architrino is therefore a convenient material origin, not the definition of the preferred frame.

This distinction fixes the level of the claim. Ontologically, the preferred frame is defined by the propagation law in the Euclidean void. Inference-wise, the concentricity test reconstructs that rest condition from transmitter-tagged wake records. At the effective observer level, the same fact need not be directly measurable, because assemblies use clocks, rulers, and signal channels that must themselves satisfy Lorentz-recovery closure.

Connections to Core Dynamics

Self-Hit and Delay-Root Geometry

The concentricity diagnostic connects directly to the geometry developed in Self-Interaction (Self-Hit Dynamics) and Causal Interaction Set (The Geometry of Delay), but the two claims must remain distinct:

- An architrino at rest ($\mathbf{V} = \mathbf{0}$) emits concentric causal isochrons, but it does not receive a delayed self-hit merely by being stationary. For $T_t < T_r$, the self-hit root condition would require $\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| = c_f(T_r - T_t)$; a stationary worldline has the left side equal to zero while the right side is positive.
- An architrino in ordinary sub-field-speed straight motion emits non-concentric transmitter-tagged isochrons, but that is still not enough by itself to create a self-hit. Self-hit is a transmitter-identity root condition, not a synonym for nonzero absolute velocity.
- Curved path history and super-field-speed history are the relevant self-hit ingredients. Once the transmitter path folds through its own emitted causal isochrons, same-transmitter roots can enter the causal-root ledger and produce non-Markovian feedback.
- In exact center-curve terms, a same-transmitter root exists when the transmitter re-enters its own forward isochron:

$$\exists\, T_t < T : \|\mathbf{Z}_a(T) - \mathbf{Z}_a(T_t)\| = c_f(T - T_t)$$

This is re-entry into the expanding-sphere foliation generated by the past center curve. It is not a requirement that the spatial curve literally intersect itself in $\mathbb{R}^3$. For closed or recurrent framed branches, the protected topology row should be stated as a linking or framed self-linking record, such as $Lk = \mathrm{Wr} + \mathrm{Tw}$ when the branch supplies a nonsingular frame. Thus absolute rest and self-hit are distinct invariants: rest is concentricity of transmitter-tagged centers, while self-hit is a transmitter-identity root with a retained wake/worldline linking or framing record when such a record is part of the branch certificate.

- For bound assemblies, the corresponding closure problem is conditional: a translating Noether braid must retune its moving-assembly deformation, clock/ruler behavior, two-way signal synchronization, and preferred-frame leakage while its internal causal-root ledgers remain admissible. Failure of that shared closure would appear as phase loss, dissociation, or unacceptable preferred-frame leakage; the disruption claim is a theorem target, not an established consequence of the rest diagnostic alone.
- This moving-assembly bias is one input to the medium-dressed inertial response of bound assemblies: acceleration skews the delayed causal ledger, while shielding determines how much of the internal energy is exposed to external probes.

The upshot: Absolute velocity is not merely a kinematic label, but the direct rest diagnostic is geometric rather than an immediate self-hit claim. The dynamical burden belongs to the Lorentz-closure ladder: moving assemblies must show stable delayed-root closure, medium-dressed deformation, and bounded preferred-frame leakage before Physical Observers can recover ordinary relativistic behavior.

Master Equation Requirements

The Master Equation demands **explicit positions** $\mathbf{X}_i(T)$ to compute:

- Separation distance r_{ij} between architrinos i and j
- Path-history positions (where was architrino j when the wake contribution currently reaching i was emitted?)

The concentric-wake diagnostic demonstrates that $\mathbf{X}_i(T)$ is physically meaningful within complete-state reconstruction. Stationarity can be identified without circular reference to pre-existing coordinate labels; coordinates enter afterward as a convenient representation of the already-defined rest condition.

Foundational Validation

This complete-state diagnostic serves as a **consistency test** for Euclidean Void and Absolute Time Defense:

- Can the theory self-consistently define its own reference frame from intrinsic physics alone?
- **Yes**: through geometric properties of continuous wake dynamics.

This prevents the preferred-frame claim from being empty inside the formal ontology. Direct empirical access remains a separate issue: it depends on the moving-assembly and photon-channel closures that determine whether Physical Observers can detect any preferred-frame leakage.

Conservation-Law Counting as a Frame Diagnostic

The absolute frame also leaves a fingerprint in pure bookkeeping: the number of continuous conservation rows the substrate supports. The proved invariance group of the Master Equation is time translation plus the Euclidean motions of the void, one time translation, three space translations, and three rotations, yielding exactly seven continuous rows: energy, three of momentum, and three of angular momentum. Newtonian mechanics with Galilean invariance supports ten rows, the boosts supplying the center-of-mass theorem, and relativistic mechanics supports the ten rows of the Poincare group. The substrate count is seven, not ten, because boosts are not substrate symmetries: c_f anchors a preferred frame, and the three missing boost rows are that frame's signature expressed as absent theorems rather than as any measured velocity. Counting conservation laws is therefore a frame-detection diagnostic in its own right, complementary to the concentricity test. The Lorentz-recovery program carries the corresponding obligation: the three missing boost rows must re-emerge as part of the effective ten-row structure in Theorem G, with the conservation-accounting side of the seven substrate rows surveyed in Information and the Wake.

Ontological Clarifications

What Is Physically Real vs. What Is Convention

Ontologically fundamental (physically real):

- **Euclidean void and absolute time**: The substrate in which all architrino dynamics occur
- **Absolute velocity**: Physically meaningful and detectable to complete-state reconstruction via transmitter-tagged wake concentricity
- **Causal wakes**: continuous source-dependent, potential-bearing causal records propagating through the void
- **Geometric relationships**: Concentricity and displacement are objective, observer-independent properties

Conventional (mathematical scaffolding):

- **Coordinate labels**: Tools for calculation and communication
- **Choice of origin**: A stationary architrino supplies a convenient material origin when available; otherwise any reconstructed emission center at a chosen time may be selected conventionally
- **Axis orientation**: The void is isotropic; no direction is physically privileged

Why Physical Observers Don't Detect the Preferred Frame

The concentric-wake diagnostic requires access to full microdynamics: something only a $\mathbb{U}_{\text{now}}$ universe-state perspective can achieve. **Physical Observers** composed of assemblies measure through assembly-based apparatus:

- **Proper time** τ via internal clocks, not absolute time T
- **Effective coordinates** via local rulers
- **Relative velocities** via Doppler shifts and aberration

Assembly-based measuring devices are themselves distorted by motion and coupling to the Noether sea. At accessible energies and weak Noether sea density gradients, the Lorentz-recovery target is that moving assemblies contract, retune their internal periods, and synchronize photon channels so that preferred-frame signatures remain below experimental detection thresholds. The absolute frame exists as the ontological foundation, but emergent effective geometry shields it from direct operational observation only if that moving-assembly closure is derived, not merely assumed.

The Source-Independence Assumption

The diagnostic relies on a critical physical assumption:

- **Wake propagation independence from transmitter motion**: once emitted, the potential-bearing wake propagates at c_f relative to the void, independent of the transmitter's subsequent trajectory.

This is analogous to **acoustic waves** in air: once a speaker emits sound, that wave propagates at the speed of sound in the medium. The wave does not follow the speaker if it moves. The analogy does not by itself answer Michelson-Morley-style null drift results; that burden is owned by the moving-assembly closure ladder, not by this complete-state diagnostic.

The reason is structural rather than rhetorical. The complete-state diagnostic operates on transmitter-tagged wake centers: transmitter identity, emission time, and support geometry are part of its data. A Michelson-Morley-style interferometer samples a summed, untagged received potential through physical clocks, rulers, mirrors, and photon channels. Null drift constrains the observer-level shielding and common-channel closure of that untagged measurement system; it does not falsify the transmitter-tagged center diagnostic unless the complete-state provenance ledger itself is inconsistent.

Tagged-Emission Injectivity Lemma

Let $\mathcal{H}_{\text{tag}}$ denote an admissible transmitter-history record and let $\mathcal{E}_{\text{tag}}(\mathcal{H}_{\text{tag}})$ denote its family of emitted supports $(a, T_t, W_a(T_t; T))$ on the declared time window. Assume that transmitter and emission-time tags are retained, wake propagation is transmitter-motion independent after emission, the center supports satisfy the declared aperture or center-fit non-degeneracy floor, and the worldlines are absolutely continuous. Then

$$\mathcal{E}_{\text{tag}}(\mathcal{H}_{\text{tag}}) = \mathcal{E}_{\text{tag}}(\mathcal{H}'_{\text{tag}}) \quad \Longrightarrow \quad \mathcal{H}_{\text{tag}} = \mathcal{H}'_{\text{tag}}$$

Proof. Equality of the nondegenerate tagged supports gives the same unique center for every (a, T_t) and therefore the same center curves. Those curves are the transmitter worldlines; absolute continuity then gives the same velocities almost everywhere, while the retained tags carry identity and polarity. Translation, rotation, and time-origin conventions enter only when the same records are presented in convention-relative charts.

This is not an observer-accessible decomposition theorem for the summed potential. The proof depends on the hypothesis that provenance tags survive in complete-state bookkeeping. If that hypothesis fails, the tagged map is unavailable; if only the later label-erasing observer map has large fibers, the preferred frame remains complete-state real but operationally hidden.

Philosophical Context

Relationalism vs. Substantivalism

- **Relationalism** (Leibniz, Mach): spatial facts are merely relations between objects; no independent Euclidean-void container is meaningful
- **Substantivalism** (Newton, this theory): the Euclidean void is a real container with intrinsic structure, existing independent of matter

In the terminology of this chapter, the substantival claim is the reality of the Euclidean void and absolute time, not the existence of a preferred coordinate chart. The architrino framework is therefore **substantivalist**, but it avoids the idea that the void comes with pre-painted coordinates. Instead, **causal-wake dynamics** reveal the structure that matters.

Neo-Lorentzian Character

This places the theory in the tradition of **Lorentz Ether Theory**:

- Absolute space and time are fundamental
- Operational Lorentz symmetry is a recovery target of the moving-assembly closure ladder, not a primitive substrate symmetry
- A preferred frame exists but must be operationally hidden at low energies by the moving-assembly closure ladder

Key distinctions from classical LET:

- The Noether sea is not a continuous classical ether; it is an assembly network rather than a coordinate grid
- The preferred frame is hidden by emergent effective geometry

- The framework states explicit closure targets and failure criteria for where symmetry-breaking signatures would appear

Summary: The Detection Method

The Question: Can a $\mathbb{U}_{\text{now}}$ universe-state perspective determine when an architrino has absolute velocity zero, without pre-existing coordinates?

The Answer: Yes, by testing the **concentricity** of transmitter-tagged outgoing causal isochrons.

Detection signatures:

- Absolute rest means all transmitter-tagged wake centers are spatially coincident.
- Absolute motion means wake centers form a displacement trajectory; for uniform segments, velocity $\mathbf{V}_{\text{abs}} = \Delta\mathbf{X}/\Delta T$.

Why this works:

- Wake speed c_f is isotropic in the void's rest frame
- Emission centers mark absolute positions in the void
- Concentricity is a coordinate-free geometric invariant of transmitter-tagged continuous potential distributions

Theoretical implications:

- The Euclidean void and absolute time have complete-state diagnostic content
- The theory can identify a preferred rest condition from intrinsic physics alone
- Operational Lorentz invariance is compatible with fundamental absolute structure

The next chapter, Constructing the Absolute Frame, uses this preferred-rest diagnostic as the starting point for constructing a complete coordinate frame.

Tagged Recovery and Observer-Hiding Theorem Target

The risk-bearing claim is two-sided. The preferred-frame program fails at the complete-state level if transmitter-tagged wake centers cannot define one consistent rest-frame structure. It fails at the observer level if physical clocks, rulers, or photon channels retain preferred-frame leakage above the declared cavity, two-way anisotropy, or PPN ceilings after moving-assembly closure is applied. The framework is therefore committed both to a real complete-state preferred frame and to a quantitatively hidden observer-sector leakage row.

In map language, the theorem target pairs the proved tagged-emission injectivity lemma with approximate observer invariance. The label-erasure map to summed observer-accessible records must make the preferred-frame orbit diameter small for physical observables across the tested boost or drift family:

$$\operatorname{diam}_{\text{obs}}\left\{\mathcal{O}\left[Q_{\text{erase}}(\mathcal{H}_{\text{tag}}^{(\mathbf{w})})\right] : \|\mathbf{w}\| \le w_{\max}\right\} \le \epsilon_{\text{PF}}$$

Here $\mathcal{H}_{\text{tag}}^{(\mathbf{w})}$ denotes the tagged record produced by re-preparing the same experiment with absolute drift $\mathbf{w}$ inside the tested low-energy comparison window, and $\mathcal{O}$ denotes the admitted observer-accessible functionals. The first condition makes the preferred frame real in complete-state geometry. The second is the Lorentz-recovery burden that makes that frame hidden from embedded Physical Observers.

Constructing the Absolute Frame

This chapter answers a simple question: if the Euclidean void has no grid painted into it, how can the theory ever use coordinates? The answer is reconstruction. A usable frame is built from complete-state wake geometry, not assumed as a label already attached to space. The ontological data are architrino worldlines, transmitter-tagged causal wakes, Euclidean distances on an absolute-time slice, and the path-history records needed to compare them. The coordinate frame reconstructed from those data is a mathematical and computational representation, not an additional constituent of the ontology.

Overview

The previous chapter showed how transmitter-tagged wake centers identify the preferred rest structure, and how a stationary architrino can supply one convenient material origin when available. The next task is more ordinary but just as important: construct a complete coordinate system. The Euclidean void provides no intrinsic markers: no origin point labeled “here,” no arrows painted “this way,” and no universal clock displaying “now = 0.” Those absences are not defects in the ontology. They are the reason coordinates must be inferred from complete-state geometry rather than treated as primitive labels attached to the void.

The conceptual sequence is: Detecting the Absolute Frame identifies absolute rest, Absolute Time Defense defends the global temporal ledger, and Proper Time and Time Dilation explains how observer-level clocks arise once the coordinate frame is in place.

The coordinate system reconstructed here is a workbench tool. It lets the theory state equations in components, run simulations, and compare descriptions. The universe itself requires none of it. Architrinos interact through transmitter-tagged causal wakes according to invariant laws that can exhibit deterministic multistability at self-hit thresholds. The physics continues whether or not any Physical Observer labels the axes.

The reader should therefore treat the construction like assigning graph paper after the geometry is already there. The graph paper helps calculate and compare; it does not create the distances, the rest condition, the causal wakes, or the architrino worldlines. This is why the reconstruction can be mathematically exact at the complete-state level while still being unavailable as a direct laboratory procedure for an embedded observer.

The claim is therefore narrow. From the $\mathbb{U}_{\text{now}}$ complete-state bookkeeping perspective, a unique oriented basis can be defined after a nondegenerate ordered architrino tuple and parity convention are fixed. That is a mathematical existence proof. It is not an operational laboratory protocol for Physical Observers made of assemblies.

The mathematical content is small but useful. The Euclidean metric plus a nondegenerate ordered tuple supplies an origin, two axes, and a parity convention. The important points are the lemma, the exact failure conditions, and the fact that coordinate parity is not dynamical chirality.

Reconstruction Existence Lemma

Fix one absolute-time slice Σ_{T_*}. Suppose complete-state wake geometry identifies an origin point O on that slice. Let $\mathbf{X}_O(T_*)$ denote that fixed Euclidean-void point, whether it is occupied by a stationary architrino or reconstructed from a transmitter-tagged emission center and carried to Σ_{T_*} by spatial identity. Now choose two architrinos A and B whose positions on Σ_{T_*} satisfy

$$\mathbf{d}_1 = \mathbf{X}_A(T_*) - \mathbf{X}_O(T_*) \neq \mathbf{0}$$

and

$$\mathbf{d}_2 = \mathbf{X}_B(T_*) - \mathbf{X}_O(T_*), \qquad \|\mathbf{d}_1 \times \mathbf{d}_2\| \neq 0$$

Then the first two unit axes are fixed by

$$\hat{\mathbf{e}}_1 = \frac{\mathbf{d}_1}{\|\mathbf{d}_1\|}$$

$$\mathbf{d}_2^{\perp} = \mathbf{d}_2 - (\mathbf{d}_2 \cdot \hat{\mathbf{e}}_1)\hat{\mathbf{e}}_1, \qquad \hat{\mathbf{e}}_2 = \frac{\mathbf{d}_2^{\perp}}{\|\mathbf{d}_2^{\perp}\|}$$

Read the first displacement as the first arrow from the origin, and the second displacement as the arrow that fixes the plane. Once those are nondegenerate, only one binary choice remains. The remaining completion has exactly two signs. Once an orientation convention is declared, the right-handed completion is

$$\hat{\mathbf{e}}_3 = \hat{\mathbf{e}}_1 \times \hat{\mathbf{e}}_2$$

Geometrically, the lemma constructs a section of the orthonormal frame bundle over the selected Euclidean point from a nondegenerate ordered tuple. In plainer language, the tuple removes the freedom to slide the origin around and spin the axes freely. The continuous freedoms removed are the translations and rotations of the special Euclidean group:

$$SE(3) = \mathbb{R}^3 \rtimes SO(3)$$

This is the identity component of the full Euclidean group $E(3) = \mathbb{R}^3 \rtimes O(3)$, while the remaining parity choice is the connected-component label of the full orthogonal group, $\pi_0(O(3)) \cong \mathbb{Z}_2$. Thus the two signs are not an extra dynamical datum. They are the residual component choice left after the ordered tuple fixes the connected Euclidean-frame freedom.

The construction fails only when the chosen reference data do not actually define a plane. That happens when the first displacement is coincident with the origin or the first two displacements are collinear:

$$\|\mathbf{d}_1\| = 0 \qquad \text{or} \qquad \|\mathbf{d}_1 \times \mathbf{d}_2\| = 0$$

For simulation and finite-precision reconstruction, exact nondegeneracy is not enough. The ordered tuple should also carry a conditioning floor

$$\frac{\|\mathbf{d}_1 \times \mathbf{d}_2\|}{\|\mathbf{d}_1\|\,\|\mathbf{d}_2\|} \geq \sin\theta_{\min} > 0$$

on the retained reconstruction window. If this floor is small, the projection defining $\hat{\mathbf{e}}_2$ is ill-conditioned and the completed $\hat{\mathbf{e}}_3$ amplifies roundoff or perturbation error. The simulator should then choose a better-conditioned tuple rather than treating the near-collinear basis as an ordinary pass.

This floor is one instance of the non-degeneracy floors used throughout the foundation stack. The common idea is simple: do not trust a reconstruction that would change wildly under a tiny perturbation. In each case the retained chart is accepted only when the relevant reconstruction map has a scale-appropriate nonzero floor. For causal-root charts this is the transversality floor, such as $|\partial_{T_t} F_{ij}| \geq \kappa_{\text{hit}}$; for basin partitions it is the separatrix floor; for this frame construction the scale-free floor is the conditioning of the normalized direction pair $(\mathbf{d}_1/\|\mathbf{d}_1\|, \mathbf{d}_2/\|\mathbf{d}_2\|)$, recorded above by the sine of their angle. The common mathematical content is controlled local invertibility: the map has a bounded inverse-Lipschitz constant on the retained chart, so small perturbations of the complete-state data do not create a different branch or frame.

If a fourth architrino C is introduced, it is non-coplanar with the first three exactly when

$$\mathbf{d}_3 = \mathbf{X}_C(T_*) - \mathbf{X}_O(T_*), \qquad V_{\text{vol}} = \mathbf{d}_3 \cdot (\mathbf{d}_1 \times \mathbf{d}_2) \neq 0$$

Here $V_{\mathrm{vol}} \neq 0$ is the structural non-coplanarity test for basis completion. The sign $\mathrm{sgn}(V_{\mathrm{vol}})$ reports which side of the already oriented plane the marker occupies relative to a declared orientation. It does not by itself turn coordinate parity into a dynamical chirality claim.

This lemma is an existence claim at the complete-state level. It does not say that the Euclidean void contains an origin or preferred axes. It says that once a nondegenerate ordered tuple is selected, the Euclidean metric supplies enough invariant structure to construct a coordinate basis for calculation.

Minimal Reconstruction Procedure

The lemma above is the full construction. Complete-state bookkeeping performs four choices. Each choice adds a piece of coordinate language without adding a new physical ingredient:

1. Choose an origin point O on Σ_{T_*}. A stationary architrino can supply a material origin, but a reconstructed transmitter-tagged emission center also suffices. If the emission time is $T_t \neq T_*$, the origin on Σ_{T_*} is the same fixed Euclidean-void point carried by spatial identity across slices, not the original event on Σ_{T_t}.
2. Choose a non-coincident architrino A and set $\hat{\mathbf{e}}_1 = \mathbf{d}_1/\|\mathbf{d}_1\|$. This fixes a reference direction but not a physically preferred direction; the tuple choice is conventional once the complete-state geometry is available.
3. Choose a non-collinear architrino B and use the orthogonal projection of $\mathbf{d}_2$ to define $\hat{\mathbf{e}}_2$. This fixes the remaining continuous roll around $\hat{\mathbf{e}}_1$.
4. Declare a parity convention and set $\hat{\mathbf{e}}_3 = \hat{\mathbf{e}}_1 \times \hat{\mathbf{e}}_2$, or use a non-coplanar fourth architrino only as a side marker for reporting the chosen convention.

The continuous freedoms removed are translation and rotation. Absolute time zero remains a separate temporal convention. The spatial basis does not need to be re-derived on every slice: once the chart is fixed on Σ_{T_*}, it transports identically across absolute-time slices because Euclidean-void points have fixed identity. In the selected c_f-isotropic rest frame, the dynamically completed Newton-Cartan connection is the flat representative described in Absolute Timespace, so this transport has trivial holonomy and is path-independent. The delayed root condition $\|\mathbf{X}_{o'}(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t)$ therefore compares positions at different times inside the same spatial chart, not inside separately reconstructed per-slice frames.

The reconstruction fails only for degenerate or ill-conditioned reference data: $\|\mathbf{d}_1\| = 0$, $\|\mathbf{d}_1 \times \mathbf{d}_2\| = 0$, or a violated conditioning floor. In that case complete-state bookkeeping must choose a different ordered tuple. The failure belongs to the selected chart data, not to the Euclidean void.

Parity Convention and Dynamical Chirality

Coordinate handedness is a basis convention. It chooses which side of the already-defined plane is called positive $\hat{\mathbf{e}}_3$. A complete-state side marker C can report that choice through

$$V_{\mathrm{vol}} = \mathbf{d}_3 \cdot (\mathbf{d}_1 \times \mathbf{d}_2)$$

with $V_{\mathrm{vol}} > 0$ and $V_{\mathrm{vol}} < 0$ selecting opposite sides of the plane after the orientation convention has been declared. The sign of V_{vol} does not turn coordinate parity into a dynamical handedness law.

Equivalently, $\operatorname{sgn}(V_{\mathrm{vol}})$ is gauge data for the selected coordinate chart, while dynamical chirality must be an invariant of the retained branch record. Coordinate parity lives in $\pi_0(O(3))$ for the chart; dynamical chirality lives in the connected-component data of framed worldline or assembly-branch configuration space. A simulation may align these signs as a reporting convention, but a nonzero V_{vol} does not imply that the assembly itself is chiral.

Dynamical chirality is reserved for an assembly-level handed marker carried by the retained branch record. Ordered precession, axial-frame exposure, reaction provenance, and Noether braid handedness may feed that marker, but the deformation-stable object should be a framed topology invariant, such as a framed self-linking sign

$$Lk(\gamma, \gamma^{\mathrm{fr}}) = \mathrm{Wr}(\gamma) + \mathrm{Tw}(\gamma, \gamma^{\mathrm{fr}})$$

for a closed framed constituent trace, or the linking number of distinct constituent worldlines. If that branch record supplies a nonzero handed marker, a simulation may choose the coordinate parity convention so that $\operatorname{sgn}(V_{\mathrm{vol}})$ reports the same sign as $\operatorname{sgn}(Lk)$. If the framed self-linking or linking row is zero, uncomputed, or not protected under branch-preserving deformation, the coordinate parity remains a reporting convention with no dynamical chirality content.

The self-linking row is defined only on a regular closed return cycle or on an explicitly closed and nonsingular framed trace. A raw open worldline does not by itself carry a deformation-invariant writhe, and a near self-hit or fold crossing is exactly where the framing can degenerate. Chirality is therefore a regular-branch certificate: it is admissible where the retained roots and nonsingular frame have positive floors, including $\kappa_{\mathrm{hit}} > 0$ for the relevant causal-root rows. At a fold, reconnection, or framing slip, Lk can jump; that jump is a branch-transition event, not a change in coordinate convention.

Coordinate Frames Are Not Ontology

The Euclidean void has no preferred origin, no intrinsic axis labels, and no substrate-level marker for clockwise versus counterclockwise. At the ontological level, architrinos move and interact through Euclidean separations, transmitter-tagged causal wakes, and line-of-action hits. Coordinates describe those relations; they do not cause them.

The reconstruction procedure serves theory-building and simulation:

- writing the master equation in component form,
- running numerical simulations,
- communicating results,
- and comparing frames.

The coordinate-invariant content of the laws does not depend on the selected frame. A left-handed coordinate system and a right-handed one produce identical predictions for measurable quantities, differing only in the coordinate signs assigned to pseudovectors and pseudoscalars.

The universe does not require a coordinate frame. Theory and simulation use one because the relevant relationships need a stable component language. Origin, first axis, and plane are enough for distances, derivatives, scalar products, and component equations. Handedness matters only when reporting cross products, pseudovectors, pseudoscalars, or parity-sensitive coordinate quantities.

Complete-State and Physical-Observer Access

This final distinction separates three layers that are easy to confuse. The substrate contains architrinos, causal wakes, absolute time, the Euclidean void, and contents of the Noether sea. Complete-state bookkeeping can infer a coordinate frame from that full record. Physical Observers access only effective records through assembly clocks, rulers, signals, and retained apparatus states.

Complete-state reconstruction:
The $\mathbb{U}_{\text{now}}$ complete-state bookkeeping perspective has access to all architrino positions and can compute wake geometries exactly. The coordinate system is a data structure: an origin offset plus three orthonormal vectors.

Physical Observer access:
Physical Observers cannot directly measure the complete transmitter-tagged wake-center geometry or identify absolute rest by this procedure. Their rulers and clocks are themselves assemblies, distorted by motion and coupling to the Noether sea. They measure:

- **Proper time** τ, not absolute time T
- **Effective coordinates** via local rulers
- **Relative velocities** via Doppler shifts and aberration

The obstruction is structural. No operator acting on the superposed received potential alone recovers the transmitter-tagged center set $\{\mathbf{Z}_a(T_t)\}$ without provenance data already in hand. Transmitter identity, emission time, and wake-center provenance are complete-state ledger entries; once a Physical Observer has only a summed effective record, those tags are not restored by a more clever coordinate reconstruction.

This can be stated as a quotient obstruction. Let $\mathcal{T}$ denote the provenance-tagged configuration record containing transmitter identity, emission time, and wake-center data, and let

$$Q_{\text{erase}} : \mathcal{T} \to \mathcal{T} / \sim_{\text{erase}}$$

be the map that forgets the labels retained only by complete-state bookkeeping. The summed observer record lies in the quotient fiber, not in $\mathcal{T}$ itself. Absolute-frame reconstruction requires a section of Q_{erase} selecting the correct tagged representative. No such section is determined by the superposed potential alone, because many tagged configurations can lie over the same unlabeled record. This is the same kind of label-erasure map that appears in the provenance-leakage bound of Architrino.

The reconstruction described here is a **foundational consistency proof**. It shows that the theory has the mathematical structure necessary to define absolute rest and an absolute-frame coordinate system **in principle** from complete ontic data. It does not claim that an embedded observer can perform the reconstruction directly. At accessible energies, the Lorentz-closure target is that moving-assembly deformation, clock/ruler retuning, and two-way signal synchronization bound preferred-frame leakage enough that Physical Observers cannot detect the absolute frame operationally, while the frame remains the ontological background beneath the effective geometry.

For the effective kinematic layer built on top of this scaffold, see Lorentz Kinematics and Emergent Metric.

Emergence of Structure

Emergence in this chapter means persistent organization formed by architrino dynamics. It does not mean that a second kind of substance or law is added on top. The substrate claim is that architrinos move in absolute time through the Euclidean void and interact through causal wakes. The effective claim is that repeated delayed interactions can settle into assemblies, branch records, and coarse variables useful at observer scales. The inferential claim is narrower still: once a preparation and measure source are declared, unresolved basin selection can be assigned branch weights without treating those weights as ontic randomness.

The chapter is therefore about how order can be real without being primitive. Architrinos supply the persistent inventory and the causal-wake law supplies the motion. Assemblies, stable patterns, and statistical weights appear only after histories are constrained, repeated, and coarse-grained. Nothing mystical is added; the hard part is proving which delayed histories become stable enough to deserve higher-level names.

Conway's Game of Life: A Discrete Touchstone

Conway's Game of Life is useful only as an introductory picture of emergence. It is a zero-player cellular automaton: cells live on a 2D grid, all cells update together at discrete time steps, and each next state depends only on the current states of nearby cells.

From these basic rules, a rich and unpredictable world of patterns appears:

- **Still Lifes:** Stable configurations that do not change over time.
- **Oscillators:** Patterns that repeat themselves over a fixed period.
- **Spaceships (like the Glider):** Patterns that move across the grid.

The lesson that carries over is narrow: simple deterministic rules can generate stable forms, periodic behavior, and moving patterns. The dynamical picture should not be carried over. The Game of Life is grid-based, memoryless, nearest-neighbor, and globally clocked. Architrino dynamics is none of those things.

The useful structural map is topological rather than cellular. A still life is the fixed-point analogue of an equilibrium link, an oscillator is the periodic-orbit analogue of a limit-cycle branch, and a glider is the translation-invariant analogue of a drift bundle in the assembly atlas.

In return-map language, these are three different components of the branch atlas. A still life corresponds to a fixed point with trivial rotation data, an oscillator corresponds to a periodic orbit with rational rotation number on a retained invariant cycle, and, in the discrete-grid case, a glider corresponds to a covering-space lift of such a periodic orbit. In the co-moving quotient the glider closes like an oscillator; in the Euclidean-void frame its lift returns only after a nonzero deck displacement. This is the precise sense in which a drift bundle is a periodic branch in the quotient whose lift carries nonzero displacement per return.

In $\mathbb{AAA}$, architrinos move in continuous space and absolute time. A receiver responds when causal wake surfaces emitted in the past intersect its worldline, so active causal roots are not synchronized by a shared update tick. Each contribution has inverse-square falloff and depends on transmitter and receiver path history. The effective evolution is therefore a nonlinear delay-differential system with formally infinite-range coupling rather than a cellular rule table.

Emergence in the Architrino Universe: Continuous Delay Dynamics

The closer pedagogical analogy is a population of coupled delayed-feedback oscillators, such as delayed Kuramoto-type phase systems, or nonlinear medium flows where phase-lagged feedback can produce synchronization, attractor basins, and persistent coherent structures. These analogies are not substitutes for the master equation. They are guides for the correct mental model. Structure forms through continuous delayed feedback and basin selection, not through grid-based cellular updates.

- **Absolute time and Euclidean void:** Unlike the Game of Life's grid and time steps, architrinos occupy positions in the Euclidean void indexed by absolute time. Their interactions are not clocked updates; they occur whenever an architrino intersects a causal isochron.
- **Delayed causal roots:** The active interaction terms depend on past transmitter positions and, in self-hit regimes, on an architrino's own earlier path. The state needed to evaluate the next motion is therefore path-history dependent rather than Markovian.
- **Infinite-range but convergence-controlled coupling:** Causal wake surfaces are not nearest-neighbor links. Their density falls as $1/r^2$, so distant structure can contribute in principle, but inverse-square dilution alone does not make an infinite three-dimensional source sum convergent. A valid branch must also declare the cancellation, screening, finite active horizon, or summation prescription that makes the retained wake sum well-defined.
- **Emergent assemblies:** Through these continuous delayed interactions, architrinos can self-organize into complex, stable or metastable configurations called **assemblies.** An assembly is not a new primitive; it is an attractor-basin structure of the delay-differential dynamics, comparable in pedagogy to synchronized oscillator clusters, vortices, or soliton-like coherent structures.

The stability of an assembly is therefore dynamic rather than static. It is not a fixed object held in place by definition. It persists because its trajectory remains inside a stable or metastable attractor basin while all dynamically active wakes continue to balance. It can dissolve, branch, or reconfigure when perturbations or self-hit thresholds push it across a basin boundary.

This makes persistence a finite-window dynamical statement. For a declared observation window W and surrounding context c, an assembly branch persists only while its path-history remains in an admitted stable or metastable basin and the retained causal-root, shielding, and provenance rows continue to close. If those rows fail, the branch has reconfigured or dissolved even when a coarse observer label could still be reused.

Context as Constraint on Basin Selection

Higher-level context does not add a rival ontology to the lower-level dynamics. It acts more like a constraint on which histories are available. A surrounding assembly or Noether sea state can select boundary conditions, admissible branch charts, finite memory windows, and effective constraints for the same architrino-level flow. In this section, context means a physical surrounding state that restricts histories, not an independent causal agent. For a regularized chart, fix $\eta > 0$, a memory horizon h, and a record window $W = [0, T]$. Let $\mathcal{H}_{\eta,h}$ be a path-history phase space compatible with the regularized master-equation assumptions, let Φ_t^c

denote the resulting delayed flow under context c, let Π_L expose the lower-level data used by a higher-level description, and let $\Gamma_{\mathrm{adm}}(c)$ collect the branch charts admitted by the surrounding assembly or Noether sea context. The context-restricted history set is then

$$\mathcal{K}_c = \{\, \phi \in \mathcal{H}_{\eta,h} \mid G_\alpha(\Pi_L \phi(0), c) = 0 \text{ for all } \alpha,\ \exists \gamma \in \Gamma_{\mathrm{adm}}(c) : \phi \in \mathcal{H}_\gamma \,\}$$

Here $\mathcal{H}_\gamma$ denotes the path-history domain associated with the branch chart γ.

The native state is $\mathsf{Z} = (\mathbf{X}, \mathbf{V})$. The constrained flow is still the lower-level causal-wake dynamics,

$$\frac{d\mathsf{Z}}{dT} = F_L(\mathsf{Z}_T), \qquad \mathsf{Z}_T \in \mathcal{K}_c$$

where $\mathsf{Z}_T(\theta) = \mathsf{Z}(T + \theta)$ is the path-history segment needed by the delayed equation of motion. The equations $G_\alpha = 0$ encode the surrounding context as constraints on which lower-level histories are available, not as independent causes outside the architrino dynamics.

The load-bearing object is therefore the context-to-chart map $c \mapsto \Gamma_{\mathrm{adm}}(c)$. One may regard the allowed context space $\mathfrak{C}$ as stratified: on an open top stratum, the admitted chart set is locally constant, while codimension-one walls mark contexts where a branch chart opens, closes, or changes regularity. A context change that turns $\mu_c(B_k) = 0$ into $\mu_{c'}(B_k) > 0$ is then a wall-crossing in $\mathfrak{C}$, not a second causal law. This places context changes in the same geometric family as root folds and basin separatrices: the active branch topology changes when a retained chart crosses a declared stratum.

Once the admissible history set is fixed, the same setup gives a compact basin-selection measure after the window and measure source are declared. Let Π_{br} be the branch-record map that reads the realized assembly branch at the end of the window. The context-restricted basin for branch k is

$$B_k^W(c) = \{\phi \in \mathcal{K}_c \mid \Pi_{\mathrm{br}} \Phi_T^c(\phi) = k,\ \Phi_s^c(\phi) \in \mathcal{K}_c \text{ for } 0 \le s \le T\}$$

The measure μ_c must come from a declared preparation, return section, coarse-graining, or unresolved Noether sea occupation rule; it is not an external probability assigned after the outcome. With that rule fixed, the context-conditioned branch weight is

$$P_c(k) = \mu_c(B_k^W(c))$$

This is only the foundation-level basin-measure form. It says how branch weights can be assigned after the physical preparation and measure source are declared. It becomes a quantum-probability recovery only after a measurement chart supplies an apparatus kernel, record map, interference or coherence bookkeeping, and a proof that the same declared measure pushes forward to Born statistics across the relevant measurement contexts. In particular, a Born-rule closure must show that these finite-window basin weights reproduce $|\psi_k|^2$ frequencies without changing the measure between outcome statistics, interference records, and thermodynamic cost. That burden belongs to the quantum recovery chapters, especially Wavefunction Ontology and Quantum Operator Mapping.

For this expression to support stable observer-level inference, the basin partition must be measurable on the declared chart. A useful admissibility target is

$$\mu_c(\partial B_k^W(c)) = 0, \qquad \mu_c\left(\mathcal{K}_c \setminus \bigcup_k B_k^W(c)\right) \leq \varepsilon_{\text{esc}}$$

This clean partition is an admissibility target, not an automatic property of delayed feedback. Basin boundaries in state-dependent delay systems can be fractal, riddled, or measure-thick under the preparation measure; in those cases $\mu_c(\partial B_k^W(c)) = 0$ can fail and the branch weights are not stable observer-level probabilities. A useful separatrix regularity row is therefore the basin analogue of a causal-root transversality floor: on the declared return-section chart, each boundary between neighboring basins should be represented outside a null exceptional set by a signed separator functional $S_{k\ell}$ with

$$S_{k\ell}(\phi) = 0, \qquad \|DS_{k\ell}(\phi)\|_* \geq \kappa_{\text{sep}} > 0$$

If no codimension-one separatrix row, equivalent null-boundary proof, or controlled fractal-boundary measure theorem is supplied, $P_c(k)$ remains a diagnostic basin volume rather than a closed branch-weight law.

Local separator smoothness is not by itself enough in an infinite-dimensional or state-dependent delay system. A valid basin chart should also rule out uncontrolled accumulation of separator sheets on the compact return-section region being measured. One useful formulation is local finiteness: for every compact K in the declared return section,

$$\#\{(k,\ell,n) : \{S_{k\ell}^{(n)} = 0\} \cap K \neq \varnothing\} < \infty$$

after discarding a μ_c-null exceptional set. Here n indexes distinct separator sheets between the same branch pair when the delayed return map creates multiple folds. This condition prevents a countable pile-up of individually smooth sheets from producing a measure-thick or riddled basin boundary. It is the basin analogue of excluding cusp accumulation in a causal-root chart.

Changing c can shift the inferred branch weights $P_c(k)$ by moving basin boundaries, suppressing some causal-root branches, or opening self-hit channels, while the underlying ontology remains the same collection of architrino worldlines and causal wakes.

Context Changes and Energy Ledger

A change in context is not a free semantic relabeling. Something physical must have changed. If a surrounding assembly or Noether sea state changes from c to c', the emergence claim is admissible only when the changed constraints alter the accessible basin support and the change can be accounted for by the same energy and provenance bookkeeping used elsewhere in the theory. The ontology-level rule remains architrino motion plus causal wakes; the effective level records which assembly branches become available.

For a candidate assembly branch B_k^W, a clean opening criterion is

$$\mu_c(B_k^W(c)) = 0, \qquad \mu_{c'}(B_k^W(c')) > 0$$

The reverse inequality pattern records branch closure, and partial changes in $\mu_c(B_k^W(c))$ record ordinary reshaping of basin weights. In each case, the context change must be tied to a physical transition rather than to a new ontology outside the architrino dynamics.

A physical transition should therefore be representable as a replayable event

$$\mathsf{e} = (\mathsf{Z}, I_{\mathsf{e}}, Y_{\mathsf{e}})$$

where Z is the local state and path-history record, I_{e} is the finite selected channel set, and Y_{e} lists outgoing assemblies, radiation or non-photon shedding, recoil targets, Noether sea updates, remnant states, and provenance records. The corresponding energy row is not an independent emergence law. It is a candidate event-ledger closure condition whose wake term must be earned, not presumed.

The row below is a closure template until E_{wake} has been defined constructively for the declared regularized delay system. Its job is to make every branch-opening event pay for itself. Time-translation invariance of a delay equation does not by itself supply a standard Noether energy. The current load-bearing route is the action-boundary or work-integral construction, because it can use the same non-Markovian causal-history rows that generate the acceleration. A local potential reconstruction is a chart-local equivalent only after its crosswalk is stated, and a convergent boundary-flux account is admissible only after the retained branch supplies the needed far-field or exhaustion law, such as the Receiver-Centered Exhaustion Lemma in the homogeneous neutral Noether sea case. The routes must be shown equivalent on the retained window before they can be treated as one conserved energy.

When this route closes, E_{wake} should be read as the Noether charge of the delayed action under absolute-time translation, not as a primitive local energy density placed on one slice. For a memory depth h, the charge is expected to be a functional of the retained history segment

$$\mathsf{Z}_T \in C([-h, 0])$$

with boundary and memory-window terms built from the same causal kernel that supplies the acceleration. In simulation, the object to discretize is therefore a path-history functional over the retained memory window, together with its endpoint and boundary increments, rather than a pointwise Hamiltonian density guessed independently of the delayed action.

$$\Delta_E(\mathsf{e}) = \Delta\left(K_{\text{mech}} + E_{\text{wake}} + E_{\text{sea}}\right)_{\text{retained}} + \sum_{\beta\in Y_{\mathsf{e}}} \Delta E_\beta - W_{\partial\Omega} = 0$$

Here K_{mech} is the μ_{arch}-weighted kinetic bookkeeping term from the Master Equation's regularized energy diagnostic for the retained architrino degrees of freedom, with assembly-level kinetic entries allowed only as derived ledger summaries after their constituent account is declared. The subscript `retained` marks the degrees of freedom kept inside the subsystem account, and $W_{\partial\Omega}$ is boundary work, positive for work done on the retained subsystem. The term E_{sea} records retained Noether sea energy changes.

The no-double-counting rule is explicit: a Noether sea update included in retained E_{sea} must not also appear as an outgoing row in Y_{e}, while a Noether sea change exported outside the retained subsystem belongs in Y_{e} rather than in retained E_{sea}. If a local potential reconstruction is used, it may replace E_{wake} as an equivalent work-integral account on the declared window; it must not be added as a second independent energy store without a crosswalk. Radiation, recoil, reaction products, remnant excitation, and unresolved medium updates must be named inside Y_{e} and closed through Reaction Ledger and Channel Closure rather than hidden inside the phrase "emergence." In plain language, a new higher-level branch becomes available because the physical constraints changed, not because a second law or substance was added on top of the lower-level dynamics.

Assembly Theory and Recursion

Assemblies enter the chapter as recursive dynamical organizations rather than as new primitives. A larger assembly is not an unexplained new object; it is a higher-level pattern built from lower-level branch records that still have to close. The recursive description is useful only when each level preserves closure, shielding, and provenance from the level below.

- **Base case:** The most basic bound-assembly candidate is the **orbiting binary**, formed by an electrino:positrino pair once the two-body branch stability certificate is supplied. This is the first assembly motif from which more complex structures can be built.
- **Recursive step:** More complex assemblies are described in terms of constituent sub-assemblies, indexed shielding support, separated radii and frequencies, and the causal-root ledgers that keep the combined motion closed.

This recursive structure implies that many stable forms can be deconstructed into simpler binary and multi-binary components, provided the branch supplies the required closure, shielding, and provenance records. The decomposition is physical only if the lower-level ledgers still explain the higher-level persistence.

Assembly-index language from origin-of-life work is useful here as an effective reconstruction comparison, not as a new ontological layer. The comparison asks for a short construction path once reusable sub-assemblies are allowed. The native $\mathbb{AAA}$ analogue is stricter: a proposed construction path counts only when the retained reaction history preserves branch identity, energy closure, shielding behavior, and provenance on the declared window. Two reaction histories may end with the same coarse assembly label, but they are not equivalent until the retained ledger shows that the same closure data survives. In this sense, abiotic selection means that an assembly branch is formed and persists under the relevant constraints; it does not import biological reproduction or agency into the substrate ontology.

The phrase "progressively stronger shielding" is a theorem target, not an automatic consequence of adding layers. A captured layer can in principle reduce external reactivity, leave it unchanged, or expose a new resonance. A useful branch target is therefore a shielding monotone on a declared window,

$$\Sigma_{\mathrm{shield}}(A;W)=\frac{\Phi_{\mathrm{int}}^{\mathrm{root}}(A;W)}{\Phi_{\mathrm{ext}}^{\mathrm{root}}(A;W)+\varepsilon_{\mathrm{reg}}}$$

where $\Phi_{\mathrm{int}}^{\mathrm{root}}$ is the retained internal causal-root flux, $\Phi_{\mathrm{ext}}^{\mathrm{root}}$ is the externally exposed root or wake flux, and $\varepsilon_{\mathrm{reg}}>0$ is a root-flux regulator. A candidate geometric estimator for the external flux ordering is the lowest unquenched polarity-signed moment of the assembly's configuration: arrangements whose low-order moments cancel expose less structure at distance, which is the moment hypothesis developed for the six-architrino Accessory Configuration. A capture step $A\to A'$ is shielding-improving only if it decreases external reactivity; an increase in Σ_{shield} is a useful witness under the declared convention when the retained internal-flux account is fixed or separately controlled, and the energy and provenance ledger still closes. If this monotonicity fails, the assembly atlas should treat the result as a side branch or metastable over-reactive intermediate rather than forcing it into the main bottom-up ladder.

Bottom-Up Structural Ladder

The recursive picture is easiest to read as a bottom-up construction ladder. The ladder is a teaching map of claim levels, not a proof that every branch has already been derived. Its discipline is simple: a higher rung cannot be more closed than the weakest rung it depends on. Closure inheritance is strict: no rung may export effective claims with a stronger status than the weakest supporting rung below it. If a fermion, bosonic channel, or composite-matter claim depends on an unclosed binary or Noether braid branch, it inherits that lower branch's target status until the supporting certificate closes.

1. **Ontological background:** status: postulate. Absolute time and the Euclidean void provide the fixed arena.
2. **Primitive transceivers:** status: primitive definition. Individual architrinos are the irreducible transmitters and receivers of causal wake structure.
3. **First bound assembly candidate:** status: branch-certificate target. A stable orbiting electrino:positrino binary is the first bound assembly once its branch stability certificate is supplied.
4. **Noether braid candidates:** status: prescribed-record analytical/conjectural construction target. Three neutral binaries can be arranged in the prescribed A1, A2, A3, and B1 coordinate classes, while Family C carries six neutral binaries in one twelve-worldline coaxial record. Current instruments evaluate declared geometry and analytical measures on prescribed records; they do not evolve or certify an assembly branch. Shielding and persistence must be computed from the complete family-declared record rather than inferred from radius order or family membership.
5. **Noether braid stabilization:** status: closure target. A retained neutral six-architrino branch is the required shielded scaffold; see Noether Braid. Its persistence must be closed through delayed phase return, energy separation, and reduced external reactivity through superposition. Isolated partner-wake diagnostics across three independent charts show the delayed kernel doing net positive work on the assembly, so a persistent braid must supply an exchange or export channel for that pumped action — internal multi-frequency exchange, same-transmitter root transitions, or medium response — rather than merely closing a static acceleration balance; see the A2 return-response question.
6. **Fermions with axial layers:** status: working map and routing target. A retained Noether braid plus a six-site axial layer is the candidate architecture for charged fermions and quark families. Any generation or shielding-tier map must be derived from the retained shielding ledger rather than assigned to a braid family. Pro/anti orientation tracks handedness within the same braid architecture rather than a separate substance type. Neutrino and near-photon branches require their own closure statements. This is the same ladder later used in Particle Masses: Emergent Inertia in the Noether sea.
7. **Collective medium:** status: effective collective-state target. Larger balanced populations of neutral braids organize into the Noether sea, so the Noether sea is a higher-order collective state of neutral braids rather than a second fundamental substrate. Its pro/anti assembly hypotheses are tracked in Noether Sea Pro/Anti Coupling.
8. **Bosonic channels:** status: channel-specific routing targets. Propagating coupled disturbances of assemblies appear as effective bosonic channels, but the channels are not interchangeable. Photons are routed through the coaxial contra-rotating polarity-conjugate planar pair branch, weak carriers through massive corridor maps, and gluonic links through color-sector reconfiguration or ribbon-like coupling targets. These belong to

the interaction/excitation branch of the hierarchy, not to a separate ontological species; see Gauge Structure Emergence.

9. **Composite matter and reactions:** status: effective summary after lower closure. Nucleons, atoms, and larger structures arise from the coupling of already-formed assemblies. A reaction is then a reorganization of conserved constituents inside a structured environment, not creation from nothing.

This ladder matters because it prevents category drift. Fermions, bosonic channels, and observer-level spacetime are not separate ontological species added by hand. They are different organizational levels or effective descriptions of the same underlying architrino dynamics.

Emergence Claim Discipline

When this corpus says that something "emerges," the claim should identify four pieces. These four pieces keep the word from becoming a shortcut for "we have not explained it yet":

1. **Mechanism:** how the effect arises from lower-level dynamics.
2. **Mapping:** which lower-level configurations correspond to the emergent object or quantity.
3. **Regime:** where the emergent description is expected to hold.
4. **Breakdown:** what changes outside that regime.

For example, Lorentz-like behavior is an emergence claim only when the text names the moving-assembly deformation law, the clock-period renormalization law, the Noether sea response mechanism, and the coefficient or theorem target that would suppress preferred-frame leakage. The claim should also state the weak-gradient or low-energy regime where the effective law is expected to hold, and identify the self-hit, separator, or strong-field conditions where the approximation can fail.

This rule makes every emergence claim auditable. The surrounding prose must state whether the mechanism is derived, simulated, conjectural, or only a routing target.

Just as important, the ladder should not be read as a single unbranched stack after the Noether braid appears. Once stable braids exist, three descriptive branches open at once:

- **Matter branch:** Noether braids carrying axial layers yield fermions and then larger composites.
- **Medium branch:** dense balanced populations of neutral braids yield the Noether sea.
- **Interaction branch:** phase-locked disturbances and exchange corridors yield effective bosonic behavior.

This separation of branches helps keep levels distinct. The theory does not place a photon, a fermion axial layer, and the Noether sea on the same explanatory rung. They are different organizations of the same underlying ingredients.

Emergent Measures and Stability Markers

The most useful observer-level quantities enter only after assemblies have formed. They are not primitive objects sitting underneath the dynamics. Their use depends on an effective mapping from persistent assembly behavior to a measured descriptor.

- **Angular momentum:** derivation target. The mechanism is organized binary circulation and ordered orientation data; the mapping is through the return-period phase and angular-momentum ledger; the regime is stable or metastable closed cycles; the breakdown occurs at separator crossings, root-ledger changes, or dissociation.
- **Chirality:** derivation target. The mechanism is ordered-frame precession plus a deformation-stable framed topology row, such as a framed self-linking sign $Lk(\gamma, \gamma^{\mathrm{fr}}) = \mathrm{Wr}(\gamma) + \mathrm{Tw}(\gamma, \gamma^{\mathrm{fr}})$ for a closed framed constituent trace, or linking number among distinct constituent worldlines. The mapping is through the Noether braid closure label and its framed-wake or linking data; the regime is branch-preserving deformation with noncollision and nonsingular frame transport; the breakdown occurs when a causal-root bifurcation, reconnection, collision-floor loss, or frame slip changes the link or framing class.
- **Apparent mass and reactivity:** effective summary with a mass-map closure burden. The mechanism is a closed internal causal-history ledger, shielding, and Noether sea response; the mapping runs through E_{internal}, shielding exposure factor ζ, and the medium-response channel; the regime is stable assemblies in a declared Noether sea context. Dissipative drag is a separate failure channel, not the default mass mechanism.

In this sense, emergence is not merely a catalog of larger objects. It is also the stage at which familiar physical descriptors become well-defined coarse variables for persistent assemblies.

The Dynamics of Structure and Asymmetry

At the substrate level, structure is carried by **dynamical geometry**. Every architrino interacts with the wakes of other architrinos and, in the relevant regimes, with its own past isochrons. This creates an infinite-scale delayed N-body problem, so no single closed-form analytical solution is expected for the evolution of a generic structure.

However, because the potential density on each causal wake surface falls off as $1/r^2$, nearby coherent roots are weighted more strongly than distant roots. This supports effective locality only after the branch also supplies convergence control for the far population. In three spatial dimensions, a homogeneous radial layer contains $O(r^2\,dr)$ possible sources, so inverse-square dilution by itself is not enough to define the infinite many-source sum.

A mathematically admissible many-source branch must satisfy the Receiver-Centered Exhaustion Lemma: it must make a limit such as

$$\lim_{R\to\infty} \sum_{\substack{j,\, T_t\in\mathcal{C}_{ij}(T_r) \\ \|\mathbf{X}_j(T_t)-\mathbf{X}_i(T_r)\|<R}} \mathbf{A}_{ij}(T_r;T_t)$$

exist under the declared receiver-centered summation prescription, or else use the corresponding continuum condition. More invariantly, one may declare an exhaustion $\Lambda_R \uparrow \mathbb{R}^3$ and take the corresponding limit over transmitter events with $\mathbf{X}_j(T_t) \in \Lambda_R$. Acceptable mechanisms include local neutrality, angular cancellation, shielding, a screened kernel, a finite active horizon, or a declared principal-value or mean-field subtraction. Without such a condition, the many-source wake sum is not mathematically well-defined.

For the weak homogeneous Noether sea case, the canonical lemma proves that statistically homogeneous, isotropic, locally neutral, vector-mixing shell contributions have variance $O(n^{-2})$ and hence converge almost surely under the declared mixing bound. This is the convergence foothold consumed by the Noether sea construction; the proof and its hypotheses remain in Receiver-Centered Exhaustion Lemma, and coherent, inhomogeneous, strong-field, or poorly screened branches retain a separate burden.

This convergence discipline is what lets **metastable assemblies** maintain their general form for long periods. Persistence requires the branch to say which wakes matter, which far contributions cancel or screen, and which histories remain in the retained account.

The infinite-history statement is therefore not a claim that every past wake carries equal computational weight. In principle, an architrino receives the delayed wake history that intersects it. In practical assembly dynamics, the active burden is bounded by inverse-square wake dilution, phase cancellation across remote populations, and any shielding or screening demonstrated by retained Noether-braid records. The mathematical task is to identify which causal-root branches remain dynamically active in a regime, not to infer shielding from an A1 label or treat the entire past universe as an undifferentiated influence of equal importance.

Self-hit is not defined by speed alone. It occurs when the same-transmitter causal-root set is nonempty:

$$\mathcal{C}_{ii}(T_r) = \{\, T_t < T_r : \|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| = c_f(T_r - T_t) \,\} \neq \varnothing$$

If $\|\mathbf{V}_i(U)\| \le c_f - \delta_v$ throughout the interval $[T_t, T_r]$ for some speed margin $\delta_v > 0$, then no self-hit root can occur on that interval, because

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| \le \int_{T_t}^{T_r} \|\mathbf{V}_i(U)\|\, dU < c_f(T_r - T_t)$$

Thus reaching or exceeding c_f somewhere along the intervening history is a necessary condition for a simple nontrivial self-hit root, apart from the degenerate straight field-speed tangent case excluded by the simple-root assumptions, but it is not sufficient. Curvature, acceleration, and branch geometry determine whether the worldline actually intersects its own emitted causal wake. The exact onset condition is root existence plus transversality, not the scalar inequality $\|\mathbf{V}\| > c_f$ alone; onset governs root existence, while an admitted self-hit acceleration contribution additionally carries the same-record transmitter-side acceleration weight.

This creates a threshold asymmetry in the system. A small acceleration caused by intersecting a wake can push an architrino into a branch chart where same-transmitter roots become admissible, or where the transversality floor fails and a degenerate causal-root regime must be resolved. The transistor analogy is only pedagogical: a small input changes which channel is available. In $\mathbb{AAA}$, the underlying mechanism is not electronics but delayed causal-root selection.

The common geometric pattern is codimension-one transition. Self-hit onset is a fold in the same-transmitter causal-root set, context opening is a wall-crossing in the admitted-chart map $c \mapsto \Gamma_{\mathrm{adm}}(c)$, and basin branching is a separatrix crossing in the return section. In each case an integer or discrete branch label changes only when the retained chart crosses a singular stratum: an active-root count jumps, an admitted branch appears or disappears, or a basin label changes. Emergence is therefore not merely "larger patterns appear"; it is the formation and reorganization of persistent branches across stratified causal-root and basin geometry.

Provenance within Emergence

A key feature of this model is that emergence does not erase identity. Since architrinos cannot be created or destroyed and each follows a unique path, they retain their individual provenance even when participating in a complex assembly. An assembly is a collective behavior, not a new primitive entity.

This has a practical consequence for reaction language. Reaction, association, dissociation, reconfiguration, and channels historically labeled as decay should be read as provenance-preserving rearrangements of constituents inside a complicated many-body environment. The local reaction region may be difficult to resolve, but the ontology still says that architrino worldlines and causal-wake provenance records are redirected, rebound, screened, or released rather than created ex nihilo.

A $\mathbb{U}_{\mathrm{now}}$ universe-state perspective could, in principle, track the complete and distinct path of every architrino as it associates, dissociates, reconfigures, and continues through time. This is an ontic bookkeeping claim, not a claim that ordinary observers can reconstruct the full provenance ledger.

Dynamics

Master Equation

This chapter answers the first dynamics question: given architrinos moving in absolute time through the Euclidean void, what exactly makes one of them accelerate? The answer is the delayed, receiver-local law used throughout the dynamics branch. It defines what counts as a causal hit, how path history selects the active emission events, and how those hits sum into the acceleration of the receiver.

For the primitive-entity ontology, see Architrino. This chapter begins where ontology becomes motion. A causal wake is not a vague field surrounding a transmitter; it is a delayed contact condition between a past emission event and a receiver event. When that condition closes, the receiver samples a line-of-action contribution whose strength is set by the density of emitted causal surfaces at the receiver event.

The chapter is long because it plays several roles at once: foundational law, theorem spine, analytic benchmark source, and numerical reference. The opening establishes the causal geometry and canonical equation. Later sections develop the delay differential equation form, self-hit structure, analytic regimes, and the energy-symmetry-conservation interface needed by binaries, Noether braids, effective geometry, and quantum closure.

Foundations and Causal Geometry

Purpose and Scope

This document presents the **Master Equation of Motion (EOM)** governing the lawful evolution of all architrinos in the Euclidean void and absolute time. It is the microscopic dynamics input for later closure programs: assemblies, effective continuum descriptions, observer-level geometry, quantum behavior, and gravity must be recovered from this law only after the corresponding assembly, coarse-graining, and validation burdens are met. The chapter keeps c_f explicit in formulas; setting $c_f = 1$ is a nondimensional convention, not a change in the causal law.

Proper time τ does not exist at this layer. The EOM is integrated exclusively over absolute substrate time. For one causal hit, T_t is the transmitter emission time and T_r is the receiver reception time, with $T_t < T_r$. Bare T remains the generic absolute-time parameter only where the discussion is not distinguishing the two events. Clock readouts, time-dilation language, and effective metric comparisons belong only to later observer-inference chapters after the assembly dynamics have supplied a branch-certified period record.

In the many-body indexed formulas below, receiver index i occupies role r and transmitter index j occupies role t on each ordered hit. Thus $\mathbf{X}_i(T_r) = \mathbf{X}_r(T_r)$ and $\mathbf{X}_j(T_t) = \mathbf{X}_t(T_t)$. The role notation prevents the generic indices from hiding which event supplies each position and velocity.

The Master EOM is:

- **Deterministic**: Given complete initial conditions at T_*, the future is determined, with **deterministic multistability** at threshold regimes; determinism is established at finite mollification η under the stated well-posedness hypotheses, and the sharp $\eta \to 0$ limit remains conditional.
- **Non-Markovian**: Depends on full path history, not just instantaneous state.
- **Event-local at the receiver**: Only delayed causal intersections at the receiver event contribute to acceleration (no action-at-a-distance).
- **Causal**: All influences propagate at finite field speed c_f.
- **Self-consistent**: Includes self-interaction (self-hit) when same-transmitter causal roots exist; super-field-speed interval history is proved necessary for simple nontrivial self-hit roots, but is not sufficient by itself.

The level distinction used throughout the chapter is:

Level	What is asserted here	What is not asserted here
Substrate ontology	Architrinos move in absolute time through the Euclidean void and emit causal wakes.	No fundamental spacetime metric, continuum field substance, or observer reconstruction is assumed.
Dynamics	Acceleration is the receiver-local sum over delayed causal-root hits.	A plotted orbit or numerical residual is not a proof unless its branch chart is certified.
Effective description	Potentials, fields, one-forms, metrics, and wave functions may be reconstructed after coarse-graining.	Effective variables are not promoted to substrate ontology by their predictive usefulness.
Inference and observation	A receiver or observer may infer transmitter configurations from hit records and assembly responses.	Inference does not determine the full ontic history unless the missing path-history data are supplied.

Claim-status convention. Postulated names the substrate law itself, while **derived** names a consequence proved from that law on its stated branch domain. **Conditional** holds only under its declared assumptions, while **certified** has passed the declared branch and residual gates, plus any required independence gate, within its stated scope. **Target** names an unproved closure obligation, **diagnostic** names a computable comparison or branch record that cannot establish the underlying dynamics by itself, and **benchmark** names a reference case whose agreement does not promote a general branch claim; these meanings apply chapter-wide, and unlabeled prose does not upgrade any claim.

Overview and Key Principle

The Central Idea

Receiver-local relevance principle:

> The only substrate-level contributions to $\mathbf{A}_r(T_r)$ are causal wake intersections at the receiver event.

At reception time T_r, the acceleration of receiver r at position $\mathbf{X}_r(T_r)$ depends only on causal wake surfaces that intersect that reception site.

- **Substrate event**: $\mathbf{X}_r(T_r)$ coincides with an expanding causal isochron emitted by a transmitter at a past time $T_t < T_r$.
- **Path-history input**: the transmitter path determines which emission times solve the causal constraint.
- **Effective reconstruction**: a potential or field value away from the receiver is useful only after one has declared a continuum or diagnostic representation.
- **Inference layer**: transmitter identity, distance, and emission velocity may be reconstructed from additional records, but they are not directly supplied by a single hit.

This is an **event-local delayed interaction rule**: the acceleration is evaluated at the receiver event, but depends on path history through the delayed causal roots.

In the absence of any causal hits, an architrino follows inertial motion: straight-line, constant-velocity trajectories in the fixed Euclidean background.

Operationally, the expanding causal wake is also the theory's minimal bridge between time and space. Absolute time orders emissions, Euclidean distance sets the propagation delay, and the receiver event is where those two inputs are rejoined into one physical interaction. The wake law is therefore not just an acceleration prescription; it is the mechanism that turns temporal ordering plus spatial separation into concrete dynamics.

Abstract Form

Postulated substrate law. The Master Equation of Motion at abstract level is:

$$\boxed{\frac{d^2\mathbf{X}_r}{dT_r^2} = \sum_{t\neq r} \mathbf{A}_{r\leftarrow t}(\text{causal history}) + \mathbf{A}_{r\leftarrow r}(\text{self-hit})}$$

where:

- $\mathbf{A}_{r\leftarrow t}(\text{causal history})$: sum of all per-hit accelerations from transmitter $t \neq r$ arriving at receiver r at T_r
- $\mathbf{A}_{r\leftarrow r}(\text{self-hit})$: sum of all self-hit acceleration contributions when the same architrino occupies both causal roles

(The per-hit acceleration $\mathbf{A}_{r\leftarrow t}(T_r; T_t)$ is defined below in canonical form. The substrate law is acceleration-first. If a force-like bookkeeping symbol is desired, introduce one universal conversion constant μ_{arch} and define $\mathbf{F}_{r\leftarrow t} \equiv \mu_{\text{arch}}\mathbf{A}_{r\leftarrow t}$.)

Key insight: Both terms have the same functional form: a radial inverse-square law weighted by the transmitter-side density of emitted causal surfaces. They differ only in whether transmitter and receiver are the same persistent architrino. The transmitter-side factor sets both root legality and transmitter-emission density. The receiver-side factor controls how a root is replayed as reception time advances; it does not multiply the instantaneous acceleration.

Path-History Sum and Integral Representation

The Master EOM is most naturally understood as a **path-history branch sum**: all of the physical content resides in the retained paths of the transmitters, and the causal constraint selects the emission events whose wakes reach the receiver event.

In integral form, the same branch-sum law can be written as

$$\frac{d^2\mathbf{X}_r}{dT_r^2} = \sum_t \kappa\, \sigma_{tr}\, |q_t q_r| \int_{-\infty}^{T_r} \mathrm{d}T_t\, \frac{\hat{\mathbf{r}}_t(T_r; T_t)}{r_t^2(T_r; T_t)} \delta\Big(g_{r\leftarrow t}(T_r; T_t)\Big)$$

where

- $\mathbf{r}_t(T_r; T_t) = \mathbf{X}_r(T_r) - \mathbf{X}_t(T_t)$ and $r_t = \|\mathbf{r}_t\|$,
- $\hat{\mathbf{r}}_t = \mathbf{r}_t / r_t$,
- $g_{r\leftarrow t}(T_r; T_t) = r_t(T_r; T_t) - c_f(T_r - T_t)$,
- $\partial_{T_t} g_{r\leftarrow t} = c_f - \hat{\mathbf{r}}_t \cdot \mathbf{V}_t(T_t) = D_t$,
- $\delta(\cdot)$ enforces the causal constraint $g_{r\leftarrow t} = 0$, and
- $\sigma_{tr} = \operatorname{sign}(q_t q_r)$ encodes attraction or repulsion.

The causal delta collapses with the standard transmitter-side root Jacobian, so the transmitter-time part of the integral evaluates to

$$\int_{-\infty}^{T_r} \mathrm{d}T_t\, f(T_t)\, \delta\big(g_{r\leftarrow t}(T_r; T_t)\big) = \sum_{T_t \in \mathcal{C}_{r\leftarrow t}(T_r)} \frac{f(T_t)}{|\partial_{T_t} g_{r\leftarrow t}(T_r; T_t)|}$$

provided the active roots are simple. This transmitter-time collapse supplies the root-selection denominator. The retained branch record must also track how the receiver path crosses the same emitted wake sequence, because that controls root playback as reception time changes. For a simple branch $T_t = T_{t,\ell}(T_r)$, define

$$D_t \equiv c_f - \hat{\mathbf{r}}_t(T_r; T_{t,\ell}) \cdot \mathbf{V}_t(T_{t,\ell}), \qquad D_r \equiv c_f - \hat{\mathbf{r}}_t(T_r; T_{t,\ell}) \cdot \mathbf{V}_r(T_r)$$

and

$$m_{r\leftarrow t} \equiv \frac{D_r}{D_t}, \qquad W^{\text{acc}}_{r\leftarrow t} \equiv \frac{c_f}{|D_t|}.$$

Here $m_{r\leftarrow t} = dT_{t,\ell}/dT_r = D_r/D_t$ is the signed root-playback derivative, while $W^{\text{acc}}_{r\leftarrow t}$ is the dimensionless transmitter-side acceleration weight. Receiver velocity changes root playback and future geometry, but it does not change the strength of a causal surface that has already arrived. Acceleration at the reception event depends on the receiver's current position and the transmitter's retained emission history, with no contribution from noncausal points on that path. The transmitter's present position at T_r is not part of the arriving-hit geometry.

For a certified branch chart, simplicity is recorded as a transversality floor:

$$|\partial_{T_t} g_{r\leftarrow t}(T_r;T_t)| = |c_f - \hat{\mathbf{r}}_t(T_r;T_t)\cdot \mathbf{V}_t(T_t)| \geq \kappa_{\mathrm{hit}} > 0$$

When this floor fails, the active root is caustic-like or degenerate and must be routed to a different branch chart or regularization regime. In special geometries the floor can be computed rather than declared; the principal circular partner branch derives $\kappa^{\mathrm{bin}}_{\mathrm{hit}} = c_f(1+\beta_f \sin(\phi/2)) > c_f$ in Binary Dynamics, where Binary Dynamics uses $\phi/2 = \xi$ for the circular delay angle used below.

Autonomous Emission-Labeled Wake Transport

The regular-domain causal-wake geometry has a self-contained present-time state realization. For each transmitter t and emission time $T_e \leq T$, retain one emitted surface label

$$\mathsf{w}_{t,e}(T) = (t, T_e, \mathbf{C}_{t,e}, R_{t,e}(T), c_f q_t\, dT_e)$$

with emission boundary data

$$\mathbf{C}_{t,e}(T_e) = \mathbf{X}_t(T_e), \qquad R_{t,e}(T_e) = 0$$

and free absolute-time update

$$\frac{d\mathbf{C}_{t,e}}{dT} = \mathbf{0}, \qquad \frac{dR_{t,e}}{dT} = c_f, \qquad \frac{d(c_f q_t\, dT_e)}{dT} = 0.$$

The center is the transmitter site at emission and remains fixed in the Euclidean void. The surface radius grows at the primitive wake speed. After emission, this kinematic state reads neither the later transmitter path nor any future receiver path.

Plain language: each instant of emission creates a labeled expanding sphere. Its center is frozen at the place where the emission occurred, while its radius grows by c_f times its age. Later transmitter motion does not drag an already emitted sphere through the void.

The surface measure is conserved during free propagation. With the conventional static-transmitter normalization absorbed into the emission measure, its uniform area density is

$$\varrho^{\mathrm{surf}}_{t,e}(T) = \frac{c_f q_t\, dT_e}{4\pi R^2_{t,e}(T)}.$$

The inverse-square factor is therefore the dilution of one fixed emitted measure over the expanding spherical area. For a finite retained spatial window, the kinematic boundary update exports the labeled surface portion when it crosses the window boundary; it is not silently deleted. This geometric export is not yet an energy or momentum flux.

Plain language: the sphere carries a fixed amount of signed emission measure. As its area grows, the same measure is spread more thinly, producing the inverse-square strength. A local simulation may hand an outgoing piece to its boundary record, but this alone says nothing about how much energy or momentum that piece carries.

For a direction $\boldsymbol{\omega} \in S^2$, a point on the emitted surface is

$$\mathbf{Y}_{t,e}(T,\boldsymbol{\omega}) = \mathbf{C}_{t,e} + c_f(T-T_e)\boldsymbol{\omega}.$$

Consequently every surface element has absolute speed c_f, and a receiver at $\mathbf{X}_r(T_r)$ intersects the surface only when

$$\|\mathbf{X}_r(T_r) - \mathbf{C}_{t,e}\| = c_f(T_r - T_e).$$

At a noncoincident intersection, the outward surface normal is

$$\boldsymbol{\omega}_{\mathsf{h}} = \frac{\mathbf{X}_r(T_r) - \mathbf{X}_t(T_e)}{\|\mathbf{X}_r(T_r) - \mathbf{X}_t(T_e)\|} = \hat{\mathbf{r}}_t.$$

Plain language: the acceleration direction is not an additional choice. It is the local normal of the actual wake sphere where that sphere meets the receiver, so it points from the emission site to the receiver.

The transparent regular-domain reception rule leaves the kinematic wake surface unchanged and adds the receiver-local acceleration contribution

$$\mathbf{A}_r(T_r) = \sum_t \kappa \sigma_{tr} |q_t q_r| c_f \int_{-\infty}^{T_r} \frac{\hat{\mathbf{r}}_t}{r_t^2} \delta(r_t - c_f(T_r - T_e))\, dT_e.$$

At fixed T_r, differentiating the support function with respect to T_e gives

$$\frac{\partial}{\partial T_e} [r_t - c_f(T_r - T_e)] = c_f - \mathbf{V}_t(T_e) \cdot \hat{\mathbf{r}}_t = D_t.$$

The coarea collapse therefore yields

$$c_f \int dT_e\, f(T_e)\, \delta(r_t - c_f(T_r - T_e)) = \sum_{T_e \in \mathcal{C}_{r \leftarrow t}(T_r)} \frac{c_f\, f(T_e)}{|D_t|}.$$

Plain language: constant emission time is pushed through the moving transmitter's sequence of sphere centers. Where successive spheres bunch together, the receiver encounters a larger surface density. That geometric conversion produces the canonical acceleration weight $c_f/|D_t|$; receiver velocity is unnecessary because reception time was held fixed during the collapse.

This state also adjudicates the inertially extrapolated direction under the current ontology. A direction-only replacement aimed at

$$\mathbf{X}_t(T_e) + \mathbf{V}_t(T_e)(T_r - T_e)$$

is not normal to the emitted surface above. Moving the surface center to that extrapolated point would instead give surface-element velocity

$$\mathbf{V}_t(T_e) + c_f \boldsymbol{\omega},$$

whose magnitude is not generally c_f. It would define a different propagation law and a different causal support. For a smoothly accelerated transmitter, fixed-reception collapse of that moving-center family has denominator

$$c_f - (T_r - T_e)\mathbf{A}_t(T_e) \cdot \hat{\mathbf{r}}_{\text{ext}},$$

not the canonical transmitter-velocity denominator.

Plain language: the alternative has only two coherent interpretations, and both leave the current wake ontology. If only the arrow changes, it no longer follows the wake surface normal. If the sphere itself moves with the extrapolated center, its points no longer propagate at the fixed absolute speed c_f, and its arrival weight changes as well.

Claim grade: **derived regular-domain state reduction** from fixed-speed causal-surface propagation, constant emission measure, and receiver-local surface-normal response. The executable reference is `scripts/equation-mapping/derive-causal-wake-update-law.mjs`; it checks center autonomy, the surface normal by an independent spatial finite difference, the source-time weight by direct mollified quadrature, and the absolute-speed failure of inertially transported centers. A fixed-speed independently evolving wake whose local normal is the extrapolated direction would refute the directional conclusion. Failure of the quadrature to converge to $c_f/|D_t|$ on a certified simple root would refute the weight reduction.

This result closes only the regular kinematic substate and its line-of-action decision. Transparent reception does not supply the missing maturity, wake energy, wake momentum, or reception-transfer accounts needed for a finite coincident same-transmitter birth and simultaneous energy, momentum, and angular-momentum closure. Those obligations remain fail closed; the present derivation must not be cited as an account-complete Master Equation closure.

Caustic Transit and Finite Impulse

The branch expression with W_{ij}^{acc} should not be interpreted as a permission to pin an architrino at an infinite pointwise acceleration. At a simple delay-map caustic, the branch chart fails, but the time-integrated velocity change can remain finite.

Let T_t denote the transmitter emission-time variable near a degenerate root $(T_{r,*}, T_{t,*})$, and assume the local delay map has the nondegenerate fold form

$$g(T_r, T_t) = \alpha(T_t - T_{t,*})^2 + \lambda(T_r - T_{r,*}) + O\big(|T_t - T_{t,*}|^3 + |T_r - T_{r,*}|\,|T_t - T_{t,*}| + |T_r - T_{r,*}|^2\big)$$

with $\alpha > 0$, $\lambda > 0$, and $r_{ij} \geq r_{\min} > 0$ on the local support. For $T_r < T_{r,*}$ the two simple roots satisfy

$$T_{t,\pm}(T_r) = T_{t,*} \pm \sqrt{\frac{\lambda}{\alpha}(T_{r,*} - T_r)} + O(T_{r,*} - T_r)$$

and the Jacobian factor scales as

$$|\partial_{T_t} g(T_r, T_{t,\pm}(T_r))| = 2\sqrt{\alpha\lambda}\sqrt{T_{r,*} - T_r} + O(T_{r,*} - T_r)$$

Thus each branch contribution has at worst the local bound

$$\|\mathbf{A}_{ij,\pm}(T_r)\| \leq \frac{C}{\sqrt{T_{r,*} - T_r}}$$

where C absorbs the bounded numerator, $r_{\min}^{-2}$, polarity factor, and coupling. The mechanical impulse through the caustic window is finite:

$$\int_{T_{r,*}-\varepsilon}^{T_{r,*}} \|\mathbf{A}_{ij,+}(T_r) + \mathbf{A}_{ij,-}(T_r)\|\, dT_r \leq 4C\sqrt{\varepsilon}$$

The same conclusion holds for a finite-order algebraic caustic $g \sim (T_t - T_{t,*})^m - \lambda(T_r - T_{r,*})$ with finite $m > 1$: the transmitter-side weight scales like $|T_r - T_{r,*}|^{-(m-1)/m}$, whose exponent remains below one, so the branch strength is locally integrable in reception time when separation stays positive. A persistent interval with $D_t = 0$, a cusp with no finite-order normal form, or a simultaneous collision-floor failure is not covered by this impulse lemma and must remain in the regularized chart. The regularized prescription is therefore to integrate the acceleration through a certified ordinary caustic transit and retain the finite $\Delta\mathbf{V}$; the state is not held exactly on $D_t = 0$ as an infinite-acceleration constraint.

The singular set should be routed by stratum, not by the single phrase “small denominator.” Let

$$\Sigma_{ij} = \{(T_r, T_t, \lambda) : g(T_r, T_t; \lambda) = 0,\ \partial_{T_t} g(T_r, T_t; \lambda) = 0\}$$

inside a declared one- or multi-parameter branch family. The finite-impulse lemma covers the fold stratum Σ^1, where $\partial_{T_t T_t} g \neq 0$ and the control parameter crosses the fold transversely. Cusp and higher strata, such as $\Sigma^{1,1}$, require extra degeneracy conditions and are not ordinary acceleration contributions. They may merge or split more than one opposite-sign root pair at once, so their ledger transition is not certified by the generic $\Delta N = \pm 2,\ \Delta D = 0$ fold law until a separate regularized normal form is supplied. Thus Σ^1 routes to finite impulse plus transition metadata, while $\Sigma^{1,1}$ or deeper routes to a singular-stratum chart before promotion.

The word “set” in $\mathcal{C}_{ij}(T_r)$ should therefore be read as a root set extracted from a continuous path-history integral, not as a replacement for that history. The transmitter path is continuous data. In the sharp causal-wake limit the delta constraint collapses the received contribution to the emission times in $\mathcal{C}_{ij}(T_r)$; with $\eta > 0$ mollification, the received contribution comes from finite-width neighborhoods of those roots. A single transmitter can contribute more than one root at the same receiver event when its worldline crosses the receiver's backward causal surface more than once, especially in curved or super-field-speed history. The same bookkeeping applies to nontrivial self-history roots when $j = i$.

Writing

$$D_{t,ij}(T_r;T_t) \equiv c_f - \hat{\mathbf{r}}_{ij}(T_r;T_t)\cdot \mathbf{V}_j(T_t), \qquad D_{r,ij}(T_r;T_t) \equiv c_f - \hat{\mathbf{r}}_{ij}(T_r;T_t)\cdot \mathbf{V}_i(T_r)$$

and

$$J^t_{ij}(T_r;T_t) \equiv \frac{D_{t,ij}(T_r;T_t)}{c_f}, \qquad W^{\mathrm{acc}}_{ij}(T_r;T_t) \equiv \frac{c_f}{|D_{t,ij}(T_r;T_t)|},$$

one obtains the exact branch-resolved form

$$\frac{d^2\mathbf{X}_i}{dT_r^2} = \sum_j \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2(T_r;T_t)} W^{\mathrm{acc}}_{ij}(T_r;T_t)\hat{\mathbf{r}}_{ij}(T_r;T_t)$$

Since $\partial_{T_t} g_{ij}(T_r;T_t) = D_{t,ij}(T_r;T_t) = c_f J^t_{ij}(T_r;T_t)$, the transmitter-time collapse supplies the transmitter-side weight. The numerator c_f fixes the static-transmitter normalization and may instead be absorbed into κ if that convention is stated consistently. Receiver motion remains in the root-playback derivative D_r/D_t, but not in the instantaneous acceleration weight.

Numerical implementations discretize this representation by sampling candidate emission times and solving for the active roots. The familiar "sum over spherical wake surfaces" is therefore a numerical realization of the same branch-selection rule, not a separate physical mechanism.

Simple-root transport lemma. Let

$$F_{ij}(T_r,S) = \|\mathbf{X}_i(T_r) - \mathbf{X}_j(S)\| - c_f(T_r - S)$$

Here S is a local placeholder for the branch's emission-time root as reception time varies; it is not a third physical time coordinate. On the physical branch, $S(T_r) = T_t$. Suppose $F_{ij}(T_r, S(T_r)) = 0$ on an interval where the active root is simple. Then $S(T_r)$ is differentiable and

$$\frac{dS}{dT_r} = \frac{c_f - \hat{\mathbf{r}}_{ij}(T_r;S)\cdot\mathbf{V}_i(T_r)}{c_f - \hat{\mathbf{r}}_{ij}(T_r;S)\cdot\mathbf{V}_j(S)} = \frac{1-\hat{\mathbf{r}}_{ij}\cdot\mathbf{V}_i/c_f}{J^t_{ij}(T_r;S)}$$

Thus a simple causal root moves continuously with receiver time as long as the denominator stays away from zero. Simulations should track this root-transport residual alongside the root residual and the J floor; failure of the transport equation is a branch-chart failure, not an ordinary acceleration fluctuation.

Transmitter-Side Roots, Acceleration Weight, and Action Residual

For a retained causal-root record (i, j, T_r, T_t), keep the transmitter-side root floor, transmitter-side acceleration weight, signed root playback, and action residual as separate equations.

Transmitter-side root floor. The transmitter, meaning the emitting architrino on this causal hit, enters the root-selection denominator through the delay-map Jacobian

$$J^t_{ij}(T_r;T_t) = 1 - \frac{\hat{\mathbf{r}}_{ij}(T_r;T_t)\cdot\mathbf{V}_j(T_t)}{c_f}, \qquad D_{t,ij}(T_r;T_t) = c_f J^t_{ij}(T_r;T_t).$$

Only the transmitter velocity projection along $\hat{\mathbf{r}}_{ij}$ appears in this transversality floor. Tangential transmitter motion still matters through the transmitter path, active root set, separation vector, and inactive-root gaps, but it is not a second instantaneous multiplier.

Signed root playback. The receiver velocity controls how the same causal root moves as reception time advances:

$$\frac{dT_{t,\ell}}{dT_r} = \frac{1 - \hat{\mathbf{r}}_{ij}(T_r;T_{t,\ell}) \cdot \mathbf{V}_i(T_r)/c_f}{1 - \hat{\mathbf{r}}_{ij}(T_r;T_{t,\ell}) \cdot \mathbf{V}_j(T_{t,\ell})/c_f}.$$

This ratio is a transport quantity, not an acceleration multiplier. The acceleration weight is

$$W^{\mathrm{acc}}_{ij}(T_r;T_{t,\ell}) = \frac{c_f}{|c_f - \hat{\mathbf{r}}_{ij}(T_r;T_{t,\ell}) \cdot \mathbf{V}_j(T_{t,\ell})|}.$$

A chart that changes only receiver velocity at a fixed reception event does not change this arriving contribution. It changes root playback, later receiver positions, and therefore future causal records.

Action residual. The variational-action question adds an independent proof burden. On a regularized action chart,

$$\mu_{\mathrm{arch}}\mathbf{A}_i(T) = \sum_j \kappa\, \sigma_{ij}|q_i q_j| \left(\mathbf{F}^{(\eta)}_{ij,\mathrm{scale}}(T) + \mathbf{C}^{(\eta)}_{ij}(T)\right),$$

and the scale-only action scaffold derives the canonical branch law only when

$$\lim_{\eta\to 0^+} \int_W \left\| \sum_j \kappa\, \sigma_{ij}|q_i q_j| \mathbf{C}^{(\eta)}_{ij}(T) \right\| dT = 0$$

with the same branch floors and boundary convention used by the branch chart. If this residual is retained rather than cancelled, it must close as a wake-history term in the same energy, momentum, and angular-momentum account. This residual condition does not alter the transmitter-side law. It is the test for promoting the action scaffold in Exact Nonlocal Lagrangian after the same transmitter-side floors, acceleration weights, signed root-playback records, and boundary convention have been declared.

Branch-Chart Closure Object

A local master-equation closure claim should be attached to an explicit branch-chart object, not just to a plotted orbit or a small acceleration residual. For a branch chart on a section $\mathcal{S}$, define

$$\mathfrak{B}(\Gamma,\mathcal{S};h,\eta,\epsilon_c) = \left(\mathcal{R}^{\mathrm{act}}, \mathcal{G}^{\mathrm{inact}}, \nu_J, \nu_{\mathrm{rec}}, h_{\mathrm{mem}}, \mathcal{R}_{\mathrm{return}}, \lambda_{\mathrm{sec}}\right)$$

Here $\mathcal{R}^{\mathrm{act}}$ is the active causal-root set retained by the chart, $\mathcal{G}^{\mathrm{inact}}$ is the collection of inactive branch-gap functions, ν_J is the active-root transmitter-side Jacobian floor, ν_{rec} is the retained transmitter-side acceleration-weight floor or certified bounded interval for W^{acc}_{ij}, h_{mem} is the required memory depth, $\mathcal{R}_{\mathrm{return}}$ is the return residual on the section, and λ_{sec} is the transverse section-stability margin.

The object is acceptable only when

$$\nu_J > 0, \qquad 0 < \nu_{\mathrm{rec}} < \infty, \qquad \inf_{\mathcal{G}^{\mathrm{inact}}} g^{ij}_a > 0, \qquad 0 < h_{\mathrm{mem}} < h < \infty, \qquad \|\mathcal{R}_{\mathrm{return}}\| \le \epsilon_{\mathrm{return}}$$

and the section return is stable, for example

$$\rho(M_{\mathcal{S}}|_{E_\perp}) \le 1 - \lambda_{\mathrm{sec}}, \qquad \lambda_{\mathrm{sec}} > 0$$

The inactive-gap condition means that nearby discarded causal roots remain separated from the active chart; the stability condition means that a small transverse section error is trapped rather than amplified.

Plain language: a branch chart is the replayable local record that says which causal roots are active, which nearby roots stay inactive, how much history is needed, and whether the returned section remains stable under small errors.

Equivalently, $\mathfrak{B}(\Gamma,\mathcal{S};h,\eta,\epsilon_c)$ is the local trivialization data for the causal-root sheaf near the retained history. Promotion requires more than naming the active roots: the map from retained history and section coordinates to active roots, receiver-side branch acceleration contributions, and wake-history increment records must be locally invertible onto the declared chart image, with inverse conditioning controlled by ν_J, ν_{rec}, the inactive gaps, the finite memory margin, and λ_{sec}. A plotted orbit with no controlled inverse is a trace, not a branch chart.

Local promotion lemma. If a candidate history supplies $\mathfrak{B}(\Gamma, \mathcal{S}; h, \eta, \epsilon_c)$ with positive active-root floors, positive inactive gaps, finite memory, bounded return residual, and stable section monodromy, then the history may support a local master-equation closure claim on that section. The lemma does not prove global closure, eliminate all folds, control the $\eta \to 0$ limit, or certify unrelated histories. It only promotes the branch chart from a numerical trace to a locally replayable causal-root closure record.

State-Dependent Delay Compatibility

A branch-chart closure object must also be compatible with the delayed history space that generates the active roots. Fix a retained history tube

$$\mathcal{U}_{\mathfrak{B}} \subset C^1\big([-h, 0], (\mathbb{R}^3)^N\big)$$

around the returned history segment. For each active branch record ℓ, write its emission offset as $\theta_\ell(\phi) \in [-h, 0)$ for a history $\phi \in \mathcal{U}_{\mathfrak{B}}$, and define

$$F_\ell(\phi, \theta) = \|\phi_i(0) - \phi_j(\theta)\| - c_f(0 - \theta)$$

The branch chart is history-compatible on $\mathcal{U}_{\mathfrak{B}}$ only if

$$F_\ell(\phi, \theta_\ell(\phi)) = 0, \qquad |\partial_\theta F_\ell(\phi, \theta_\ell(\phi))| \geq c_f \nu_J > 0$$

and if every inactive complement remains separated by the declared positive gap. Under these conditions the implicit-function theorem gives C^1 dependence of θ_ℓ on the retained history, so the branch acceleration, root-transport residual, transmitter-side acceleration-weight record, and wake-history Noether increments are functionals on one local history chart rather than pointwise records that only happen to close at one evaluation time. This is the reconstruction-regularity content of the branch chart: the root reconstruction has an inverse bound controlled by the transversality floor, schematically $\|D\theta_\ell\| \lesssim (c_f \nu_J)^{-1}$ times the history-evaluation norm, until a fold or chart boundary is reached.

This compatibility condition is a theorem-target requirement, not a new acceleration law. It says that a promoted branch chart must define a locally replayable delayed functional system: nearby retained histories must keep the same root identities, positive transmitter-side Jacobian floor, bounded transmitter-side acceleration-weight record, inactive gaps, and finite memory depth until a declared fold, branch transition, or chart boundary is reached.

Local-To-Global Branch-Chart Gluing Target

The branch-chart object above also defines a candidate causal-root sheaf for global closure. For an open history or parameter neighborhood U, let

$$\mathcal{F}_{\mathrm{root}}(U) = \{\text{admissible branch charts on } U \text{ with the declared regularization data}\}$$

and restrict a chart from U to $V \subset U$ by restricting its active-root records, inactive gaps, memory tube, and endpoint convention. The implicit-function theorem supplies the local restriction maps while the root identities remain simple.

Global closure is the additional statement that local sections of $\mathcal{F}_{\mathrm{root}}$ glue. On an overlap $U_\alpha \cap U_\beta$, two local charts must agree not merely on the plotted trajectory but on the signed causal-root ledger, branch labels, endpoint convention, wake-history charges, and transition metadata. The global branch charts are the H^0 sections of this sheaf over the declared history window. A mismatch on triple overlaps defines a Cech-style obstruction class in $\check{H}^1(\{U_\alpha\}; \mathcal{F}_{\mathrm{root}})$: locally replayable charts may exist while no single global branch chart exists. This is a theorem target, not a new postulate. It gives proof programs an explicit failure mode between “local residuals are small” and “the Master Equation branch is globally closed.”

Dual-Mollified Absolute-Time Evolution Law

For proof work, branch sums should be derived from one regularized absolute-time law rather than treated as the primary definition through every causal fold. Fix a memory horizon

$$h > 0$$

a causal-wake-surface width

$$\eta > 0$$

and a short-distance core scale

$$\epsilon_c > 0$$

Define

$$\mathbf{r}_{ij}(T_r, T_t) \equiv \mathbf{X}_i(T_r) - \mathbf{X}_j(T_t), \qquad r_{ij}(T_r, T_t) \equiv \|\mathbf{r}_{ij}(T_r, T_t)\|$$

and, away from the zero vector,

$$\hat{\mathbf{r}}_{ij}(T_r, T_t) \equiv \frac{\mathbf{r}_{ij}(T_r, T_t)}{r_{ij}(T_r, T_t)}$$

The dual-mollified finite-memory evolution law is

$$\boxed{\frac{d^2\mathbf{X}_i}{dT_r^2} = \kappa \sum_j \sigma_{ij} |q_i q_j| \int_{T_r - h}^{T_r} \frac{\mathbf{r}_{ij}(T_r, T_t)}{\left(r_{ij}^2(T_r, T_t) + \epsilon_c^2\right)^{3/2}} c_f \delta_\eta\big(r_{ij}(T_r, T_t) - c_f(T_r - T_t)\big)\, dT_t}$$

At $\mathbf{r}_{ij} = \mathbf{0}$, the softened vector kernel multiplying
δ_η is defined by its continuous extension, which is $\mathbf{0}$.

The sign convention remains

$$\sigma_{ij} = \operatorname{sign}(q_i q_j)$$

This is the convention used in the exact branch law. For equal-magnitude charges

$$|q_i| = \epsilon$$

the factor

$$|q_i q_j|$$

reduces to

$$\epsilon^2$$

This equation is the reference law for certification work on the dual-mollified problem. The causal-surface mollifier

$$\delta_\eta$$

selects causal surfaces with finite width, while

$$\epsilon_c$$

smoothly regularizes the near-collision inverse-square amplitude. The factor
c_f supplies the static-transmitter normalization. On a finite simple-root

chart, collapse of the causal-surface delta function gives

$$\int \frac{\mathbf{r}_{ij}}{\left(r_{ij}^2+\epsilon_c^2\right)^{3/2}} c_f\, \delta(g_{ij})\, dT_t = \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \frac{\mathbf{r}_{ij}}{\left(r_{ij}^2+\epsilon_c^2\right)^{3/2}} \frac{c_f}{|D_{t,ij}|}$$

Thus the $\epsilon_c \to 0^+$ limit away from coordinate coincidence recovers the canonical inverse-square transmitter-side branch law. Branch-resolved formulas are local reductions of this equation on finite simple-root charts. They should not be used as the global definition across causal folds, caustic transit, or chart-boundary verification.

The two regulators quarantine different singular loci. The width η regularizes the causal-surface collapse, branch folds, and caustic-transit impulse; the core scale ϵ_c regularizes the coincidence or diagonal collision locus. A theorem packet may refine them together for computation, but a sharp-limit claim must state which of $\eta \to 0^+$ and $\epsilon_c \to 0^+$ is being taken, and why the other singular locus remains controlled during that limit.

Coordinate coincidence is also a provenance question, not an annihilation rule. Two architrinos may share $\mathbf{X}_i(T) = \mathbf{X}_j(T)$ on one absolute-time slice only as a boundary case of the retained history record; the next admissible update is determined by their identities, polarities, velocities, past causal-wake ledgers, and the same η, ϵ_c convention. If two like-polarity records agree through the retained memory window up to label permutation, the deterministic law is quotient-degenerate: relabeling the records changes no acceleration contribution until a provenance-visible history distinguishes them. If the polarities, velocities, or retained path histories differ, later incoming causal wakes can separate the records even though their current coordinates coincided. Thus the $r = 0$ stratum is not a contact interaction or annihilation channel. It is a regularized or quarantined branch condition whose continuation must preserve provenance.

Finite-Regulator Pathology Quarantine Theorem Target

The classical point-transceiver pathologies are not closed by the sharp branch formula alone. The theorem target is finite-η, branch-chart local, and conditional on one regularized action and energy convention. Fix a finite architrino set, a finite window $W = [T_a, T_b]$, a memory depth $h < \infty$, a causal-surface width $\eta > 0$, a core scale $\epsilon_c > 0$, and a branch chart

$$\mathfrak{B}(\Gamma, \mathcal{S}; h, \eta, \epsilon_c)$$

whose retained records are generated by the dual-mollified evolution law above.

The admissibility assumptions are:

1. The evolution is causal in absolute time: every acceleration contribution is generated from $T_t < T_r$, and the self-coincident endpoint is excluded by the $H(0) = 0$ convention or by the declared core regularization.
2. The retained chart has finite memory, positive inactive-root gaps, a declared transmitter-side acceleration-weight interval, and either a positive active-root transmitter-side Jacobian floor $\nu_J > 0$ or an explicitly declared finite-order caustic transit integrated in the dual-mollified law.
3. The active support stays away from an unregularized collision: either $r_{ij,\ell} \geq d > 0$ on the retained records or the same ϵ_c cutoff is used in the acceleration, action, and energy records.
4. The regularized right-hand side is locally Lipschitz on the retained history tube, so the finite-η state-dependent delay problem has existence, uniqueness, and continuation until a declared boundary of the admissible class is reached.
5. The same regularized action or compatible realized-trajectory reconstruction supplies the acceleration contribution, wake-history energy, momentum, and angular-momentum records. Endpoint leakage, omitted branch records, and period-cut terms must appear as residuals rather than hidden corrections.

Under these assumptions, the finite-η theorem packet should prove the following local conclusions.

- **Divergent self-energy is quarantined.** There is no accepted instantaneous self-kick, no unregularized $r = 0$ self-root inside the chart, and every retained self-hit contribution is bounded by the declared d, ϵ_c, η, ν_J, and transmitter-side acceleration-weight data. Any remaining divergence is therefore a failure of the branch floor, core convention, memory window, or $\eta \to 0^+$ convergence claim, not an accepted finite-η state. A coincident same-transmitter root birth is not an accepted transition under this theorem target.

- **Runaway solution branches are quarantined.** If the same action-level bookkeeping gives

$$E_{\text{tot}}^{(\eta)}(T) = K_\mu(T) + E_{\text{wake}}^{(\eta)}(T), \qquad E_{\text{wake}}^{(\eta)}(T) \geq U_{\min}^{(\eta)} > -\infty,$$

then $K_\mu(T)$ remains bounded on W. A branch with $V_{\max} \to \infty$ must therefore leave the admissible class by driving the interaction charge downward without bound, losing a floor, or breaking the declared action-energy residual.

- **Pre-acceleration is excluded at finite η.** The acceleration at T is a functional of the retained history segment $[T - h, T)$, together with the current receiver event, and contains no future state. A proposed action repair is admissible only when its endpoint convention contributes a wake-history boundary term or a vanishing residual, not a future-boundary acceleration selection rule.
- **Caustic and Jacobian blow-up are quarantined.** Simple-root charts require $\nu_J > 0$. A finite-order caustic may be crossed only through the dual-mollified equation with finite integrated impulse and stable transition metadata. Persistent $J = 0$, cusp behavior outside a finite-order normal form, simultaneous collision-floor failure, or regulator-dependent transition observables are chart failures rather than ordinary acceleration contributions.
- **Finite deterministic multistability is routed, not quarantined.** At a fold boundary, if the regularized post-transit data supply exactly one admissible continuation chart, the event is an ordinary branch transition. If they supply two or more inequivalent admissible charts with positive floors and finite memory, the complete microstate still selects one deterministic continuation, but a record-limited comparison must route the event to a finite basin-weight or multistability record. Multistability is a failure only when the finite continuation family is empty, infinite, unlabeled, or lacks the common branch data needed for comparison.

The failure boundary for the theorem packet is the union of the following conditions:

$$\partial\mathcal{A}_\eta = \{\nu_J = 0\} \cup \{r_{ij,\ell} = d\} \cup \{\inf \mathcal{G}^{\text{inact}} = 0\} \cup \{h_{\text{mem}} \geq h\} \cup \{E_{\text{wake}}^{(\eta)} \downarrow -\infty\} \cup \{\text{non-vanishing action or boundary residual}\}$$

The first component is refined as

$$\{\nu_J = 0\} = \Sigma_{\text{transit}} \sqcup \Sigma_{\text{bif}}^{\text{multi}} \sqcup \Sigma_{\text{sing}}^{\text{fail}}$$

where Σ_{transit} has a unique finite post-transit chart, $\Sigma_{\text{bif}}^{\text{multi}}$ has a finite labeled family of admissible continuations, and $\Sigma_{\text{sing}}^{\text{fail}}$ lacks a promoted finite chart. A trajectory crossing this boundary is not promoted as a closed Master Equation solution until the appropriate route is certified. It is routed to branch transition, finite multistability, caustic transit, core-regularization repair, finite-window leakage, or η-ladder failure according to which boundary component is reached.

The validation residuals consumed by this theorem target are the root residual, root-transport residual, active transmitter-side Jacobian floor, transmitter-side acceleration-weight interval, inactive-gap residual, finite-memory residual, return residual, finite-window energy residual $\mathcal{R}_E$, momentum residual $\mathcal{R}_P$, angular-momentum residual $\mathcal{R}_J$, Euler residual of the same action, endpoint or period-cut leakage, transition-observable residuals across η refinement, and the symplectic residual $\mathcal{R}_\Omega$ when the branch is promoted to a reduced Hamiltonian chart. The theorem is finite-η only; any zero-width or infinite-system statement requires the separate convergence boundary stated in the regularization package.

Regularized Action-Energy Diagnostic

For computation with finite causal-wake-surface width $\eta > 0$, an energy diagnostic must use the same time-normalized scalar kernel as the nonlocal action. When one wants a quadratic kinetic bookkeeping proxy, use a single universal conversion constant μ_{arch} rather than particle-specific substrate masses:

$$E_{\text{tot}}^{(\eta)}(T_r) = \sum_i \frac{1}{2}\mu_{\text{arch}} \left\|\mathbf{V}_i(T_r)\right\|^2 + E_{\text{wake}}^{(\eta)}(T_r)$$

with

$$E_{\text{wake}}^{(\eta)}(T_r) = \frac{1}{2}\sum_{i,j} \mu_{\text{arch}}\kappa\,\sigma_{ij}\,|q_i q_j| \int_{T_r-h}^{T_r} dT_t\, \frac{\delta_\eta\big(\tilde{g}_{ij}(T_r,T_t)\big)}{r_{ij}(T_r;T_t)}.$$

Here h bounds the retained causal memory. On a simple sharp root, integrating the delta function produces the transmitter-side factor once:

$$E_{\text{wake}}^{\text{sharp}}(T_r) = \frac{1}{2}\sum_{i,j}\sum_{T_t\in\mathcal{C}_{ij}(T_r)} \mu_{\text{arch}}\kappa\,\sigma_{ij}|q_i q_j|\frac{W_{ij}^{\text{acc}}(T_r;T_t)}{r_{ij}(T_r;T_t)}.$$

The ordered sum and factor $1/2$ count each pair once. The positive sign is required by the declared polarity convention: for a static like-polarity pair, outward acceleration must lower a positive interaction charge. An inverse-square expression would mix an acceleration density with an energy kernel, have dimensions of acceleration rather than energy, and insert the root weight before a delta collapse that generates it.

Plainly: the energy row uses a $1/r$ action kernel. Its delta function supplies the moving-transmitter weight during root evaluation; that weight is not inserted by hand a second time.

This expression remains a diagnostic unless it is derived from the same time-translation-invariant action regularization as the acceleration and boundary charge. If the dual-mollified law uses a core cutoff ϵ_c, the energy diagnostic must carry the same cutoff convention. The theorem-level nonlocal charge is the boundary functional in Action-Level Wake-Energy Functional at a Time Boundary.

Causal Interaction Set (The Geometry of Delay)

Definition of Causal Emission Times

For a receiver at position $\mathbf{X}_i(T_r)$ and a transmitter with worldline $\mathbf{X}_j(T')$, the **causal emission times** $\mathcal{C}_{ij}(T_r)$ are all past times $T_t < T_r$ such that a causal wake surface emitted by transmitter j at T_t arrives at receiver i at reception time T_r.

Causal constraint:

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t)$$

where c_f is the field speed (set to 1 in natural units).

Notation:

$$\mathcal{C}_{ij}(T_r) = \Big\{T_t < T_r \;\Big|\; \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t)\Big\}$$

Causal-Time Map and Root Topology

For fixed reception time T_r, define the causal-time map

$$f_{T_r}^{(ij)}(T_t) \equiv T_t + \frac{1}{c_f}\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\|, \qquad F_{T_r}^{(ij)}(T_t) \equiv f_{T_r}^{(ij)}(T_t) - T_r$$

Then causal emission times are exactly the roots:

$$T_t \in \mathcal{C}_{ij}(T_r) \quad\Longleftrightarrow\quad F_{T_r}^{(ij)}(T_t) = 0$$

Operationally, this is the branchwise transmitter-to-receiver reading of the dynamics. The transmitter path supplies a path-history map $T_t \mapsto (\mathbf{X}_t(T_t), \mathbf{V}_t(T_t))$, while the receiver supplies the event data $(\mathbf{X}_r(T_r), \mathbf{V}_r(T_r), T_r)$. Solving $F_{T_r}^{(r\leftarrow t)}(T_t) = 0$ selects exactly those transmitter-history points whose causal isochrons are received at that event. Each selected root therefore maps one transmitter-history branch into one receiver-local line of action; the delay-map Jacobian below records how the uniform transmitter emission-time measure is mapped into a compressed or dilated received causal-surface density. When multiple roots exist, the causal-root ledger is the bookkeeping of these simultaneous transmitter-to-receiver branch matches.

The one-dimensional delay-map Jacobian is

$$\frac{dF_{T_r}^{(ij)}}{dT_t} = 1 - \frac{\hat{\mathbf{r}}_{ij}(T_r; T_t) \cdot \mathbf{V}_j(T_t)}{c_f}$$

On a bounded history interval I_{T_r} (e.g., simulation memory window), define:

- Unsigned root count: $N_{ij}(T_r) \equiv \#\mathcal{C}_{ij}(T_r)$,
- Signed Brouwer degree:

$$D_{ij}(T_r) \equiv \deg(F_{T_r}^{(ij)}, I_{T_r}, 0) = \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \operatorname{sign}\left(\frac{dF_{T_r}^{(ij)}}{dT_t} \Big|_{T_t} \right)$$

Delay-Map Theorem Pack (Formalized)

Fix a bounded history interval $I_{T_r} = [a, b] \subset (-\infty, T_r)$ and define regularity conditions:

- **(R1) Boundary regularity:** $0 \notin F_{T_r}^{(ij)}(\partial I_{T_r})$ (no root crossing at a or b).
- **(R2) Simple roots:** if $F_{T_r}^{(ij)}(T_t) = 0$, then $\frac{dF_{T_r}^{(ij)}}{dT_t}(T_t) \neq 0$.

Theorem 1 (Degree invariance on regular families).
For any continuous deformation of worldlines/parameters that preserves (R1)-(R2), the signed degree $D_{ij}(T_r) = \deg(F_{T_r}^{(ij)}, I_{T_r}, 0)$ is invariant.

Proof sketch: In 1D, D_{ij} is the oriented count of simple roots. Under a regular homotopy, roots move continuously and cannot appear/disappear in the interior without becoming critical, and cannot enter/leave through the boundary by (R1). Hence the oriented count is constant.

Proposition 2 (Sub-c_f monotonic single-hit regime).
If there exists $V_* < c_f$ such that $\|\mathbf{V}_j(T_t)\| \leq V_*$ for all $T_t \in I_{T_r}$, then

$$\frac{dF_{T_r}^{(ij)}}{dT_t} \geq 1 - \frac{V_*}{c_f} > 0$$

so $F_{T_r}^{(ij)}$ is strictly increasing on I_{T_r}. Therefore it has at most one root. If additionally $F_{T_r}^{(ij)}(a) < 0 < F_{T_r}^{(ij)}(b)$, then exactly one root exists and

$$N_{ij}(T_r) = 1, \qquad D_{ij}(T_r) = +1$$

Proof sketch: Strict positivity of the Jacobian gives monotonicity, hence injectivity. Existence under endpoint sign change follows by the intermediate value theorem.

This proposition is retained-interval local. It controls roots whose emission times lie inside the declared interval I_{T_r}; it does not remove older path-history roots emitted outside I_{T_r}, including self-hit candidates from an earlier super-field-speed interval that remain inside a longer memory window. If the model retains such persistent-memory roots, the speed bound must be checked on the enlarged interval that contains their emission times.

Proposition 3 (Fold criterion and even-jump law).
In a one-parameter family $F^{(ij)}(T_t; \lambda)$ (with λ a control parameter, e.g. receiver time or orbit parameter), interior root-count changes occur only at fold points:

$$F^{(ij)}(T_t; \lambda) = 0, \qquad \partial_{T_t} F^{(ij)}(T_t; \lambda) = 0$$

For generic folds ($\partial_{T_t T_t} F \neq 0$, $\partial_\lambda F \neq 0$), one root pair is created/annihilated, so

$$\Delta N_{ij} = \pm 2, \qquad \Delta D_{ij} = 0$$

between regular intervals.

Proof sketch: Local normal form near a generic fold is equivalent to $u^2 \pm \mu = 0$, yielding either 0 or 2 simple roots. The two roots carry opposite Jacobian signs, so the degree is unchanged.

This delay-map theorem pack is foundational rather than merely model-specific. Within this chapter it serves as the fold-geometry reference for delayed-root constructions: regular charts preserve signed degree, while branch creation or annihilation requires a Jacobian-degenerate fold.

Signed Causal-Root Complex

For a receiver-transmitter pair (i, j) on a regular interval, the root ledger can be sharpened from an unsigned set to a two-term signed complex. Split the simple active roots by Jacobian sign:

$$C_+^{ij}(T_r) = \mathrm{span}\{T_{t,\ell} \in \mathcal{C}_{ij}(T_r) : \partial_{T_t} F_{T_r}^{(ij)}(T_{t,\ell}) > 0\}, \qquad C_-^{ij}(T_r) = \mathrm{span}\{T_{t,\ell} \in \mathcal{C}_{ij}(T_r) : \partial_{T_t} F_{T_r}^{(ij)}(T_{t,\ell}) < 0\}.$$

Then

$$N_{ij} = \dim C_+^{ij} + \dim C_-^{ij}, \qquad D_{ij} = \dim C_+^{ij} - \dim C_-^{ij}.$$

At a generic fold, the local boundary pairing creates or removes one positive and one negative generator, preserving D_{ij} while changing N_{ij} by two. In this reading, Theorem 1 is invariance of the Euler-characteristic-like signed count, and Proposition 3 is the elementary opposite-sign pair surgery.

An admissible retained record therefore reports the signed grading (C_+^{ij}, C_-^{ij}), not only raw hit counts. The binary and Noether braid ledgers N_s and M_p are admissible topological labels only after their self-hit and partner-hit entries inherit this signed-root-complex data, together with the phase-return degree data used by the assembly topological charge and resonance-lock chapters.

Proposition 4 (forward partner-root starvation under field-speed drift).
Let a candidate translating branch have center drift $u\hat{\mathbf{e}}$ on the retained interval, with $u \geq 0$ and $\|\hat{\mathbf{e}}\| = 1$. Write two partner constituents as

$$\mathbf{X}_i(T_r) = uT_r\,\hat{\mathbf{e}} + \boldsymbol{\rho}_i(T_r), \qquad \mathbf{X}_j(T_t) = uT_t\,\hat{\mathbf{e}} + \boldsymbol{\rho}_j(T_t)$$

where i is the receiver and $j \neq i$ is the transmitter. Suppose the retained partner root is forward-directed in the co-moving branch chart:

$$d_\parallel(T_r, T_t) \equiv \hat{\mathbf{e}} \cdot \big(\boldsymbol{\rho}_i(T_r) - \boldsymbol{\rho}_j(T_t)\big) \geq d_{\min} > 0$$

For any positive-delay candidate root with $\Delta = T_r - T_t > 0$,

$$c_f\Delta = \big\|u\Delta\,\hat{\mathbf{e}} + \boldsymbol{\rho}_i(T_r) - \boldsymbol{\rho}_j(T_t)\big\| \geq u\Delta + d_{\min}$$

Hence

$$(c_f - u)\,\Delta \geq d_{\min}$$

If $u \geq c_f$, no such forward partner root exists. If $u < c_f$, any such root has the lower delay bound

$$\Delta \geq \frac{d_{\min}}{c_f - u}$$

so the required memory depth diverges as $u \to c_f^-$.

This is a kinematic starvation result, not an acceleration-balance approximation. It says that a forward structural partner root cannot be retained at or above field-speed center drift because the causal wake cannot catch the leading receiver. A bound assembly branch that requires at least one such forward partner root for structural closure therefore cannot preserve the same causal-root ledger for sustained drift $u \geq c_f$. The proposition does not impose a speed cap on a single architrino, on internal curved self-hit motion, or on history-supported super-field-speed components; it applies to center translation of an internally bound branch whose leading-side partner closure is part of the retained ledger.

With finite retained memory h and internal branch period T_{int}, the same obstruction has a graded scale:

$$\Lambda_{\text{starv}} = \frac{\Delta_{\text{fwd}}}{T_{\text{int}}} \geq \frac{d_{\min}}{(c_f - u)T_{\text{int}}}.$$

The forward root remains available to the retained chart only while $\Delta_{\text{fwd}} < h$, equivalently

$$u < u_{\text{crit}} \equiv c_f - \frac{d_{\min}}{h}.$$

Thus starvation is a root-complex obstruction before it is a speed slogan: if the assembly requires that forward generator, the bare causal kernel cannot carry the same branch chart through u_{crit}. Any promoted supra-u_{crit} branch must show a Noether-sea or assembly reorganization that removes or replaces the forward root without hiding a memory-window failure.

This is not the same event as the interior fold law of Proposition 3. A generic interior fold creates or removes one positive and one negative generator and therefore preserves the signed degree D_{ij}. Forward-root starvation is a memory-boundary event: a generator leaves the retained interval $[T_r - h, T_r)$ because its required delay has crossed the available history depth. The finite-window signed degree $D_{ij}^{(h)}$ may therefore change unless a replacement generator enters through the boundary or the branch chart is reorganized by the Noether sea. The retained branch ledger records this as boundary-exit degree bookkeeping, not as a $\Delta N = \pm 2, \Delta D = 0$ fold.

Separator Taxonomy

Three distinct events terminate a simple-root branch chart. They have different degeneracy conditions, different velocity arguments, and different ledger consequences, and a proof program that keys its arc partition to a single “field-speed separator” will conflate them.

Event	Condition	Velocity that appears	Root ledger	Branch strength	Certificate route
Transmitter-side fold	$D_{t,ij} = 0$, i.e. $\mathbf{V}_j(T_t) \cdot \hat{\mathbf{r}}_{ij} = c_f$	transmitter, at emission time	fold: $\Delta N_{ij} = \pm 2$, $\Delta D_{ij} = 0$ (Proposition 3)	$W_{ij}^{\text{acc}} \to \infty$	finite-order caustic normal form and the finite-impulse lemma; cusps and higher strata route to a singular-stratum chart
Receiver-side playback turn	$D_{r,ij} = 0$, i.e. $\mathbf{V}_i(T_r) \cdot \hat{\mathbf{r}}_{ij} = c_f$	receiver, at reception time	unchanged: $\Delta N_{ij} = 0$, $\Delta D_{ij} = 0$	acceleration remains finite when $D_t \neq 0$	signed root playback reverses; no acceleration event route is needed
Memory-boundary exit	$T_r - T_{t,\ell} \to h$	either, through the delay	$\Delta N_{ij} = \pm 1$ possible; $D_{ij}^{(h)}$ may change	finite	boundary-exit degree bookkeeping (Proposition 4); *not* a fold

Two consequences follow immediately.

First, $\|\mathbf{V}_i(T_r)\| = c_f$ is by itself none of these. It is a receiver-side playback turn only for branches whose line of action is aligned with the receiver’s motion, and it is a transmitter-side fold only for the transmitter, at emission time, on the branches it emitted. A reduction that identifies the two manufactures a caustic at $\|\mathbf{V}_i\| = c_f$ that the exact law does not have. Locally affine branch tables are candidate generators; they may not be used to locate separators.

Second, a closed-cycle parity ledger cannot be written over folds alone. On a cycle, $\sum_\Sigma \Delta N_{ij} = 0$ and $\sum_\Sigma \Delta D_{ij} = 0$ hold only after boundary-exit events are counted in the same sum, and those events carry odd unsigned jumps. Requiring every local jump to be even is a sufficient test only on charts certified free of memory-boundary exit.

Single-Hit Regime

In the **sub-field-speed regime** ($\|\mathbf{V}_j(T_t)\| < c_f$ locally), Proposition 2 applies, and the map is strictly monotone:

$$\frac{dF^{(ij)}_{T_r}}{dT_t} \geq 1 - \frac{\|\mathbf{V}_j(T_t)\|}{c_f} > 0$$

so $f^{(ij)}_{T_r}$ is a diffeomorphic time map on I_{T_r}, and the causal set is generically a singleton:

$$N_{ij}(T_r) = 1, \qquad D_{ij}(T_r) = +1$$

Intuition: If the transmitter is moving slower than the field speed, its past emissions form a non-overlapping family of concentric (or nearly concentric) isochrons. Any given receiver location lies on exactly one of those causal surfaces.

Multi-Hit Regime

In the **super-field-speed regime** ($\|\mathbf{V}_j\| > c_f$ at some past times), the delay map can fold when $\hat{\mathbf{r}}_{ij} \cdot \mathbf{V}_j > c_f$, i.e. when $dF^{(ij)}_{T_r}/dT_t$ changes sign. Then $\mathcal{C}_{ij}(T_r)$ can contain multiple solutions:

$$\mathcal{C}_{ij}(T_r) = \{T_{t,1}, T_{t,2}, \ldots, T_{t,m}\}$$

Fold bifurcations create/annihilate roots in pairs. The signed degree D_{ij} stays topologically fixed between folds, while the unsigned branch count N_{ij} jumps by even integers.

Any assembly-level use of a folded root-count transition must define its persistent indices, action partition, and frequency-lock map in the owning assembly chapter. The even-jump theorem alone supplies none of those additional identifications.

Intuition: If the transmitter outruns its own emissions, it can emit multiple wake surfaces that later converge and intersect the same receiver location simultaneously (or nearly so, within regularization width η).

Example: In uniform circular motion at $\|\mathbf{V}\| > c_f$, a receiver can be hit by wake surfaces from multiple points on the transmitter's orbit (different "winding numbers" m due to self-hit dynamics).

Self-Hit Regime

When $j = i$ (transmitter and receiver are the same architrino), the causal set $\mathcal{C}_{ii}(T_r)$ represents **self-hits**: times when architrino i intersects its own past emissions.

Self-hit condition:

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| = c_f(T_r - T_t), \quad T_t < T_r$$

This equation nominates a same-transmitter causal root. It becomes an admitted self-hit contribution only on a retained branch chart: the coincident $T_t = T_r$ branch is excluded by the $H(0) = 0$ convention, the root has positive separation or explicit regularization data, the transversality/Jacobian floor is positive, the same-record transmitter-side acceleration weight W^{acc}_{ii} is retained on its floor or certified bounded interval ν_{rec}, the active-root count is controlled, inactive-root gaps and finite memory are certified, and the stability/action ledger entries required by the claimed assembly branch close.

Interval-speed lemma. Let $\Delta = T_r - T_t > 0$ and suppose $\mathbf{X}_i$ is absolutely continuous on $[T_t, T_r]$. If

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| = c_f \Delta$$

then

$$\frac{1}{\Delta} \int_{T_t}^{T_r} \|\mathbf{V}_i(T')\| \, dT' \geq c_f$$

This follows immediately from the triangle inequality. Therefore strict sub-field-speed motion on the whole interval forbids a nontrivial self-hit. A simple noncoincident self-hit requires super-field-speed motion somewhere along the interval, except for the degenerate straight field-speed case where the causal branch is tangent and the simple-root Jacobian condition fails.

Critical requirements for self-hit:

1. **Curvature**: Straight-line motion admits no self-hits (the worldline never intersects its own past causal isochrons).
2. **Super-field-speed interval history**: along the interval from emission to reception, the architrino must have exceeded c_f somewhere, unless the branch is the degenerate straight field-speed case excluded by the simple-root assumptions.
3. **Regular branch admissibility**: the same-transmitter root must be retained on a branch chart with a positive transversality/Jacobian floor, a retained same-record transmitter-side acceleration-weight interval (W_{ii}^{acc} on its floor or certified bounded interval ν_{rec}), controlled distance or regularization data, inactive-root gaps, finite memory, and the stability/action ledger entries required by the claimed assembly branch.

Key clarification:

- **Self-hits can be plural**: $\mathcal{C}_{ii}(T_r)$ can contain multiple emission times (e.g., multiple winding numbers in circular motion).
- **Persistent memory**: Once an architrino has exceeded $\|\mathbf{V}\| > c_f$ in its past, it can **later slow down** to $\|\mathbf{V}\| < c_f$ and **still receive self-hits** from wake surfaces emitted during the super-field-speed phase. The self-hit regime is **not** instantaneously tied to current velocity; it depends on **path history**.

Implication: Self-hit is a **non-Markovian memory effect**. The architrino's current acceleration depends on whether it **ever** exceeded c_f in the past and curved, not just on its current state.

Geometric Interpretation

Visualize the causal constraint as:

- Receiver at $\mathbf{X}_i(T_r)$ "now"
- Transmitter path $\{\mathbf{X}_j(T') : T' < T_r\}$ in the past
- Field-speed causal wake surface: the expanding isochron at radius $c_f(T_r - T_t)$ centered at $\mathbf{X}_j(T_t)$
- **Causal emission times**: where this wake surface **intersects** the receiver's current location

For each $T_t \in \mathcal{C}_{ij}(T_r)$, draw a line from $\mathbf{X}_j(T_t)$ to $\mathbf{X}_i(T_r)$; this is the **line of action** $\hat{\mathbf{r}}_{ij}$ for the acceleration.

This geometry should be read in terms of the transmitter path, the expanding causal isochrons centered on past emission points, and the receiver event at which one or more of those isochrons are intersected.

Reduced Translating-Loop Delay Checkpoint

To obtain a nontrivial analytic checkpoint from the same causal constraint, consider a translating phase-locked two-leg internal loop, with one leg parallel to motion and one transverse. Let the loop center translate with speed v through the Euclidean void while every wake still propagates at the primitive field speed c_f. Define

$$\beta_f \equiv \frac{v}{c_f}, \qquad C(v) \equiv \frac{L_\parallel(v)}{L_0}$$

with rest bond length L_0.

Parallel round-trip delay:

$$T_\parallel(v) = \frac{L_\parallel}{c_f - v} + \frac{L_\parallel}{c_f + v} = \frac{2L_0}{c_f}\frac{C(v)}{1-\beta_f^2}$$

Transverse one-way delay satisfies

$$c_f^2\Delta_\perp^2 = L_0^2 + v^2\Delta_\perp^2 \;\Rightarrow\; \Delta_\perp = \frac{L_0}{c_f\sqrt{1-\beta_f^2}}$$

so

$$T_\perp(v) = 2\Delta_\perp = \frac{2L_0}{c_f}\frac{1}{\sqrt{1-\beta_f^2}}$$

If internal phase locking is operationally isotropic (no orientation-dependent clock leakage),

$$T_\parallel(v) = T_\perp(v)$$

then necessarily

$$C(v) = \sqrt{1-\beta_f^2}, \qquad T(v) = \frac{T_0}{\sqrt{1-\beta_f^2}}, \quad T_0 = \frac{2L_0}{c_f}$$

This gives a purely substrate-level period-stretch checkpoint. It says only that preserving the same internal phase closure while the receiver translates forces the physical period T to increase in absolute time unless the longitudinal leg shortens. The full unresolved step is proving the same absolute-period scaling for the complete multi-hit NFDE Noether braid dynamics without reducing to a two-leg closure model.

The forward parallel leg carries the same starvation constraint as Proposition 4 with $d_{\min}$ replaced by the leading longitudinal leg length $L_\parallel$. Let $h_b^{\mathrm{lock}}(v)$ be the retained-history depth measured on the locked moving branch, distinct from the generic analysis horizon h. The two-leg checkpoint is admissible as a retained-record model only in the starvation-free regime

$$v < c_f - \frac{L_\parallel}{h_b^{\mathrm{lock}}(v)}.$$

Above that scale, the checkpoint no longer tracks the same causal-root ledger: the full Noether braid proof must show a ledger reorganization, a sea-mediated replacement record, or a declared failure of the translating-loop reduction.

The two-leg loop is only a checkpoint. It has two phase points and one chosen orientation relative to the absolute motion. A real assembly has an effective internal phase distribution over a finite three-dimensional volume, and operational isotropy has to hold for all loop orientations at once. The closure target is therefore a full oblate-envelope-to-sphere reduction in the internal Family-A phase space, not just the equality

$$T_\parallel = T_\perp$$

for one leg pair.

In spherical-harmonic language this checkpoint is the $\ell = 0$ isotropy projection of the moving internal delay record. The next leakage record is the $\ell = 2$ quadrupole anisotropy, denoted schematically by Q_A for assembly A. A retained Lorentz or clock-universality claim must show that Q_A is either cancelled by the full three-dimensional branch ledger or bounded below the relevant anisotropy ceiling; otherwise the two-leg period result is only an orientation-specific delay identity.

Accelerated motion adds a second burden. Even if the inertial translating-loop scaling is recovered, acceleration requires a transport law for the internal phase ledger through the Noether sea. For a stable branch with rest size L_0, center speed $v(T)$, and small acceleration scale $a(T)$, the dynamics target is a branch-period transport law of the schematic form

$$T_q[v(T), a(T)] = T_q[v(T), 0]\left(1 + O\left(\frac{a^2 L_0^2}{c_f^2}\right)\right)$$

with every term evaluated in absolute time. The residual is the finite-loop-size, non-Markovian correction caused by acceleration during one internal phase cycle. Observer-inference chapters may later translate a branch-certified period record into clock and metric language, but no such translation is part of the Master EOM.

Master Equation and DDE Formulation

The Master Equation (Canonical Form)

Per-Hit Acceleration

For each causal emission time $T_t \in \mathcal{C}_{ij}(T_r)$, define:

Separation vector and distance:

$$\mathbf{r}_{ij}(T_r; T_t) = \mathbf{X}_i(T_r) - \mathbf{X}_j(T_t), \quad r_{ij} = \|\mathbf{r}_{ij}\|$$

Unit direction (line of action):

$$\hat{\mathbf{r}}_{ij} = \frac{\mathbf{r}_{ij}}{r_{ij}} = \frac{\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)}{\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\|}$$

Polarity sign factor:

$$\sigma_{ij} = \mathrm{sign}(q_i q_j) = \begin{cases} +1 & \text{like polarities (repel)} \\ -1 & \text{unlike polarities (attract)} \end{cases}$$

Transmitter-side factor, transmitter-side weight, and signed root playback:

$$D_{t,ij}(T_r; T_t) \equiv c_f - \mathbf{V}_j(T_t) \cdot \hat{\mathbf{r}}_{ij}(T_r; T_t), \qquad D_{r,ij}(T_r; T_t) \equiv c_f - \mathbf{V}_i(T_r) \cdot \hat{\mathbf{r}}_{ij}(T_r; T_t)$$

$$W_{ij}^{\mathrm{acc}}(T_r; T_t) \equiv \frac{c_f}{|D_{t,ij}(T_r; T_t)|}, \qquad m_{ij}(T_r; T_t) \equiv \frac{D_{r,ij}(T_r; T_t)}{D_{t,ij}(T_r; T_t)}$$

Per-hit acceleration contribution:

$$\mathbf{A}_{ij}(T_r; T_t) = \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\mathrm{acc}}(T_r; T_t)\, \hat{\mathbf{r}}_{ij}$$

If a force-like bookkeeping symbol is desired, define

$$\mathbf{F}_{ij}(T_r; T_t) \equiv \mu_{\mathrm{arch}}\, \mathbf{A}_{ij}(T_r; T_t)$$

where μ_{arch} is a universal conversion constant used only for force/energy bookkeeping. It is not a particle-specific inertial mass.

where:

- κ: universal coupling constant
- q_i, q_j: intrinsic polarities of receiver and transmitter ($\pm\epsilon$ for electrinos/positrinos)
- r_{ij}: distance from emission point to reception point
- $\hat{\mathbf{r}}_{ij}$: radial direction from emission to reception
- $D_{t,ij}$: transmitter-side factor controlling root transversality and emitted-wake compression/dilation
- $D_{r,ij}$: receiver-side factor used in signed root playback
- W_{ij}^{acc}: dimensionless transmitter-side acceleration weight
- m_{ij}: signed rate at which the active emission root changes with reception time

Note on interaction structure: The per-hit acceleration $\mathbf{A}_{ij}(T_r; T_t)$ is **radial in direction**: it points along the line of action $\hat{\mathbf{r}}_{ij}$ from the transmitter's past position to the receiver's current position. There are **no velocity-dependent cross-product terms** in the fundamental interaction kernel. The acceleration magnitude is the inverse-square density multiplied by the transmitter-side acceleration weight. Receiver velocity is absent from the instantaneous multiplier.

Implication for emergent velocity dependence: Any observer-level velocity-dependent response must arise from delayed geometry, root playback, wake-state evolution, and superposition of radial hits, not from an intrinsic receiver-velocity multiplier or cross-product term in the fundamental law.

Fixed-hit acceleration-order boundary. At one fixed causal hit, the canonical multiplier reads the transmitter position and velocity at T_t, the receiver position at T_r, and the polarity and coupling data. It does not read transmitter acceleration or any higher transmitter derivative. This derived statement is local to one evaluated hit. A retained sequence of hits can still encode changing transmitter velocity, root timing, and line of action, so it may carry information about an accelerated history.

Plainly: acceleration is absent as a separate input field at one hit, but an accelerated path can still change the later sequence of hits.

This boundary proves neither absence nor presence of radiation. The inverse-square acceleration falloff alone does not determine an energy flux at infinity because the wake-energy current and its constitutive relation have not yet been derived. Likewise, the canonical law contains no primitive instantaneous acceleration-derivative self-term, but delayed self-hits, assembly recoil, wake-state exchange, and photon emission remain possible effective reaction channels. A contrary per-hit code path that reads transmitter acceleration would falsify the fixed-hit statement; a derived wake-energy current with a nonzero far-boundary limit would establish radiative transport without changing it.

Total Acceleration (Sum Over All Causal Hits)

The total acceleration on receiver i at reception time T_r is the **vector sum** over:

1. All transmitters $j \neq i$ (partner hits)
2. All causal emission times $T_t \in \mathcal{C}_{ij}(T_r)$ for each transmitter
3. Self-hits ($j = i$), if any exist

Master Equation of Motion (Canonical Form):

$$\boxed{\frac{d^2\mathbf{X}_i}{dT_r^2} = \sum_j \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\text{acc}}(T_r; T_t)\,\hat{\mathbf{r}}_{ij}}$$

where:

- Outer sum: over all transmitters j (including $j = i$ for self-hits)
- Inner sum: over all causal emission times $T_t \in \mathcal{C}_{ij}(T_r)$
- Each term: radial inverse-square acceleration with sign σ_{ij} and transmitter-side acceleration weight W_{ij}^{acc}

Explicit separation of partner and self-hit terms:

$$\frac{d^2\mathbf{X}_i}{dT_r^2} = \underbrace{\sum_{j \neq i} \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\text{acc}}(T_r; T_t)\,\hat{\mathbf{r}}_{ij}}_{\text{Partner hits}} + \underbrace{\sum_{T_t \in \mathcal{C}_{ii}(T_r)} \kappa\,\sigma_{ii}\,\frac{|q_i q_i|}{r_{ii}^2} W_{ii}^{\text{acc}}(T_r; T_t)\,\hat{\mathbf{r}}_{ii}}_{\text{Self-hits}}$$

Note: $\sigma_{ii} = +1$ (like polarities repel), so self-hits are always **repulsive**.

This sum can be viewed as a **path-history branch sum**: each emission time in $\mathcal{C}_{ij}(T_r)$ marks where the receiver's worldline crosses the causal wake surface emitted at T_t. The integral representation above is simply the distributional encoding of this branch-selection rule.

Conventions and Exclusions

Heaviside Convention ($H(0) = 0$):

The emission at $T_t = T_r$ (instantaneous self-acceleration) is **excluded**. Formally, this is enforced by writing:

$$\mathcal{C}_{ij}(T_r) = \left\{ T_t < T_r \;\middle|\; \|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t) \right\}$$

(Strict inequality $T_t < T_r$; no $T_t = T_r$ allowed.)

Physical justification: The causal wake surface at the instant of emission ($r = 0$, $\Delta = 0$) has not yet expanded; it cannot produce self-acceleration on the transmitter at that same event. This endpoint exclusion does not certify a finite transition when a nontrivial same-transmitter root is born from that endpoint.

No accepted $r = 0$ sharp roots:

Because $r = c_f(T_r - T_t)$, $r = 0$ implies $\Delta = T_r - T_t = 0$. This case is excluded by $H(0) = 0$. A coincident same-transmitter birth, simultaneous core/transmitter-side-factor failure, or regulator-dependent continuation remains uncertified and must fail closed.

This also fixes the status of later short-distance regularizations. A finite core cutoff or core mollifier is not a hard exclusion sphere, an elastic contact collision, or a primitive rule saying that causal wakes are blocked by or transmitted through an opaque core. It is a declared mathematical control on the near-origin amplitude inside a regularized branch chart. In the canonical branch law, a transmitter contribution is admitted by the causal-root constraint, polarity sign σ_{ij}, separation or regularization data, transmitter-side transversality and transmitter-side control, active-root count, and the required stability/action/event accounts. A polarity-dependent short-distance kernel would therefore be an additional model term that must be derived and validated; it cannot be inserted as an unproved like-versus-opposite collision or opacity rule.

Superposition Principle

The Master EOM is **linear in transmitter contributions** on a declared branch chart:

$$\mathbf{A}_{\text{total}}(T) = \sum_j \mathbf{A}_j(T)$$

The causal-wake distributions from distinct transmitters superpose without mutual interference, and the receiver sums the branch accelerations that actually intersect it. Effective potentials reconstructed from those wakes also superpose in the corresponding linear diagnostic or continuum limit, but the substrate law remains the receiver-local branch sum.

Consequence: The problem of N interacting architrinos reduces to solving N coupled delay differential equations (DDEs), one per architrino, with each depending on the retained history of all transmitters and on the certified active causal-root records.

Terms and Conventions (Detailed Breakdown)

Direction and Sign

Direction of $\hat{\mathbf{r}}_{ij}$:

$\hat{\mathbf{r}}_{ij}$ points **from the transmitter's historical position $\mathbf{X}_j(T_t)$ to the receiver's current position $\mathbf{X}_i(T_r)$**.

Sign of the acceleration:

- **Like polarities** ($\sigma_{ij} = +1$): acceleration along $+\hat{\mathbf{r}}_{ij}$ (repulsion; pushes receiver away from emission point)
- **Unlike polarities** ($\sigma_{ij} = -1$): acceleration along $-\hat{\mathbf{r}}_{ij}$ (attraction; pulls receiver toward emission point)

Two-body checks (stationary transmitters):

- Electrino + Electrino (like polarities): repulsion
- Positrino + Positrino (like polarities): repulsion
- Electrino + Positrino (unlike polarities): attraction
- For stationary pair geometry, swapping transmitter and receiver reverses the line-of-action unit vector and leaves the acceleration magnitude unchanged, so the two acceleration contributions are equal and opposite. This static

statement does not extend to delayed moving histories; see Exact Fixed Point-Cloud Residual.

Scaling and Normalization

The $1/r^2$ factor:

Reflects the **surface density** of potential on the causal isochron. As that surface grows, the potential spreads over area $4\pi r^2$, so the density at any point scales as $1/r^2$.

The transmitter-side acceleration weight W_{ij}^{acc}:

Continuous uniform-emission rule (declared premise). Each architrino emits its causal wake at every absolute emission time T_t in its worldline domain. Uniformity means that the emitted wake measure is proportional to the absolute-time measure,

$$\mathrm{d}\mu_{\mathrm{em},j}(T_t) = \lambda_{\mathrm{em}}\,\mathrm{d}T_t, \qquad \lambda_{\mathrm{em}} > 0 \text{ constant}$$

This density is independent of the transmitter's state of motion. In the normalization used here, λ_{em} is absorbed into κ, so the path-history integral uses $\mathrm{d}T_t$ directly. The causal surfaces are continuously indexed by T_t; an equal-ΔT sequence is only a numerical discretization of this continuum, not the substrate emission law. This emission measure is inherited from the transceiver postulate in Architrino: Constant-Time Emission Measure, its canonical home, and is a declared conditionality of the canonical boxed law above, not a derived result of this chapter.

Under the continuous uniform-emission rule stated above, transmitter motion maps the uniform $\mathrm{d}T_t$ measure onto a history-dependent family of expanding causal surfaces. Along a simple branch, surfaces with nearby emission labels T_t and $T_t + \mathrm{d}T_t$ have local normal separation $|D_t|\,\mathrm{d}T_t$, where $D_t = c_f - \hat{\mathbf{r}}_{ij}\cdot\mathbf{V}_j(T_t)$. The received causal-surface density per unit local normal distance is therefore proportional to $\lambda_{\mathrm{em}}/|D_t|$. Motion of the transmitter toward the active branch increases that density; motion away from the branch decreases it. After static-transmitter normalization, the geometric acceleration weight is

$$W_{ij}^{\mathrm{acc}} = \frac{c_f}{|c_f - \hat{\mathbf{r}}_{ij}\cdot\mathbf{V}_j(T_t)|}.$$

Absorption of geometric constants into κ:

All geometric normalization factors (for example, $1/(4\pi)$ from spherical surface area) are absorbed into the coupling constant κ by convention. The canonical per-hit law is therefore written with an explicit inverse-square factor together with the dimensionless transmitter-side acceleration weight W_{ij}^{acc}.

Dimensional analysis:

$$[\kappa] = \frac{[\mathrm{Length}]^3}{[\mathrm{Time}]^2[\mathrm{Polarity}]^2}, \quad [\mathbf{A}] = \frac{[\mathrm{Length}]}{[\mathrm{Time}]^2}$$

If the force-like bookkeeping variable $\mathbf{F} = \mu_{\mathrm{arch}}\mathbf{A}$ is introduced, then $[\mathbf{F}] = [\mu_{\mathrm{arch}}][\mathrm{Length}]/[\mathrm{Time}]^2$. In natural units with $c_f = 1$, $[\mathrm{Length}] = [\mathrm{Time}]$, and κ has dimensions of $[\mathrm{Length}]/[\mathrm{Polarity}]^2$.

Receiver Kinematics (Radial vs Orthogonal Components)

At a given hit $(T_r; T_t)$, decompose the receiver's velocity into components parallel and orthogonal to the line of action $\hat{\mathbf{r}}_{ij}$:

$$\mathbf{V}_i(T_r) = V_r\hat{\mathbf{r}}_{ij} + \mathbf{V}_\perp$$

where:

- $V_r = \mathbf{V}_i(T_r)\cdot\hat{\mathbf{r}}_{ij}$ (radial component; positive = moving away from emission point)
- $\mathbf{V}_\perp = \mathbf{V}_i(T_r) - V_r\hat{\mathbf{r}}_{ij}$ (orthogonal component)

Instantaneous effect of the hit:

Because $\mathbf{A}_{ij}(T_r;T_t) \parallel \hat{\mathbf{r}}_{ij}$, its instantaneous effect satisfies:

$$\frac{d}{dT_r}\mathbf{V}_\perp\Big|_{\text{hit}} = \mathbf{0}, \quad \frac{d}{dT_r}V_r\Big|_{\text{hit}} = \mathbf{A}_{ij}\cdot\hat{\mathbf{r}}_{ij} = \kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2}W_{ij}^{\text{acc}}(T_r;T_t)$$

Plain language: A hit only changes the along-the-line velocity component right now; sideways motion continues unaffected at the instant of the hit. Over time, the changing radial motion alters the trajectory and thus the subsequent orthogonal component.

Translating-assembly deformation requirement: The receiver kinematics described here must mechanically produce the moving-assembly deformation, branch-period stretch, and two-way signal-synchronization records that later observer-inference chapters consume. If Noether braids do not squash along the direction of motion and do not preserve one retained causal-root ledger while translating through the Noether sea, the downstream recovery program fails at the dynamics layer.

Work and Power

The **instantaneous power** (rate of kinetic energy change) from a single hit is:

$$\frac{dE_k}{dT_r}\Big|_{\text{hit}} = \mathbf{F}_{ij}\cdot\mathbf{V}_i = \big(\mu_{\text{arch}}\mathbf{A}_{ij}\cdot\hat{\mathbf{r}}_{ij}\big)V_r = \mu_{\text{arch}}\,\kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2}W_{ij}^{\text{acc}}(T_r;T_t)\,V_r$$

Key insight: There is **no instantaneous work** on the orthogonal component. Power depends only on the radial velocity V_r .

Radial motion and the $1/r^2$ factor (local trend):

- **Inward motion** ($V_r < 0$, receiver moving toward the emission point): decreases r_{ij} between close successive hits, tending to **increase** subsequent per-hit strengths via $1/r^2$ (all else equal).
- **Outward motion** ($V_r > 0$): increases r_{ij}, tending to **decrease** subsequent per-hit strengths.

Important caveat: Path-history delay shifts both the causal root T_t and $\hat{\mathbf{r}}_{ij}$ over finite intervals, so these are strictly **local** statements about infinitesimal time evolution. The global trajectory depends on the full history of all transmitters.

Moving Transceiver Geometry and Received Branch Strength

Critical modeling note:

- **Emission rule**: continuous and uniform in absolute time, as stated above
- **Spatial deposition**: velocity dependent because the surface indexed by T_t is centered at the historical position $\mathbf{X}_j(T_t)$

The **emitted potential pattern in space** is velocity dependent because a moving transmitter centers the continuously indexed causal surfaces at different historical positions. On a simple root, the resulting transmitter-side weight is

$$W_{ij}^{\text{acc}} = \frac{c_f}{|c_f - \hat{\mathbf{r}}_{ij}\cdot\mathbf{V}_j(T_t)|}.$$

The receiver's instantaneous velocity is absent from this weight. Receiver motion still matters in three causal ways:

1. the receiver's current position selects the arriving root, separation, and line of action;
2. the signed derivative D_r/D_t controls how that root is replayed as reception time advances;
3. acceleration changes the receiver's later path and therefore changes future transmissions and receptions.

For a uniformly moving transmitter and a fixed receiver, let

$$\mathbf{X}_j(T_t) = \mathbf{X}_{j,0} + \mathbf{V}_{j,0}T_t, \qquad \beta_f = \frac{\|\mathbf{V}_{j,0}\|}{c_f}, \qquad \cos\theta = \frac{\mathbf{V}_{j,0}\cdot\hat{\mathbf{r}}_{ij}}{\|\mathbf{V}_{j,0}\|}.$$

Then

$$W_{ij}^{\mathrm{acc}} = \frac{1}{|1-\beta_f\cos\theta|},$$

so transmitter motion compresses the emitted surface density in forward directions and dilates it in trailing directions. This is a transmitter-history effect, not a receiver-cadence multiplier and not an imported observer-level field law.

Proposition 5 (exact transverse projection for a uniformly translating point cloud; derived).
Let two architrinos translate with the same constant velocity
$\mathbf V = V\hat{\mathbf e}$, where $V = \|\mathbf V\|$ and
$0 \le \beta_f = V/c_f < 1$. At a
reception time T_r, write their instantaneous ordered separation as

$$\mathbf s \equiv \mathbf X_i(T_r) - \mathbf X_j(T_r) = d\hat{\mathbf n}, \qquad \hat{\mathbf n}\cdot\hat{\mathbf e} = \cos\psi, \qquad d > 0.$$

Define

$$\alpha(\beta_f,\psi) \equiv \sqrt{1-\beta_f^2\sin^2\psi}, \qquad p(\beta_f,\psi) \equiv \alpha - \beta_f\cos\psi.$$

For the unique positive-delay partner root, let
$y \equiv c_f(T_r - T_t)/d$. Uniform translation of the fixed point cloud and the causal-root
constraint give

$$\|\hat{\mathbf n} + \beta_f y\hat{\mathbf e}\| = y, \qquad (1-\beta_f^2)y^2 - 2\beta_f\cos\psi\, y - 1 = 0$$

and therefore

$$y = \frac{\alpha + \beta_f\cos\psi}{1-\beta_f^2} = \frac{1}{p}.$$

The arriving separation, line of action, transmitter-side factor, and
acceleration weight are consequently

$$r_{ij} = dy, \qquad \hat{\mathbf r}_{ij} = p\hat{\mathbf n} + \beta_f\hat{\mathbf e}, \qquad D_{t,ij} = c_f\alpha p, \qquad W_{ij}^{\mathrm{acc}} = \frac{1}{\alpha p}.$$

Substitution into the canonical per-hit law gives the exact
general-orientation acceleration

$$\boxed{\mathbf A_{ij} = \kappa\,\sigma_{ij}\,\frac{|q_iq_j|}{d^2}\,\frac{p^2\hat{\mathbf n} + \beta_f p\hat{\mathbf e}}{\alpha}}$$

and, with
$\hat{\mathbf n}_{\perp}
\equiv
\hat{\mathbf n}-(\hat{\mathbf n}\cdot\hat{\mathbf e})\hat{\mathbf e}$,
its transverse projection is

$$\boxed{\mathbf A_{ij,\perp} = \kappa\,\sigma_{ij}\,\frac{|q_iq_j|}{d^2}\,\frac{p^2}{\alpha}\hat{\mathbf n}_\perp, \qquad \|\mathbf A_{ij,\perp}\| = \kappa\,\frac{|q_iq_j|}{d^2}\,\frac{\sin\psi\,\left(\sqrt{1-\beta_f^2\sin^2\psi} - \beta_f\cos\psi\right)^2}{\sqrt{1-\beta_f^2\sin^2\psi}}}$$

For perpendicular instantaneous separation, $\psi = \pi/2$, define

$$\gamma_f \equiv \frac{1}{\sqrt{1-\beta_f^2}}.$$

Here γ_f is only an abbreviation produced by the Euclidean causal-root algebra; no relativistic transformation or observer-level law has entered the derivation. In this configuration $\alpha = p = 1/\gamma_f$, so

$$\boxed{\mathbf{A}_{ij} = \kappa\,\sigma_{ij}\,\frac{|q_iq_j|}{d^2}\left(\beta_f\hat{\mathbf{e}} + \frac{1}{\gamma_f}\hat{\mathbf{n}}\right), \qquad \|\mathbf{A}_{ij,\perp}\| = \kappa\,\frac{|q_iq_j|}{\gamma_f d^2}}$$

with no expansion or truncation in β_f. The general-orientation formula depends explicitly on ψ, so the $1/\gamma_f$ result is not an orientation-independent identity. Perpendicular separation is the only fixed orientation for which the displayed equality holds identically in β_f; isolated β_f-dependent angles may equal the same numerical value but do not extend the identity to a general orientation.

This proposition is derived from the canonical per-hit acceleration, the causal-root constraint, uniform translation of the fixed point cloud, and the declared uniform absolute-time emission measure that supplies W_{ij}^{acc}. Its scope is one ordered partner hit with $0 \le \beta_f < 1$ and nonzero instantaneous separation. The independent reference is the closed-form perpendicular projection $\kappa|q_iq_j|/(\gamma_f d^2)$; numerical evaluation can check the algebra but does not establish the proposition.

Scope boundary and explicit non-claims.

Full-vector non-claim. The full perpendicular-configuration vector does not reproduce the observer-level two-body comparison target. It retains the longitudinal component

$$\mathbf{A}_{ij,\|} = \kappa\,\sigma_{ij}\,\frac{|q_iq_j|}{d^2}\beta_f\hat{\mathbf{e}}$$

which is first order in β_f. Reversing the ordered transverse separation reverses the transverse component but leaves this longitudinal component unchanged.

Parallel-separation non-claim. For instantaneous separation parallel to the translation, the trailing receiver has magnitude $\kappa|q_iq_j|(1+\beta_f)/d^2$ and the leading receiver has magnitude $\kappa|q_iq_j|(1-\beta_f)/d^2$. The observer-level comparison target instead assigns $\kappa|q_iq_j|(1-\beta_f^2)/d^2$ to both. The symmetric part is therefore already wrong at order β_f^2.

Fixed-point-cloud drift non-claim. The perpendicular pair sum is nonzero:

$$\mathbf{A}_{ij} + \mathbf{A}_{ji} = 2\kappa\,\sigma_{ij}\,\frac{|q_iq_j|}{d^2}\beta_f\hat{\mathbf{e}}$$

Thus a two-member configuration with fixed perpendicular separation cannot keep the assumed common constant velocity under the canonical partner-hit law.

This is an acceleration statement, not a primitive mechanical-momentum claim.

Covariance and recovery non-claim. The result does not establish Lorentz covariance of the substrate law, an observer-level two-body law, a translating assembly branch, or a common clock-ruler-momentum response.

The result is therefore one exactly recovered projection obtained without relativistic input. It shows that the canonical transmitter-side acceleration weight contains the required geometric factor on this branch, while the longitudinal residual and pair sum sharpen the separate question of what is missing from the line of action. The fixed-point-cloud translation geometry does not by itself identify the transmitter-side origin uniquely: because $\mathbf{V}_i = \mathbf{V}_j$ here, replacing D_t by D_r leaves the weight unchanged. The transmitter-side attribution instead comes from the uniform-emission causal-surface-density derivation above.

Falsifiers and attribution check.

1. In normalized units $c_f = 1$ with $\kappa = |q_i q_j| = d = 1$, the perpendicular projection must equal $\sqrt{1-\beta_f^2}$. At $\beta_f = 0.9$ and 0.99 it must be, respectively, approximately 0.4358898944 and 0.1410673598. Any departure at any order overturns the exact projection claim.
2. At any $\beta_f > 0$, direct evaluation of the full perpendicular vector must retain a longitudinal component of signed magnitude $\kappa\sigma_{ij}|q_i q_j|\beta_f/d^2$. A vanishing component contradicts the proposition and indicates an incorrect evaluator.
3. Replacing transmitter velocity by receiver velocity inside the weight on this fixed point-cloud branch must leave the result unchanged because the velocities are equal. That outcome overturns any claim that this projection alone uniquely identifies a transmitter-side weight, but it does not overturn the projection algebra. A discriminating check must instead hold the arriving root and transmitter state fixed while changing receiver velocity, or use $\mathbf{V}_i \neq \mathbf{V}_j$: the canonical per-hit strength must remain unchanged, and any receiver-velocity dependence falsifies the transmitter-side-only acceleration weight.

Exact Fixed Point-Cloud Residual

This calculation is a deliberately restricted negative control. Assume $\mathbf{X}_i(T) = \mathbf{R}_i + \mathbf{U}T$ for every member, so every internal velocity relative to the group center vanishes and every pair distance is constant. Candidate braids do not satisfy those assumptions: their members orbit internally and their pair distances generally vary with time.

Plainly: this subsection tests whether a frozen point cloud can drift without deforming. It does not test an orbiting assembly.

The perpendicular example is one orientation of the resulting general three-dimensional formula. Let an instantaneous unordered pair have unit separation

$\hat{\mathbf{n}}_{ij}$, common drift
$\mathbf{V} = \beta_f c_f \hat{\mathbf{e}}$, and signed inverse-square coefficient

$$w_{ij} \equiv \sigma_{ij} \frac{|q_i q_j|}{d_{ij}^2}.$$

Adding the two ordered canonical partner hits gives

$$\boxed{\mathbf{A}_{ij} + \mathbf{A}_{ji} = 2\kappa\beta_f w_{ij} \left[\hat{\mathbf{e}} - 2(\hat{\mathbf{n}}_{ij} \cdot \hat{\mathbf{e}})\hat{\mathbf{n}}_{ij}\right].}$$

This expression is exact only for the fixed-point-cloud common-translation ansatz and does not assume that the pair lies in a selected plane.

Plainly: delayed partner hits do not usually cancel when the whole pair is assigned one common velocity. Their leftover depends only on the drift direction and the pair's instantaneous direction and signed strength.

This is not repaired by replacing the velocity sum with a polarity-weighted one. Like-polarity weighting preserves the common-mode residual; for an unlike-polarity pair it instead leaves a nonzero separation-direction component. More generally, a universal differentiable mechanical map $\sum_i f(\mathbf{V}_i)$ has local rate $Df(\mathbf{V}) \sum_i \mathbf{A}_i$ on a common-drift state, so any nondegenerate local response inherits the obstruction. The theory has not derived f, and the quadratic K_μ map remains a bookkeeping convention.

Plainly: the acceleration test does not depend on a mass or momentum definition. A future kinetic account can change the conservation ledger, but it cannot make an assumed constant velocity constant when its calculated time derivative is nonzero.

For an N-member fixed point cloud, define the signed second-moment operator

$$W \equiv \sum_{i<j} w_{ij}, \qquad \mathsf{M} \equiv \sum_{i<j} w_{ij} \hat{\mathbf{n}}_{ij} \hat{\mathbf{n}}_{ij}^{\mathsf{T}}, \qquad \mathsf{K} \equiv W\mathsf{I} - 2\mathsf{M}.$$

The total common-mode acceleration residual is

$$\boxed{\sum_i \mathbf{A}_i = 2\kappa\beta_f\, \mathsf{K}\hat{\mathbf{e}}.}$$

Therefore the exact null condition for a declared drift direction is

$$\mathsf{K}\hat{\mathbf{e}} = \mathbf{0}, \qquad \text{equivalently} \qquad \mathsf{M}\hat{\mathbf{e}} = \frac{W}{2}\hat{\mathbf{e}}.$$

Plainly: cancellation is a signed directional-balance condition, not merely a head count or a visual symmetry claim.

In a plane containing the drift direction, write $\hat{\mathbf{n}}_{ij} = (\cos\psi_{ij}, \sin\psi_{ij}, 0)$ in that plane. The null condition becomes the vanishing signed second harmonic

$$\sum_{i<j} w_{ij} e^{2\mathrm{i}\psi_{ij}} = 0.$$

A regular triangle and regular square satisfy this planar condition for equal like-polarity weights. An alternating-polarity square also satisfies it because its edge and diagonal direction orbits cancel separately. By contrast, rotational symmetry about the drift axis only removes transverse components in three dimensions; it does not by itself impose the required polar second moment. For example, an equal-weight regular tetrahedron has
M $= (W/3)\mathbf{I}$, hence
K $= (W/3)\mathbf{I}$ and no nonzero drift-direction null.

Plainly: threefold symmetry is sufficient only in the appropriate planar second-harmonic setting. A three-dimensional object can look highly symmetric and still retain a common-drift residual.

If the fixed point cloud has an eigenmode
K$\hat{\mathbf{e}} = \lambda\hat{\mathbf{e}}$ and
$\mathbf{U} = N^{-1}\sum_i \mathbf{V}_i$, then the local common-mode estimate is

$$\frac{d\mathbf{U}}{dT} = \frac{2\kappa\lambda}{Nc_f}\mathbf{U}, \qquad \tau_{\text{drift}} = \frac{Nc_f}{2\kappa|\lambda|}.$$

Writing $\kappa|\lambda|/N = C_g a_{\text{int}}$ and
$t_{\text{dyn}} = v_{\text{int}}/a_{\text{int}}$ gives

$$\frac{\tau_{\text{drift}}}{t_{\text{dyn}}} = \frac{c_f}{2C_g v_{\text{int}}}.$$

Within this fixed point-cloud ansatz, the often-used
c_f/v_{int} scaling is therefore only an order-of-magnitude statement with a geometry coefficient; comparison with a full cycle adds the cycle's own numerical factor. A time-dependent internal geometry requires a return-map or Floquet calculation rather than this frozen exponential estimate.

Plainly: a nonzero residual forbids indefinite translation of that fixed point cloud, but it does not by itself say whether visible deformation takes one cycle or many.

The independent reference for the pair formula is direct closed-form addition of the two ordered roots in Proposition 5. The point-cloud analyzer `scripts/equation-mapping/analyze-fixed-point-cloud-residual.mjs` separately checks the matrix identity, planar nulls, and the tetrahedral negative control. It is not a Borg-catalog evaluator. Sampling a prescribed orbit at frozen phases while discarding its internal velocities does not evaluate that orbit's history and supplies no necessary condition for a moving assembly.

Plainly: the point-cloud analyzer checks the algebra above and nothing more. It cannot pass or fail an orbiting candidate.

Relative-Periodic Moving-Assembly Test

A translating orbiting assembly must be tested on its actual moving history. For drift speed u along $\hat{\mathbf{e}}$, write a candidate branch as

$$\mathbf{X}_a^{(u)}(T) = uT\hat{\mathbf{e}} + \boldsymbol{\xi}_a^{(u)}(T).$$

The internal orbit may change with u; it is not required to remain an undeformed copy of the rest orbit. Relative-periodic closure requires a period P_u and an allowed member permutation π such that

$$\boldsymbol{\xi}_a^{(u)}(T+P_u)=\boldsymbol{\xi}_{\pi(a)}^{(u)}(T),\qquad \dot{\boldsymbol{\xi}}_a^{(u)}(T+P_u)=\dot{\boldsymbol{\xi}}_{\pi(a)}^{(u)}(T).$$

Plainly: after one cycle, the assembly may have moved as a whole and identical members may have exchanged roles, but the complete internal position and velocity pattern must return.

The pair distances are periodic under the same relabeling, not constant:

$$d_{ab}(T+P_u)=d_{\pi(a)\pi(b)}(T).$$

The branch must satisfy the full master-equation residual on the evolved history,

$$\mathbf{R}_a^{(u)}(T_r)\equiv\ddot{\mathbf{X}}_a^{(u)}(T_r)-\sum_j\sum_{T_t\in\mathcal{C}_{aj}(T_r)}\mathbf{A}_{aj}(T_r;T_t)=\mathbf{0}.$$

Plainly: orbital acceleration and every delayed hit remain in the test. A snapshot-only cancellation cannot substitute for this equation.

The delayed ledger must close with the orbit. Each retained root must map as

$$(a,j,T,T_t)\longmapsto(\pi(a),\pi(j),T+P_u,T_t+P_u),$$

with root identity, multiplicity, D_t, acceleration weight, inactive intervals, finite-memory contents, and event conventions preserved. Acceptance then requires an EOM-solver evolution record, the full position-velocity return residual modulo translation and permutation, the master-equation residual along the orbit, and the applicable stability or Floquet certificate.

Plainly: a successful moving assembly is a repeated solution of the complete delayed dynamics, not a sequence of geometrically attractive pictures.

Prescribed-geometry records may be checked for closure of their declared chart, but that is an integrity check only. Because they were not produced by the EOM solver, they cannot establish or refute existence or stability of a relative-periodic moving branch.

For a small-drift continuation from a rest branch, the useful first-order expansion is

$$\boldsymbol{\xi}^{(u)}=\boldsymbol{\xi}^{(0)}+u\boldsymbol{\chi}+O(u^2).$$

Substitution into the full delayed equation gives a periodic correction problem of the form

$$\mathcal{L}\boldsymbol{\chi}=-\mathbf{B}_{\hat{\mathbf{e}}},$$

after the neutral translation, phase, and allowed relabeling modes are fixed. Here $\mathcal{L}$ is the full delayed linearization about the rest branch and $\mathbf{B}_{\hat{\mathbf{e}}}$ is the uniform-drift defect.

Plainly: the correct first question is whether the internal orbit can deform slightly so that all delayed accelerations still close. Freezing that deformation to zero recovers the fixed point-cloud restriction, not a necessary condition for the moving branch.

Claim grade: the relative-periodic conditions are derived acceptance obligations, not evidence that a branch exists. A certified EOM-solver record that satisfies the full residual, root-ledger return, state return, and stability conditions passes this test. Failure of any one condition falsifies that particular claimed branch; failure of a frozen point-cloud overlay does not.

Restricted Transmitter-History Cancellation Family

The canonical law's perpendicular projection differs from the commonly used observer-level two-body comparison target in its longitudinal component. A constant rescaling of κ cannot reconcile the two forms because their relative gap varies as γ_f^2.

That mismatch does not prove that receiver velocity is mathematically necessary. Define the inertially extrapolated separation at a causal hit,

$$\mathbf{s}_{ij} \equiv \mathbf{r}_{ij} - \mathbf{V}_j(T_t)(T_r - T_t),$$

and consider the transmitter-history-only candidate family

$$\mathbf{A}_{ij}^H = \kappa\sigma_{ij}|q_i q_j|\, H(b_j^2, \zeta_{ij}^2)\frac{\mathbf{s}_{ij}}{\|\mathbf{s}_{ij}\|^3},$$

where

$$b_j^2 = \frac{\|\mathbf{V}_j(T_t)\|^2}{c_f^2}, \qquad \zeta_{ij} = \frac{\mathbf{V}_j(T_t)\cdot\mathbf{s}_{ij}}{c_f\|\mathbf{s}_{ij}\|}, \qquad H(b^2, 0) = \sqrt{1-b^2}.$$

For fixed-point-cloud common translation, reversing the pair sends $\mathbf{s}_{ij} \mapsto -\mathbf{s}_{ij}$ while leaving the two scalar arguments unchanged. The pair therefore cancels exactly, receiver velocity remains absent, and the declared transverse target is recovered. The simplest member uses $H = \sqrt{1-b^2}$.

Plainly: the three requested algebraic properties can coexist without adding receiver velocity. The price is a different line of action and a different transmitter weight.

This family is guessed, not derived. It is not the canonical law, does not follow from the current uniform-emission surface-density argument, and has not been obtained from the accepted scalar action scaffold. It changes both the emission-site line of action and the root-density weight. The live closure question is therefore whether an Architrino-native wake construction derives one such member while preserving the accepted causal and conservation obligations. Deriving the canonical emission-site line of action and uniform emission measure from that family would falsify the stated incompatibility; showing that every admissible transmitter-history action reduces to the canonical residual would eliminate the family.

At kernel-class comparison level, a scalar causal kernel
$\delta(\tilde{g})/r$ supplies only a scalar root Jacobian, whereas a
vector-current direct-action comparison contains an additional
velocity-contraction numerator. Replacing that contraction by a constant is
therefore a plausible structural source of the missing cancellation terms.
This is an inferred comparison, not a derivation: causal-only time asymmetry
and unresolved variation residuals can also contribute. A complete variation
that closes the fixed-point-cloud residual without such a contraction would overturn this
diagnosis.

Receiver Turning Is Not an Acceleration Singularity

The receiver-side factor

$$D_{r,ij} = c_f - \hat{\mathbf{r}}_{ij} \cdot \mathbf{V}_i(T_r)$$

appears in the signed root-playback derivative

$$\frac{dT_{t,\ell}}{dT_r} = \frac{D_{r,ij}}{D_{t,ij}}.$$

When $D_{r,ij} = 0$, the tracked emission time has a stationary point as a function of reception time. The causal root does not disappear, and its acceleration does not go silent. A static transmitter with $D_t = c_f$ supplies $W^{\mathrm{acc}} = 1$ whether the receiver is stationary, momentarily satisfies $D_r = 0$, or has $D_r < 0$.

This cleanly separates two events:

- $D_t = 0$ is a transmitter-side fold or higher singularity and requires the declared fold or singular-event route.
- $D_r = 0$ is a root-playback turning point. It changes the sign of branch playback but is not an acceleration pole, zero, or chart boundary.

There is therefore no receiver-velocity resistance tensor and no primitive field-speed barrier in the Master Equation. Any effective damping, velocity-dependent assembly response, or observer-level magnetic-like behavior must be derived from delayed multi-branch geometry and wake-state evolution rather than inserted as an instantaneous receiver multiplier.

Delay Differential Equation (DDE) Formulation

State Vector and Evolution

Define the **state vector** for architrino i:

$$\mathsf{Z}_i(T) = \begin{pmatrix} \mathbf{X}_i(T) \\ \mathbf{V}_i(T) \end{pmatrix} \in \mathbb{R}^6$$

The Master EOM is a **second-order ODE** in $\mathbf{X}_i$, or equivalently a **first-order system** in Z_i:

$$\frac{d\mathsf{Z}_i}{dT} = \begin{pmatrix} \mathbf{V}_i(T) \\ \mathbf{A}_i(T) \end{pmatrix}$$

At a receiver evaluation event, set the generic evolution parameter to $T = T_r$. The branch-resolved acceleration is then

$$\mathbf{A}_i(T_r) = \sum_j \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\mathrm{acc}}(T_r; T_t)\, \hat{\mathbf{r}}_{ij}$$

Causal Functional Form

The acceleration $\mathbf{A}_i(T_r)$ depends on the **history** of all worldlines $\{\mathbf{X}_j(T') : T' < T_r\}$ through the implicit causal constraint:

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t)$$

This makes the system a **delay differential equation (DDE)** with **state-dependent delays** (the delay $\Delta_j = T_r - T_t$ is not constant; it depends on the solution itself).

Functional notation:

$$\frac{d\mathsf{Z}_i}{dT} = \mathcal{F}\Big[\mathsf{Z}_i(T), \{\mathsf{Z}_j(\cdot)\}_j, T\Big]$$

where $\mathcal{F}$ is a **causal functional**: it depends on the current state $\mathsf{Z}_i(T)$ and the past states $\{\mathsf{Z}_j(T') : T' < T\}$ of all architrinos (including i itself for self-hits).

Mollified Causal-Wake Regularization

The ideal model uses **surface-delta causal isochrons** in the emission-time integral. On a simple branch with a distance floor and a Jacobian floor, the delta collapses to a continuous reception-time branch contribution weighted by the transmitter-side acceleration weight; singular or impulse-like behavior arises only when branches hit collision support, lose transversality, accumulate, or are sampled as unresolved numerical events. One may treat the singular limit as a measure-valued branch law, or regularize by replacing the surface delta with a narrow wake surface of thickness $\eta > 0$:

$$\delta(r - c_f\Delta) \longrightarrow \delta_\eta(r - c_f\Delta) = \frac{1}{\sqrt{2\pi}\,\eta}\exp\Big(-\frac{(r - c_f\Delta)^2}{2\eta^2}\Big)$$

while preserving total emission q.

Effect: Under the finite-branch, distance-floor, and transversality assumptions stated below, this supports **continuous-in-time acceleration diagnostics** and classical C^1 solutions for $\mathbf{X}_i(T)$ given C^1 initial data.

In the super-field-speed regime ($\|\mathbf{V}_a\| > c_f$), multiple self-roots can occur; summing over all causal times with an integrable regularization gives a finite contribution only while the active-root count, separation floor, Jacobian floor, and transmitter-side acceleration weight remain controlled.

Convergence requirement: As $\eta \to 0$, numerical solutions must converge to a well-defined limit. If a theorem or simulation also introduces a short-distance core mollifier ϵ_c, it must declare whether the amplitude remains polarity-blind apart from $\sigma_{ij}|q_i q_j|$ or whether a derived polarity-dependent kernel has been added. The default law uses the former convention; the latter is a new closure claim and must preserve the same causal-root, symmetry, and event-ledger checks before it can be used in an assembly or blackbody argument.

Conditional Well-Posedness for the Regularized Exact Model

To make the existence/uniqueness claim precise for the finite-η regularization used in this chapter, we formalize the dynamics as a state-dependent delay system in first-order form:

$$\frac{d\mathbf{Y}}{dT} = \mathcal{G}(\mathbf{Y}_T), \qquad \mathbf{Y}_T(\theta) = \mathbf{Y}(T+\theta),\ \theta \in [-h, 0]$$

with phase space $\mathcal{H} = C^1([-h,0], \mathbb{R}^{6N})$.
This is the convenient proof scaffold used here because the active-root extraction uses the implicit-function theorem on

$$C^1$$

histories. For sharper state-dependent delay work, especially when acceleration bounds rather than classical second derivatives are the natural control, the phase space may need to be

$$W^{1,\infty}([-h,0], \mathbb{R}^{6N})$$

or an absolutely continuous history class. The exact choice is a regularity burden of the theorem being proved, not a change in the causal law.

Assumptions (regularized regime):

- **(W1) Kernel regularity:** δ_η is C^1, bounded, and integrable.
- **(W2) Uniform branch finiteness:** on the considered history neighborhood, each pair (i, j) has at most $B_{ij} < \infty$ active causal branches.
- **(W3) Root transversality:** for every active branch $\Delta_{ij,\ell}$,

$$|\partial_\Delta g_{ij}(\Delta, \phi)| \geq \nu > 0, \qquad g_{ij}(\Delta, \phi) = \|\phi_i(0) - \phi_j(-\Delta)\| - c_f \Delta$$

- **(W4) Distance floor on the branch support:** $\|\phi_i(0) - \phi_j(-\Delta_{ij,\ell}(\phi))\| \geq d_{\min} > 0$.
- **(W5) Bounded charges/couplings:** κ, $|q_i|$ finite.

Conditional theorem (local well-posedness and continuation).
Under (W1)-(W5), for any initial history $\phi^0 \in \mathcal{H}$ there exists $T > 0$ and a unique solution

$$\mathbf{Y} \in C^1([T_{\text{init}} - h, T_{\text{init}} + \Delta T), \mathbb{R}^{6N}), \qquad \mathbf{Y}_{T_{\text{init}}} = \phi^0$$

The solution extends uniquely to a maximal interval $[T_{\text{init}} - h, T_{\max})$. If on every finite interval

$$\sup_{T<T^*} \|\mathbf{V}(T)\| < \infty, \qquad \inf_{T<T^*,\, i,j,\ell} r_{ij,\ell}(T) > 0, \qquad \inf_{T<T^*,\, i,j,\ell} |\partial_\Delta g_{ij,\ell}(T)| > 0$$

and

$$\sup_{T<T^*,\, i,j} B_{ij}^{\text{active}}(T) < \infty$$

then $T_{\max} = \infty$.
Here $r_{ij,\ell}(T)$ denotes the transmitter-receiver distance on branch ℓ, and

$$B_{ij}^{\text{active}}(T)$$

denotes the number of active causal branches of pair

$$(i, j)$$

inside the chosen memory horizon at receiver time

$$T$$

Proof.

1. By (W3), each active delay branch is simple; the Implicit Function Theorem gives $\Delta_{ij,\ell}(\phi) \in C^1$ on a neighborhood of ϕ^0.
2. Each per-branch acceleration term is a composition of C^1 maps (evaluation, subtraction, norm, mollifier, and unit-direction projection). By (W4), denominators stay away from zero; by (W5), coefficients are bounded. Hence each branch term is locally Lipschitz in ϕ.
3. By (W2), only finitely many branches contribute, so their sum $\mathcal{G}$ is locally Lipschitz on an open subset of $\mathcal{H}$ where (W3)-(W4) hold.
4. State-dependent DDE existence/uniqueness theory on Banach spaces is invoked, yielding a unique local C^1 solution and a maximal extension. For state-dependent delays the applicable results (solution-manifold / almost-Lipschitz frameworks, e.g. Walther-class theorems) impose conditions that are not verified here.
5. Continuation follows from the same theorem: finite-time breakdown can occur only by leaving every bounded subset of the admissible set, i.e. via unbounded speed, vanishing separation on active support, transversality loss/root accumulation, or unbounded active branch-count growth.

Therefore the regularized delayed dynamics are locally well-posed, with global existence whenever those failure modes are excluded. This conditional statement applies to the finite-η regularized model; the ideal $\eta \to 0$ surface-delta limit still requires separate control of root accumulation and Jacobian-degenerate branches. The conclusion is conditional on the cited framework's hypotheses; their verification for this system is an open obligation, so no closing tombstone is claimed.

Finite-Continuation Criterion for Global Comparisons

The well-posedness theorem is the dynamics-side home for global-continuation comparisons used later in General Relativity and Singularity Resolution. It should not be read as a claim that observer records determine a unique global spacetime. Its native claim is narrower: a declared finite history, boundary wake record, and branch chart either determine a finite continuation family or they do not.

For a compact subsystem Ω and window $W = [T_i, T_f]$, let $\mathcal{A}^{(\eta)}_{\Omega,W}$ be the set of branch charts that satisfy the regularized assumptions (W1)-(W5), the bounded active-branch condition, the distance floor, and the root-transversality floor on W using the same finite boundary data $\mathcal{B}_{\partial\Omega}|_W$. The dynamics-side continuation family is

$$\mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} = \left\{ \mathbf{Y}^a_{T_f} : a \in \mathcal{A}^{(\eta)}_{\Omega,W},\ \mathbf{Y}^a_{T_f} \text{ is generated by the regularized master equation from } (\mathbf{Y}_{T_i}, \mathcal{B}_{\partial\Omega}|_W) \right\}$$

The comparison passes only if

$$0 < \left| \mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \right| < \infty$$

with every element carrying the causal-root ledger, energy diagnostic or exact charge used for the run, and the boundary wake data that selected it. Empty, infinite, or unlabeled families are not global closure; they mark an unresolved continuation ambiguity. A later strong-field or cosmology chapter may quotient this family by observer-accessible records, but the quotient must be derived from the same master-equation data rather than imposed as a global-hyperbolicity assumption.

The cardinality is itself a structural diagnostic:

- $\left| \mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \right| = 0$ means no compatible global section of the declared branch-chart data exists.
- $\left| \mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \right| = 1$ means the finite data select a unique deterministic continuation.
- $2 \leq \left| \mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \right| < \infty$ means deterministic multistability: the complete state occupies one branch, while record-limited comparisons must use the basin weights induced on the finite labeled family.
- $\left| \mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \right| = \infty$ means root accumulation, noncompact branch freedom, or unresolved chart gluing, not a mature global comparison.

Equivalently, this is the section count of the causal-root gluing target over the finite window:

$$\mathfrak{S}^{\mathrm{ME},\eta}_{\Omega,W} \subset H^0(W; \mathcal{F}_{\mathrm{root}})$$

after the finite boundary data and regularization convention have been fixed. Finite labeled multistability is an admissible branch-statistics object. Empty, infinite, unlabeled, or non-gluing continuation families remain closure failures, and the obstruction should be reported as a local admissibility failure, an accumulation failure, or a nonzero gluing class in $\check{H}^1$.

Operational Principles, Self-Interaction, and Examples

Core Principles (Operational Summary)

Superposition

Statement: The potential wake contributions from all transmitters **superpose linearly**. The net potential at any point is the sum of the individual wake potentials:

$$\Phi_{\text{net}}(\mathbf{X}, T) = \sum_i \Phi_i(\mathbf{X}, T)$$

The total acceleration on a particle at any instant is the **vector sum** of the contributions from every causal entry in its path history.

Operational implication: Every architrino is continuously immersed in the superposed wakes of all others (and, when the same-transmitter root condition permits, its own). Tractability comes from treating each causal emission independently with $1/r^2$ distance weighting modulated by the transmitter-side acceleration weight W^{acc}, branch gaps, and screening or cancellation assumptions that make the retained sum finite.

Inverse-square dilution alone is not a global convergence theorem. For an infinite transmitter family, a branch chart must declare a summation or continuum prescription under which

$$\lim_{R\to\infty} \sum_{j:\|\mathbf{X}_j\|<R} \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \mathbf{A}_{ij}(T_r; T_t)$$

exists, or it must supply local neutrality, angular cancellation, shielding, a screened kernel, finite active horizon, or a mean-field/principal-value subtraction. Without this condition, the many-transmitter wake sum is not a well-defined acceleration law even though each individual hit has the correct surface-density falloff.

Velocity Dependence

Statement: The dynamics are **delayed** and **radial in direction**. The received acceleration magnitude is modulated by the transmitter-side acceleration weight W_{ij}^{acc}. Transmitter motion controls this factor. Receiver motion controls signed root playback and affects the kinetic-rate diagnostic through its radial velocity, but it does not multiply the arriving acceleration.

Self-interaction requirement: Self-hit requires super-field-speed interval history: the worldline must exceed c_f somewhere along a nontrivial emission-to-reception interval, except for the degenerate field-speed tangent case excluded by the simple-root branch condition. Curvature alone is insufficient if $\|\mathbf{V}_a\| < c_f$ everywhere on the relevant interval.

Persistent memory: Once an architrino has exceeded $\|\mathbf{V}\| > c_f$ in its past and emitted wake surfaces, it can **later slow down** to $\|\mathbf{V}\| < c_f$ and **still receive self-hits** from those earlier emissions. The self-hit regime is **not instantaneously tied to current velocity**; it is a **path-history memory effect**.

Causality and Locality

Causal structure: Event A at $(T_A, \mathbf{X}_A)$ can influence event B at $(T_B, \mathbf{X}_B)$ only if:

$$T_B > T_A \quad \text{and} \quad \|\mathbf{X}_B - \mathbf{X}_A\| \le c_f(T_B - T_A)$$

This defines a **field-speed causal cone** centered at each event. The filled inequality is the reachability condition; exact hits still occur only on causal wake surfaces satisfying the equality root.

No action-at-a-distance: All influences propagate at finite speed c_f. There are no instantaneous interactions across spatial separation.

Event-locality at the receiver: The Master EOM is evaluated **at the receiver event**: only the causal wake surfaces intersecting $\mathbf{X}_i(T_r)$ contribute to the acceleration there and then. However, it is **path-history dependent**: the active branches depend on the **entire past worldline** of all transmitters.

Self-Interaction (Self-Hit Dynamics)

Self-Hit Condition

An architrino i experiences self-hit at reception time T_r if there exists $T_t < T_r$ such that:

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| = c_f(T_r - T_t)$$

Geometric interpretation: The architrino's current position $\mathbf{X}_i(T_r)$ lies on the causal isochron emitted from its past position $\mathbf{X}_i(T_t)$.

Requirements:

1. **Curvature**: The worldline must curve (straight-line motion admits no self-hits).
2. **Super-field-speed interval history**: the speed must exceed c_f somewhere on the interval from emission to reception, except for the degenerate straight field-speed riding case excluded by the branch Jacobian condition.

Multiple Self-Hits (Plural)

Key insight: An architrino can experience **multiple self-hits simultaneously** (or within a regularization window η).

Mechanism: In curved motion at super-field-speed, the worldline may intersect **multiple past isochrons** at the same reception time T_r. Each intersection corresponds to a distinct emission time $T_{t,k} \in \mathcal{C}_{ii}(T_r)$.

Example: In uniform circular motion at speed $\|\mathbf{V}\| > c_f$, an architrino can be hit by wake surfaces from multiple points on its own orbit, corresponding to different "winding numbers" $m = 0, 1, 2, \ldots$ (see Maximum-Curvature Orbit).

Sum over all self-hit roots:

$$\mathbf{A}_{ii}(\text{self-hit}) = \sum_{T_t \in \mathcal{C}_{ii}(T_r)} \kappa\, \sigma_{ii} \frac{|q_i q_i|}{r_{ii}^2} W_{ii}^{\text{acc}}(T_r; T_t)\, \hat{\mathbf{r}}_{ii}$$

where $\sigma_{ii} = +1$ (like polarities repel), so each self-hit contributes an **outward** (repulsive) acceleration.

Persistent Memory (Self-Hit After Slowing Down)

Critical clarification:

Self-hit is **not** instantaneously tied to current velocity. An architrino that has **previously** exceeded $\|\mathbf{V}\| > c_f$ and emitted wake surfaces can **later slow down** to $\|\mathbf{V}\| < c_f$ and **still receive self-hits** from those earlier emissions.

Scenario:

1. At time T_1: Architrino accelerates to $\|\mathbf{V}\| > c_f$ and emits wake surfaces while in super-field-speed regime.
2. At time $T_2 > T_1$: Architrino slows down to $\|\mathbf{V}\| < c_f$ (e.g., due to partner attraction or external acceleration contributions).
3. At time $T_3 > T_2$: The architrino's trajectory curves such that it intersects one of the wake surfaces emitted at T_1 (when $\|\mathbf{V}\| > c_f$).

Result: Self-hit occurs at T_3 even though current velocity $\|\mathbf{V}(T_3)\| < c_f$.

Implication: Self-hit is a **path-history memory effect**. The architrino's current acceleration depends on **whether it ever exceeded c_f in the past and curved**, not just on its instantaneous state.

Non-Markovian nature: Knowing $\mathbf{X}_i(T_r)$ and $\mathbf{V}_i(T_r)$ is insufficient to determine $\mathbf{A}_i(T_r)$. The **full past worldline** $\{\mathbf{X}_i(T') : T' < T_r\}$ is needed to identify all causal self-hit times $T_t \in \mathcal{C}_{ii}(T_r)$.

Self-Hit as an Outward Barrier Mechanism

Role in binary formation: Self-hit provides a **repulsive radial contribution** that opposes the attractive pull of opposite-polarity partners. On the uniform circular chart, this contribution is always outward, so it can furnish a floor against collapse but cannot furnish the centripetal acceleration needed to maintain the circle. This competition produces:

- **Maximum-curvature candidates**: the circular toy model identifies where a minimum-radius barrier must be analyzed.
- **Transmitter-side fold boundary**: $D_t = 0$ is a transmitter-side pole. Ordinary folds require finite-impulse certification; coincident same-transmitter birth and undeclared higher singularities fail closed.

- **A closure test, not a closure proof**: the same transmitter-side acceleration weight multiplies tangential as well as radial projections, so a transmitter-side null branch does not by itself prove vanishing tangential power or an exact locked orbit.

Self-hit root existence is field-speed gated. On any stored interval with $\|\mathbf{V}_i\| \le c_f - \sigma$ for $\sigma > 0$, the exact bound $\|\mathbf{X}_i(T_r) - \mathbf{X}_i(T_t)\| \le (c_f - \sigma)(T_r - T_t) < c_f(T_r - T_t)$ forbids a nontrivial same-transmitter causal root. Therefore a candidate self-hit orbit must reach field speed somewhere in its retained history. This is a root-existence condition, not a damping theorem or a proof of binding. Under the transmitter-side law the receiver-velocity resistance term does not exist; stabilization, if present, must be demonstrated by the full delayed branch geometry, singular-event routing, and conserved wake-state accounts.

Connection to quantum behavior: At this chapter's claim level, non-Markovian memory and deterministic-but-complex self-hit dynamics are a candidate substrate mechanism for effective quantum-like behavior, not yet a derivation of the quantum formalism:

- effective guidance by self-interference and causal-wake history,
- discrete stable states as attractors in phase space,
- measurement uncertainty as receiver-level informational ambiguity.

An important open problem is to map the phase-space attractor landscape for self-hit binaries, including basin size for maximum-curvature orbits, escape conditions, and the existence of secondary attractors such as long-lived elliptical families.

Worked Examples (Analytic Baselines)

Stationary Opposite Charges (Radial Fall)

Setup:

- Two architrinos: Electrino at $\mathbf{X}_1(T)$, Positrino at $\mathbf{X}_2(T)$
- Initial conditions: Both at rest, separated by distance d_0
- No self-hits (speeds remain $< c_f$ if d_0 is not too small)

Symmetry: By polarity symmetry, both fall toward their common center of mass.

Equations: On a retained partner branch, the radial coordinate
$r(T) = \|\mathbf{X}_2(T) - \mathbf{X}_1(T)\|$ has the canonical receiver-side schematic form
with transmitter-side acceleration weight:

$$\frac{d^2 r}{dT^2} = -\frac{2\kappa\epsilon^2}{r^2} W_p^{\mathrm{acc}} \quad \text{on the retained branch}$$

where the factor of 2 comes from the symmetry when both sides consume the same
retained partner record. The stripped inverse-square form is only the
near-rest, single-branch calibration $W_p^{\mathrm{acc}} \approx 1$, not a
canonical proof record.

Solution structure: The slow, single-branch calibration has the same
quadrature structure as Keplerian radial fall. A promoted branch must keep the
same-record D_t, D_r, and W^{acc} record.

Key insight: Partner attraction dominates; no self-hit (speeds remain sub-field-speed for moderate d_0).

Sub-Field-Speed Circular Orbit

Setup:

- Two opposite polarities in symmetric circular orbit at radius R, speed $v < c_f$

- No self-hits (sub-field-speed regime)

Partner contribution: The circular transmitter-side geometry nominates an inward radial diagnostic and a tangential-sign diagnostic. In the canonical Master EOM, those records are not acceleration verdicts until the same partner branch emits D_t, D_r, and W^{acc}.

Result: The transmitter-side circular sign record is an orientation diagnostic, not the proof. The exact receiver-side calculation later in this chapter supplies the canonical weighted acceleration and proves that the principal partner branch cannot be a constant-speed circle because its tangential acceleration is strictly positive. Stability of a broader multi-root or medium-coupled branch remains a separate question.

Maximum-Curvature Orbit (Self-Hit Barrier)

Setup:

- A candidate opposite-polarity branch reaches super-field-speed curved history after a non-circular contraction, capture, or forced branch transition
- Self-hits activate → repulsive outward acceleration

Geometric definition (Null Separatrix):
For an active causal root $T_t \in \mathcal{C}_{ii}(T_r)$ on the self-hit branch, define

$$J_{ii}(T_r; T_t) \equiv 1 - \frac{\mathbf{V}_i(T_t) \cdot \hat{\mathbf{r}}_{ii}(T_r; T_t)}{c_f}$$

The maximum-curvature binary (MCB) boundary is the Jacobian-degenerate set

$$J_{ii}(T_r; T_t) = 0$$

with approach from the admissible side $J_{ii} > 0$. Geometrically, this is the state where the receiver trajectory is tangent to the causal wake surface of its own past emission (the “riding-the-shock” limit).

Why this is a hard wall in the exact theory:
In the exact branch-resolved acceleration, the self-hit contribution carries the factor

$$\frac{W_{ii}^{\mathrm{acc}}(T_r; T_t)}{r_{ii}^2(T_r; T_t)}$$

On a generic off-circular branch, $D_{t,ii} \to 0$ makes the ideal branch-resolved pointwise response diverge whenever the remaining geometry stays regular. A uniform-circular retained root is a special chart: the circular root-playback identity gives $D_{r,ii} = D_{t,ii}$, so both factors vanish together and the event must be handled as a fold rather than under a bounded-nonzero-D_r hypothesis. In either case, the divergence should not be treated as a literal state pinned at infinite acceleration. Across a simple caustic transit, Caustic Transit and Finite Impulse shows that the integrated velocity change can remain finite; with finite numerical regularization $\eta > 0$, the event appears as a large but finite impulse that sharpens as $\eta \to 0$.

This transmitter-side fold is therefore an **amplitude pole** for the self branch. It is not, by itself, a theorem of circular closure. The same transmitter-side acceleration weight multiplies every projection of the self-hit acceleration, including the tangential component, so contact with $D_{t,ii} = 0$ requires a certified event treatment and does not by itself establish a periodic orbit or zero net cycle-averaged kinetic-rate change.

Operational characterization of MCB:

- The inner branch evolves by caustic grazing near $J_{ii} = 0$, with finite impulses across the regularized boundary rather than exact pinning on an infinite-acceleration surface.

- The minimum radius $R_{\min}$ is the smallest orbit radius compatible with $J_{ii} \geq 0$ on active roots.
- Tangential power must be controlled separately; near-zero cycle-average power is an additional closure condition, not a consequence of $J_{ii} = 0$ alone.

Significance:

- Nominates a candidate inner scale $R_{\min}$; it does not define a fundamental length until one retained bound branch is certified
- Supplies an outward null-separatrix barrier candidate against $r \to 0$ collapse, subject to a finite accepted transition rule at the singular event
- Supplies one geometric ingredient in candidate stable assemblies such as Noether braids without acting as their centripetal binder

Status split (analytic vs numeric):

- **Derived:** Existence of the Jacobian-null boundary and the outward sign of every circular self-hit radial projection.
- **Measured on the unregularized circular simple-root chart:** Algebraic partner-plus-self acceleration-balance candidates exist, but they are not retained or stable branch records.
- **Numeric still required:** A common finite singular-event convention, retained-history persistence, basin size, return-map stability, and long-time capture probability for realistic multi-body assemblies.

Informational Ambiguity at the Receiver

Limited Information Per Hit

From the perspective of the receiving architrino, the information carried by an intersecting causal isochron is **limited**. The receiver only knows:

1. The **net strength** of the potential at the point of intersection (through the acceleration magnitude $\|\mathbf{F}\|$ when force bookkeeping is used).
2. The **unoriented line of action** through its current position (the line along which the acceleration points).

The receiver does **not** have direct knowledge of:

- The transmitter's identity (which architrino j?)
- The transmitter's precise distance r_{ij} (without additional assumptions)
- The transmitter's velocity at emission $\mathbf{V}_j(T_t)$

Ambiguity: Electrino vs Positrino on Opposite Sides

A particularly important ambiguity: the receiver cannot distinguish between:

- A **negative potential** due to an Electrino (polarity $-\epsilon$) on one side of the line of action, and
- A **positive potential** due to a Positrino (polarity $+\epsilon$) on the **opposite side** of the same line,

if the resulting radial acceleration is the same.

Example: An acceleration **towards** a point along the line of action could be interpreted as:

- Attraction to a Positrino at that point, **or**
- Repulsion from an Electrino located at the diametrically opposite point on the same line.

Rest-Frame Recast (Useful Inference Device)

Any single hit can be **equivalently described** with a **stationary surrogate transmitter** ($\|\mathbf{V}\| = 0$) placed somewhere along the same unoriented line of action, with the actual transmitter speed at emission accounted for by an adjusted emission time and, if desired, a surrogate location along that line.

Key property: The same emission law is preserved in this recast; the velocity dependence is transferred into the adjusted emission geometry and the matched transmitter-side acceleration weight.

Utility: This recast simplifies some analytic calculations and provides intuition for the receiver's "inference problem" (what transmitter configurations are consistent with a given hit?).

Superposition Complicates Inference

The ambiguity is compounded by **superposition**: The net potential at any instant is the sum of all intersecting expanding causal wake surfaces. A measured potential along a single radial can be the consequence of a **complex confluence of wakes** from many different transmitters located along that line of action, arriving from both directions.

Consequence: The receiver experiences a **deterministic acceleration** (given full microstate knowledge, as known to the $\mathbb{U}_{\text{now}}$ universe-state perspective), but has **incomplete local information** about the transmitter configuration.

Connection to Quantum Measurement Uncertainty

This limited, unoriented, and transmitter-ambiguous information at the hit level is a candidate bridge to effective quantum-like behavior and measurement uncertainty from deterministic micro-dynamics. The bridge remains a closure target until the coarse-grained state map and record-formation dynamics are derived:

- **Wave function transition**: ψ may be interpreted as a coarse-grained representation of the wake-defined potential landscape only after a density/phase map has been supplied.
- **Measurement interaction**: an outcome is a record formed by assembly interactions and causal-hit history, not by adding a fundamental collapse postulate at this level.
- **Uncertainty**: the native candidate mechanism is informational ambiguity at the receiver plus unresolved microstate sensitivity, not ontic randomness.

Parameters and Numerical Implementation

Parameter Definitions

The core parameters entering the Master Equation are:

Parameter	Symbol	Working convention	Dimensional	Comment
Wake speed	c_f	Set to 1 in natural units unless otherwise stated	$\mathrm{L\,T^{-1}}$	Propagation speed in the causal constraint
Coupling constant	κ	Universal coupling parameter	$\mathrm{L^3\,T^{-2}\,Q^{-2}}$	Controls the strength of the inverse-square interaction
Architrino polarity unit	ϵ	$\lvert e\rvert/6$	Q	Fundamental polarity magnitude
Causal-wake-surface thickness (regularization)	η	Positive regularization width used in analysis and simulation	L	Mollifies delta singularities

In this document, c_f is treated primarily as a unit-setting convention, κ as the universal coupling scale of the delayed interaction law, ϵ as the fundamental polarity unit, and η as a regularization parameter used only when a smooth surrogate of the exact causal-wake dynamics is required.

Numerical Implementation Notes

Delay Root-Finding Algorithms

At each reception step T_r, the numerical integrator must solve the **implicit causal constraint** for each transmitter j:

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t), \quad T_t < T_r$$

Algorithm (schematic):

1. For each transmitter j, search the history buffer $\{\mathbf{X}_j(T') : T' < T_r\}$ for all T_t satisfying the constraint.

2. Use **bisection** or **Newton-Raphson** to refine roots to tolerance ϵ_{root}.
3. If multiple roots exist (multi-hit regime), enumerate all; sum their contributions.
4. If no roots exist (transmitter too far away or not yet causal), skip transmitter j at this time step.

Efficiency: Use **history binning** or **spatial hashing** to avoid exhaustive search over all past times.

Spatial Hashing for History Buffers

Efficiency requirement: Naïve all-pairs history search scales as $O(N^2 T_{\text{history}})$, intractable for $N > 100$ particles.

Required optimization: Implement spatial hash grid with cell size $\sim c_f \Delta T_{\max}$; only search cells within causal range of receiver. Expected scaling: $O(N \log N)$.

Implementation notes:

- Partition spatial domain into cubic cells of side length $\Delta_{\text{cell}} \approx c_f T_{\text{history,max}}$
- At each time step, bin all architrino positions into cells
- For receiver at $\mathbf{X}_i(T)$, only search cells within causal radius $r_{\max} = c_f T_{\text{history}}$
- Update hash grid incrementally (not from scratch each step)

Time-Stepping Schemes for DDEs

The Master EOM is a **state-dependent DDE** (delay depends on the solution itself). Standard ODE integrators (e.g., RK4) must be adapted:

Recommended methods:

- **Fixed-point iteration** with predictor-corrector (for implicit delays)
- **Adaptive time-stepping** (small ΔT when roots are close or numerous)
- **Event detection** for exact root crossings (optional; improves accuracy in sharp-hit regime)

Stability: Ensure $\Delta T < \eta / c_f$ (resolve mollified wake surface width); adjust η and ΔT together in convergence tests.

Emission-to-Receiver Provenance Tracking

For debugging and interpretation:

At each hit, log:

- Transmitter ID j
- Emission time T_t
- Emission position $\mathbf{X}_j(T_t)$
- Reception time T_r
- Reception position $\mathbf{X}_i(T_r)$
- Per-hit acceleration contribution (bookkeeping variable $\mathbf{F}_{ij}(T_r; T_t)$)

Use cases:

- Visualize causal cones and causal isochrons
- Identify self-hit events and winding numbers
- Trace energy transfer pathways
- Validate superposition (sum of logged accelerations = total acceleration?)

Analytic Regimes and Research Roadmap

Summary and Key Takeaways

What This Document Establishes

The **Master Equation of Motion** is the deterministic law governing the evolution of all architrinos:

$$\frac{d^2\mathbf{X}_i}{dT_r^2} = \sum_j \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\mathrm{acc}}(T_r;T_t)\, \hat{\mathbf{r}}_{ij}$$

Key features:

1. **Event-local at the receiver**: Only intersecting delayed causal wake surfaces contribute (no action-at-a-distance).
2. **Non-Markovian**: Depends on full path history (self-hit memory).
3. **Superposition**: Linear sum over all transmitters and causal roots.
4. **Self-hit**: Repulsive same-transmitter interaction when $\mathcal{C}_{ii}(T_r)$ is nonempty with a valid transversality floor and a retained transmitter-side acceleration weight; super-field-speed interval history is proved necessary for simple nontrivial roots and can persist as memory after slowing down.
5. **Radial line of action with transmitter-side weighting**: No magnetic or velocity-cross-product terms; all per-hit accelerations point along $\hat{\mathbf{r}}_{ij}$, with magnitude modulated by $W_{ij}^{\mathrm{acc}} = c_f/|D_{t,ij}|$.

Implications for Emergent Phenomena

The equation supplies the microscopic input for later emergence claims, but it does not by itself prove those claims. The status split is:

- **Binary stabilization**: supported by self-hit barriers and circular/spiral benchmarks; exact stable branches still require certified branch charts and tangential-power closure.
- **Noether braids and particle assemblies**: downstream assembly claims that must be derived from multi-body causal-root locking and hierarchy averaging.
- **Quantum behavior**: an effective closure target based on non-Markovian memory, attractor basins, and receiver-level informational ambiguity.
- **Observer-level geometry and gravity**: effective descriptions that must be recovered from Noether sea constitutive response and clock/ruler closure, not inserted into the substrate law.
- **Cosmology**: an effective observer-side program tied to Noether sea evolution, transport, and clock-rate comparison; the Euclidean void itself is not claimed to expand.

Fully general case (arbitrary N, arbitrary trajectories)

The master EOM is a coupled system of **state-dependent delay differential equations** with:

- non-linear dependence on all worldlines,
- implicit causal roots defined by
  $\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t)$,
- potentially **multiple roots** per pair (multi-hit, self-hit),
- non-smooth behavior in the $\eta \to 0$ limit.

In PDE/DDE theory, systems of this type almost never admit closed-form analytic solutions except in toy limits.

- **Claim:** There is no expectation of general analytic solutions for arbitrary N and trajectories.
- The tractable analytic targets are:
  - Existence/uniqueness theorems in broad classes,
  - qualitative theory (invariants, attractors, bifurcations),
  - asymptotic approximations (multipole / far-field, continuum limits),

- special highly symmetric exact solutions.

This status is not exceptional: even Newtonian N-body gravity is analytically intractable in the generic case, and the Master EOM adds state-dependent delays and self-hit branch structure.

Ideal / symmetric cases where analytic work is realistic

The most tractable cases are the highly symmetric regimes in which closed forms or controlled approximations remain plausible.

Static / quasi-static limit (Coulomb analogue)

Assumptions:

- All particles move slowly: $\|\mathbf{V}_j\| \ll c_f$,
- Configuration changes on timescales long compared to light-crossing time across the system,
- No self-hits (sub-c_f everywhere, weak curvature).

Then:

- For each pair (i, j), the causal root is essentially unique and very close to the current quasi-static causal emission time.
- We can neglect acceleration and velocity corrections in the past-emission position.

To leading order, we should recover:

- A **Coulomb-like 1/r^2 law** between quasi-static sources,
- The usual Kepler-like two-body dynamics.

Analytic status:

- Two-body problem in this limit: solvable exactly (ellipses, etc.).
- N-body: same qualitative status as Newtonian gravity/electrostatics—no closed form in general, but standard perturbation methods apply.

This is the basic consistency-check regime of the theory.

Two-body, 1D radial motion (head-on, no angular momentum)

Setup:

- Two opposite polarities on a line, starting at rest, moving directly toward each other,
- Symmetry: center-of-mass at rest, only radial variable $r(T)$,
- Speeds sub-c_f so no self-hit.

Then:

- Causal delay gives a small correction; in the slow regime we can treat it perturbatively.
- To zeroth order, the reduced equation is:

$$\frac{d^2r}{dT^2} = -\frac{2\kappa\epsilon^2}{r^2}$$

which has an exact analytic solution for $r(T)$ (same mathematics as Kepler fall-to-center).

We can:

- Write the exact integral for $T(r)$, and invert in special cases.
- Then treat causal delay as a small parameter $\epsilon_{\text{delay}} \sim r/c_f T$ and develop a systematic expansion.

The reduced problem is analytic up to standard quadratures, with causal-delay corrections available as a systematic perturbation series.

For the local origin-crossing theorem program in the self-hit-capable collinear reduction, the working 1D model is dual-mollified rather than merely causal-surface-regularized: the causal-surface mollifier δ_η still selects delayed roots, while a separate core mollifier ϵ_c is imposed on the inverse-square amplitude so the post-crossing local vector field remains finite.

Sub-Field-Speed Two-Body Uniform Circular Orbit

Consider the symmetric opposite-polarity circular ansatz

$$\mathbf{X}_1(T) = R(\cos\omega T, \sin\omega T, 0), \qquad \mathbf{X}_2(T) = -\mathbf{X}_1(T), \qquad \beta_f \equiv \frac{v}{c_f} = \frac{\omega R}{c_f} \in (0,1)$$

Fix receiver 1 at reception time T_r and let the unique partner emission time be $T_t = T_r - \Delta$, with

$$\xi \equiv \frac{\omega\Delta}{2} \in \left(0, \frac{\pi}{2}\right)$$

Write $\mathbf{e}_r(T_r) = (\cos\omega T_r, \sin\omega T_r, 0)$ and
$\mathbf{e}_\theta(T_r) = (-\sin\omega T_r, \cos\omega T_r, 0)$ for the receiver polar frame.

Proposition (Unique partner branch and exact delay equation)

In the symmetric sub-c_f circular ansatz, the partner branch is unique and its delay angle ξ is the unique solution of

$$\cos\xi = \frac{\xi}{\beta_f}, \qquad 0 < \xi < \frac{\pi}{2}$$

Proof.
The partner separation is

$$\mathbf{r}_{12}(T_r; T_t) = \mathbf{X}_1(T_r) - \mathbf{X}_2(T_t) = R\big(\mathbf{e}_r(T_r) + \mathbf{e}_r(T_r - \Delta)\big)$$

so

$$r_{12}(T_r; T_t) = 2R\cos\frac{\omega\Delta}{2} = 2R\cos\xi$$

The causal condition $r_{12} = c_f\Delta$ therefore becomes

$$2R\cos\xi = c_f\frac{2\xi}{\omega}$$

hence $\cos\xi = \xi/\beta_f$.
Define $h_{\beta_f}(\xi) = \cos\xi - \xi/\beta_f$ on $[0, \pi/2]$. Then

$$h_{\beta_f}(0) = 1 > 0, \qquad h_{\beta_f}\left(\frac{\pi}{2}\right) = -\frac{\pi}{2\beta_f} < 0, \qquad h'_{\beta_f}(\xi) = -\sin\xi - \frac{1}{\beta_f} < 0$$

So h_{β_f} is strictly decreasing and has exactly one root on $(0, \pi/2)$. □

Lemma (Circular root-playback identity)

On every nondegenerate root of the uniform circular partner and self-hit charts,
the receiver-side factor equals the transmitter-side factor:

$$D_r = D_t.$$

For the partner branch below, both transmitter and receiver velocity projections onto $\hat{\mathbf{r}}_{12}$ equal $-v\sin\xi$. For a uniform circular self root, the
same rotational symmetry makes the transmitter and receiver projections equal on the same signed chord sheet. Thus the signed playback derivative is one, but the acceleration weight remains

$$W^{\mathrm{acc}} = \frac{c_f}{|D_t|} = \frac{1}{|J^t|}.$$

Root playback and acceleration strength do not cancel one another.

Proposition (Exact partner-only circular receiver-side decomposition)
For the unique partner branch above,

$$\hat{\mathbf{r}}_{12} = \cos\xi\,\mathbf{e}_r(T) - \sin\xi\,\mathbf{e}_\theta(T), \qquad r_{12} = 2R\cos\xi, \qquad J^t_{12} = 1 + \beta_f\sin\xi, \qquad W^{\mathrm{acc}}_{12} = \frac{1}{1+\beta_f\sin\xi}$$

Since the charges are opposite, the partner acceleration on receiver 1 is

$$\mathbf{A}_{12} = -\frac{\kappa|q_1q_2|}{4R^2\cos^2\xi}\frac{1}{1+\beta_f\sin\xi}\left(\cos\xi\,\mathbf{e}_r(T) - \sin\xi\,\mathbf{e}_\theta(T)\right)$$

Therefore the exact radial and tangential components are

$$a_r^{(\mathrm{part})} = -\frac{\kappa|q_1q_2|}{4R^2\cos\xi\,(1+\beta_f\sin\xi)} < 0$$

$$a_\theta^{(\mathrm{part})} = \frac{\kappa|q_1q_2|\,\sin\xi}{4R^2\cos^2\xi\,(1+\beta_f\sin\xi)} > 0$$

Proof.
Using

$$\mathbf{e}_r(T-\Delta) = \cos(2\xi)\,\mathbf{e}_r(T) - \sin(2\xi)\,\mathbf{e}_\theta(T)$$

one finds

$$\mathbf{r}_{12} = R\big(\mathbf{e}_r(T) + \mathbf{e}_r(T-\Delta)\big) = 2R\cos\xi\,(\cos\xi\,\mathbf{e}_r(T) - \sin\xi\,\mathbf{e}_\theta(T))$$

which gives the stated r_{12} and $\hat{\mathbf{r}}_{12}$.
The transmitter velocity at emission is

$$\mathbf{V}_2(T_t) = -v\,\mathbf{e}_\theta(T-\Delta)$$

and

$$\mathbf{e}_\theta(T-\Delta)\cdot\hat{\mathbf{r}}_{12} = \sin\xi$$

so

$$\mathbf{V}_2(T_t)\cdot\hat{\mathbf{r}}_{12} = -v\sin\xi, \qquad J^t_{12} = 1 - \frac{\mathbf{V}_2(T_t)\cdot\hat{\mathbf{r}}_{12}}{c_f} = 1 + \beta_f\sin\xi$$

The receiver velocity is $\mathbf{V}_1(T) = v\mathbf{e}_\theta(T)$, and

$$\mathbf{V}_1(T)\cdot\hat{\mathbf{r}}_{12} = -v\sin\xi.$$

Therefore $D_r = D_t = c_f(1 + \beta_f \sin\xi)$ and
$W_{12}^{\mathrm{acc}} = (1 + \beta_f \sin\xi)^{-1}$ on this uniform circular branch.
Because $\sigma_{12} = -1$ for opposite polarities, the canonical branch acceleration is
$-\kappa|q_1 q_2|\hat{\mathbf{r}}_{12}/[r_{12}^2(1 + \beta_f \sin\xi)]$,
and projecting onto $\mathbf{e}_r(T)$ and $\mathbf{e}_\theta(T)$ yields the
stated components. Since $\xi \in (0, \pi/2)$, every denominator is positive and
$\sin\xi > 0$, proving the sign claims. □

Corollary (Tangential positivity and circular instability)

Within the isolated partner-only circular ansatz, the tangential power is strictly positive:

$$\mathbf{A}_{12} \cdot \mathbf{V}_1(T) = v\, a_\theta^{(\mathrm{part})} > 0$$

Therefore an isolated opposite-polarity binary cannot realize an exact constant-speed circular orbit from partner delay alone.

Interpretation.
These are the exact transmitter-side partner-only circular formulas needed elsewhere in the chapter. They show that the delayed partner branch supplies inward radial pull, but it also drives the motion forward along $\mathbf{e}_\theta$. The transmitter-side transmitter-side denominator rescales both projections without changing their signs. Any tightening history must be certified on a non-circular branch or by an explicit finite-window conserved-account closure.

Super-Field-Speed Single-Architrino Uniform Circular Self-Hit

This is the key toy model for self-hit/maximum curvature.

Take:

- One architrino on a circle of radius R, angular speed ω, velocity $v = \omega R > c_f$.
- We ignore partner acceleration contributions; pure self-hit geometry.

Then causal condition:

$$\|\mathbf{X}(T) - \mathbf{X}(T_t)\| = 2R\left|\sin\frac{\omega(T_r - T_t)}{2}\right| = c_f(T_r - T_t)$$

Let $\Delta = T_r - T_t > 0$. Then:

$$2R\left|\sin\frac{\omega\Delta}{2}\right| = c_f\Delta$$

Introduce the dimensionless variables

$$\beta_f = \frac{v}{c_f} = \frac{\omega R}{c_f}, \qquad \xi = \frac{\omega\Delta}{2}$$

Then the circular self-hit condition becomes

$$|\sin\xi| = \frac{\xi}{\beta_f}, \qquad 0 < \xi < \beta_f$$

For fixed $\beta_f > 1$, the admissible self-hit set is therefore **finite**, not infinite: roots are exactly the intersections of $|\sin\xi|$ with the line ξ/β_f inside the compact interval $(0, \beta_f)$. Dropping the absolute value restricts the calculation to the positive-sine sheets and omits physical roots on alternating half-windings.

The principal branch turns on at $\beta_f = 1$. Writing $\beta_f = 1 + \mu$ with $\mu > 0$ small, the smallest root obeys

$$\xi_0 \sim \sqrt{6\mu}, \qquad \Delta_0 \sim \frac{2\sqrt{6\mu}}{\omega}, \qquad r_0 = c_f \Delta_0 \sim 2R\sqrt{6\mu}$$

The associated circular transmitter-side Jacobian diagnostic is

$$J_n = 1 - \frac{\mathbf{V}(T-\Delta_n)\cdot\hat{\mathbf{r}}_n}{c_f} = 1 - \beta_f \cos\xi_n = 1 - \xi_n \cot\xi_n$$

On the principal branch,

$$J_0 \sim 2\mu$$

The transmitter-side coarea diagnostic therefore scales like

$$\frac{1}{r_0^2|J_0|} \sim \frac{1}{48R^2\,\mu^2}$$

This is also the canonical transmitter-side scaling on the nondegenerate side of the uniform circular chart, because $W_0^{\mathrm{acc}} = 1/|J_0|$. Thus the principal self-root amplitude scales as $O(\mu^{-2})$ near its coincident endpoint birth. The endpoint exclusion alone does not make that transition finite; it remains a failed singular event until one regularized treatment certifies a finite accepted impulse and the corresponding conserved accounts.

Higher branches are also tractable. For the circular root function

$$g_{\beta_f}(\xi) \equiv \sin\xi - \frac{\xi}{\beta_f}$$

new admissible roots can appear only at interior tangencies satisfying

$$g_{\beta_f}(\xi) = 0, \qquad g'_{\beta_f}(\xi) = 0$$

Eliminating β_f gives the tangency equation

$$\tan\xi = \xi$$

and the corresponding threshold speed is

$$\beta_f^\star = \sec\xi^\star$$

At every such tangency,

$$J^\star = 1 - \beta_f^\star \cos\xi^\star = 0$$

So each new circular self branch is born directly on a Jacobian-null boundary: branch creation and null-separatrix contact are the same event in the uniform circular toy model.

> **Proposition (Signed higher-winding circular branch birth).**
> The circular distance equation should be read branchwise as

$$> g_{\beta_f,s}(\xi) \equiv s\sin\xi - \frac{\xi}{\beta_f} = 0, > \qquad > s = \mathrm{sign}(\sin\xi) \in \{+1,-1\}. >$$

> For each higher half-winding $n \ge 1$, set

$$> I_n = \left(n\pi, \left(n+\frac{1}{2}\right)\pi\right), > \qquad > s_n = (-1)^n, >$$

> and let $\xi_n^\star \in I_n$ be the unique positive solution of

$$> \tan \xi_n^\star = \xi_n^\star. >$$

> The signed branch-birth speed is

$$> \beta_n^\star >=> s_n \sec \xi_n^\star >=> |\sec \xi_n^\star| >=> \sqrt{1+(\xi_n^\star)^2}. >$$

> If

$$> a_n = \left(n + \frac{1}{2}\right)\pi, >$$

> then

$$> \xi_n^\star = a_n - \frac{1}{a_n} + O(a_n^{-3}), > \qquad > \beta_n^\star = a_n - \frac{1}{2a_n} + O(a_n^{-3}). >$$

> For $\beta_f = \beta_n^\star + \mu$ with $0 < \mu \ll 1$, the two newly active roots satisfy

$$> \xi_{n,\pm}(\beta_f) >=> \xi_n^\star > \pm > \sqrt{\frac{2\mu}{\beta_n^\star}} > +O(\mu), >$$

> and their transmitter-side Jacobians have opposite signs:

$$> J_{n,\pm} >=> 1 - \beta_f s_n \cos \xi_{n,\pm} >=> \pm \xi_n^\star > \sqrt{\frac{2\mu}{\beta_n^\star}} > +O(\mu). >$$

> Thus a higher-winding fold creates a signed root pair on a Jacobian-null boundary. Since $r_{n,\pm} \to 2R\xi_n^\star/\beta_n^\star \neq 0$, the transmitter-side diagnostic part of the branch kernel scales as

$$> \frac{1}{r_{n,\pm}^2 |J_{n,\pm}|} >=> O(\mu^{-1/2}). >$$

> The causal-action coarea weight is a separate collapse factor:

$$> g'_{\beta_f,s_n}(\xi_{n,\pm}) >=> s_n \cos \xi_{n,\pm} - \frac{1}{\beta_f} >=> -\frac{J_{n,\pm}}{\beta_f}, >$$

> so the action-counting density carries an additional $|g'_{\beta_f,s_n}|^{-1}$ and scales as $O(\mu^{-1})$ at fixed nonzero $r_n^\star$. Under the transmitter-side law the acceleration weight is already $W^{\mathrm{acc}} = c_f/|D_t| = 1/|J^t|$. Action counting remains a separate variational question and may not be inferred by multiplying the acceleration by signed root playback.
>
> Consequently the circular self-hit combinatorics remain linearly bounded in β_f. A one-sign subchart has

$$> N_{\mathrm{self}}^{(+)}(\beta_f) = \frac{\beta_f}{\pi} + O(1), >$$

> while the full signed $|\sin \xi|$ chart has the same no-proliferation form with the convention-dependent leading constant.

> **Benchmark Proposition (Circular branch-count bound).**
> In the symmetric circular benchmark, if the speed ratio obeys

$$> |\beta_f(T)| \leq \beta_{\max} < \infty >$$

> uniformly, then the active circular self-hit count is uniformly bounded:

$$> N_{\mathrm{self}}(T) >\leq> \frac{\beta_{\max}}{\pi} + C_{\mathrm{circ}}, >$$

> where

$$> C_{\mathrm{circ}} >$$

> is an absolute endpoint-count constant for the circular root equation. This supplies the missing branch-count input in the continuation criterion for that benchmark. A general super-field-speed trajectory still needs its own no-proliferation theorem; tight spirals or repeatedly folded histories can otherwise leave the finite-branch chart even without speed blowup, collision, or a single Jacobian floor loss. The natural generalization is a curvature-bounded no-proliferation lemma: on a retained interval with bounded speed, bounded curvature or total turning, positive separation, and the declared transversality floor away from finite folds, active causal roots should remain uniformly finite. Until such a lemma is proved for a trajectory class, the circular bound is a benchmark, not a global branch-count theorem.

This circular benchmark already:

- Gives us analytic control of the causal roots (as solutions of a simple scalar transcendental),
- Lets us write the transmitter-side self-acceleration target as

$$\mathbf{A}_{\mathrm{self}}(T) = \sum_n \kappa \frac{q^2}{r_n^2} W_n^{\mathrm{acc}} \hat{\mathbf{r}}_n$$

with $r_n = c_f \Delta_n$, $W_n^{\mathrm{acc}} = 1/|J_n|$ on nondegenerate uniform circular roots, and directions that can be written explicitly in terms of the phase difference.

The benchmark does not provide an elementary closed-form sum, but it gives the following controlled inputs:

- the root geometry is explicitly analyzable,
- At high speed the number of admissible roots grows only linearly with β_f because all roots lie in $(0, \beta_f)$,
- Large-n roots admit asymptotic expansions,
- the canonical self-acceleration series can be studied away from circular root-map degeneracies,
- and the asymptotic radial/tangential components can be recomputed as functions of v/c_f.

Near a circular transmitter-side degeneracy, D_r approaches zero with D_t, so the signed root-playback derivative stays equal to 1 on the nondegenerate roots. The acceleration weight $W_n^{\mathrm{acc}} = c_f/|D_t|$ instead grows without bound as the simple-root chart approaches $D_t = 0$. The pointwise simple-root formula does not continue through the birth event; only an accepted finite transition rule could replace it there.

This is therefore a root-transversality and branch-birth statement, not a closure theorem. A circular self branch born on $D_t = 0$ marks a chart boundary; it does not supply a singular receiver-side amplitude on the uniform circular ansatz. Any locked-orbit claim must still control the signed radial and tangential sums on a retained branch chart.

The circular benchmark is therefore useful for:

- deriving a condition for equilibrium between self-repulsion and an imposed centripetal requirement,
- defining $R_{\min}(v)$ and in particular the extremal radius / speed.

The same circular chart also gives a branchwise acceleration decomposition. On the positive-sine self-hit subchart, every active root satisfies

$$\sin\xi = \frac{\xi}{\beta_f}, \qquad r = 2R\sin\xi = 2R\frac{\xi}{\beta_f}, \qquad J = 1 - \beta_f\cos\xi = 1 - \xi\cot\xi$$

Resolving the line-of-action direction into the instantaneous circular frame gives

$$\hat{\mathbf{r}}(\xi) = \sin\xi\,\mathbf{e}_r + \cos\xi\,\mathbf{e}_\theta$$

With

$$C = \frac{\kappa q^2}{4R^2}$$

and uniform-circular transmitter-side acceleration weight

$$W_s^{\mathrm{acc}}(\xi) = \frac{c_f}{|D_t(\xi)|} = \frac{1}{|J(\xi)|},$$

the branchwise self-hit projections are therefore

$$a_r(\xi) = C\frac{\beta_f}{\xi|J(\xi)|}, \qquad a_\theta(\xi) = C\frac{\beta_f^2\cos\xi}{\xi^2|J(\xi)|}$$

Thus the radial projection is outward on every active self root, while the tangential projection is controlled entirely by the sign of $\cos\xi$.

> **Proposition (Circular self-hit radial sign and principal tangential threshold).**
> On every nondegenerate root of the full uniform-circular self-hit equation, the radial projection is strictly outward. On the principal root $\xi_0 \in (0,\pi)$, the tangential projection is forward for $1 < \beta_f < \pi/2$, zero at $\beta_f = \pi/2$, and backward for $\beta_f > \pi/2$.
>
> **Proof.** On the full signed chart, let

$$> s_\xi = \operatorname{sign}(\sin\xi) >$$

> so

$$> \hat{\mathbf{r}}(\xi) >=> |\sin\xi|\,\mathbf{e}_r + s_\xi\cos\xi\,\mathbf{e}_\theta >$$

> The canonical multiplier $C/(\sin^2\xi\,|J|)$ is positive away from a fold. Therefore the radial coefficient is proportional to $|\sin\xi| > 0$, while the tangential sign is $\operatorname{sign}(s_\xi\cos\xi)$. On the principal branch $s_\xi = +1$ and

$$> \beta_f = \frac{\xi_0}{\sin\xi_0} >$$

> is strictly increasing on $(0,\pi)$ because $\sin\xi_0 - \xi_0\cos\xi_0 > 0$. The tangential sign changes only at $\xi_0 = \pi/2$, where the root equation gives

$$> \beta_f = \frac{\pi/2}{\sin(\pi/2)} = \frac{\pi}{2} >$$

> This proves both statements. □

The threshold $\beta_f = \pi/2$ is exact for the principal root of this uniform-circular chart with the present emission-point-to-reception-point line of action. It is not a speed-only theorem for a non-circular history, a multi-architrino assembly, or a kernel whose line of action is defined from another point.

Here "tangential power" means the kinematic rate $\mathbf{A}\cdot\mathbf{V} = v\,a_\theta$ on the circular chart, so it has the same sign as a_θ. Converting that rate into the quadratic assembly-level energy bookkeeping uses $\mu_{\mathrm{arch}}\mathbf{A}\cdot\mathbf{V}$ and does not assign physical mass to an architrino.

The branch sheets have the following one-sign structure:

Sheet	Root status for $\sin\xi = \xi/\beta_f$	Radial projection	Tangential projection
Negative sine lobes	No roots, because $\xi/\beta_f > 0$	Inactive	Inactive
First positive lobe	One nonzero root for $\beta_f > 1$	Outward	Forward for $\cos\xi > 0$, backward for $\cos\xi < 0$
Higher positive left sheets	One root after birth from a Jacobian-null fold	Outward	Forward
Higher positive right sheets	Paired root after the same birth	Outward	Backward

Away from fold neighborhoods, substituting the canonical transmitter-side weight $W_s^{\mathrm{acc}} = 1/|J|$ gives the formal large-β_f sums

$$A_{r,\mathrm{src}}^{\mathrm{diag}}(\beta_f) = \frac{C}{\pi}\log\beta_f + O(C)$$

and

$$A_{\theta,\mathrm{src}}^{\mathrm{diag}}(\beta_f) = -\frac{C\beta_f}{12} + O(C\log\beta_f)$$

The corresponding absolute tangential activity is

$$\sum_{\xi_n} |a_{\theta,\mathrm{src}}^{\mathrm{diag}}(\xi_n)| = \frac{C\beta_f}{6} + O(C\log\beta_f)$$

These are formal simple-root transmitter-side sums, not accepted global acceleration certificates, because their treatment of fold neighborhoods and coincident branch births is incomplete. The signed tangential constants must be recomputed with the same regulated event convention before any cancellation estimate is promoted.

The full signed $|\sin\xi|$ circular chart uses $s = \mathrm{sign}(\sin\xi)$ and

$$s\sin\xi = \frac{\xi}{\beta_f}, \qquad J = 1 - \beta_f s\cos\xi, \qquad \hat{\mathbf{r}}(\xi) = |\sin\xi|\,\mathbf{e}_r + s\cos\xi\,\mathbf{e}_\theta$$

Thus the full signed-chart projections, including the canonical transmitter-side weight, are

$$a_r^{|\sin|}(\xi) = C\frac{\beta_f}{\xi|J(\xi)|}, \qquad a_\theta^{|\sin|}(\xi) = C\frac{\beta_f^2 s\cos\xi}{\xi^2|J(\xi)|}$$

The radial contribution is still outward on every active self root. The tangential contribution is forward on each left sheet and backward on each right sheet, independent of the sine-lobe sign. Pure circular self-hit is therefore not tangentially neutral branchwise; it supplies outward radial support and signed forward/backward tangential activity that must be summed on the retained receiver-side ledger, without by itself proving or disproving full binary closure.

The complete root census follows from the absolute-value equation, not from the positive-sine subchart alone. In each higher lobe $\xi \in (n\pi, (n+1)\pi)$, $n \geq 1$, a pair is born when

$$\tan\xi_n^\star = \xi_n^\star, \qquad \beta_{f,n}^\star = \sqrt{1 + (\xi_n^\star)^2}$$

The first two pair-birth speeds are

$$\beta_{f,1}^\star \approx 4.6033388488, \qquad \beta_{f,2}^\star \approx 7.7897057675$$

At $\beta_f = 8$, the five self-hit delay angles $\phi = 2\xi$ are approximately

$$319.2409^\circ, \quad 413.6433^\circ, \quad 632.7112^\circ, \quad 859.1794^\circ, \quad 911.8419^\circ$$

The three-angle positive-sine census omits the two roots at 413.6433° and 632.7112°. The additional pairs can reverse the sign of the summed self tangential contribution: on the formal simple-root chart, the first post-birth reversal occurs at $\beta_f \approx 4.6914503106$, with analogous reversals after later births. Because every pair is born at $J = 0$, these sign reversals are branch-chart measurements rather than accepted finite-event dynamics.

The independently executable instrument `scripts/equation-mapping/analyze-circular-self-hit-binary.mjs` enumerates each monotone half-lobe, checks every root against the Euclidean chord residual, and evaluates acceleration from the position and velocity vectors rather than replaying the scalar component formulas. In units $\kappa|q^2|/R^2$ with outward radial sign positive, its scan over $1 < \beta_f < 20$ gives two distinct results:

1. With the principal partner root plus every physical self root, the tangential total has no zero; its measured minimum is approximately 0.2389668633 at $\beta_f \approx 1.7972747766$. The radial total crosses from outward to inward at $\beta_f \approx 1.8471246228$, so that crossing is real but has no exact relation to $\pi/2$.
2. With every physical partner root and every physical self root, the simple-root circular ledger does have simultaneous tangential-zero and inward-radial points. The first occurs at

$$\beta_f \approx 3.0703566254, \qquad A_{\tan} \approx 0, \qquad A_{\mathrm{rad}} \approx -0.8196069638$$

and the radial equation selects $R/R_* \approx 0.0869416735$. The partner-root Jacobian floor at this point is approximately 0.7071.

These are measured algebraic facts of the unregularized uniform-circular simple-root chart, not retained-branch or stability results. The null result for the restricted principal-partner ledger is not a theorem on $(1, \infty)$, while the first full-ledger zero already establishes numerical existence inside the searched interval. Promotion to a circular MCB requires the same finite singular-event convention for the folds that created the older roots, a retained-history certificate, wake-boundary closure, and a stable return map.

The line-of-action sensitivity can be recomputed without changing the causal-root measure. In the counterfactual inertially extrapolated construction, retain the actual roots, emission-site distance, and canonical transmitter-side acceleration weight, but replace the acceleration direction by

$$\hat{\mathbf{d}}_{\mathrm{ext}} = \frac{\mathbf{d}_{\mathrm{ext}}}{\|\mathbf{d}_{\mathrm{ext}}\|}, \qquad \mathbf{d}_{\mathrm{ext}} = \mathbf{X}_r(T_r) - [\mathbf{X}_t(T_t) + \mathbf{V}_t(T_t)(T_r - T_t)]$$

For a circular self root with receiver at $(R, 0)$ and delay half-angle ξ, its dimensionless extrapolated separation is

$$\frac{\mathbf{d}_{\mathrm{ext}}^{\mathrm{self}}}{R} = (1 - \cos 2\xi - 2\xi \sin 2\xi,\ \sin 2\xi - 2\xi \cos 2\xi)$$

This closed form is the independent directional reference used by the executable check.

The full branchwise recomputation changes the existence verdict for that counterfactual. At the first three canonical emission-site candidates $\beta_f \approx 3.0703566254$, 6.2184549634, and 9.3764360282, the extrapolated-direction radial coefficients are respectively $+0.1986630540$, $+0.1969175233$, and $+0.1881554019$, while the tangential coefficients are -0.3350989817, -0.1271086141, and -0.0742863069. Each row is outward and tangentially unbalanced. The counterfactual ledger develops replacement tangential zeros near $\beta_f \approx 3.2253960989$, 6.2226379612, and 9.3769260902, but their radial coefficients remain outward. A scan through $1 < \beta_f < 20$ finds six tangential zeros and no simultaneous inward-radial point.

Claim grade: **measured counterfactual**. This result shows that the canonical algebraic candidates are line-of-action sensitive; it does not promote the extrapolated construction into the Master Equation. The autonomous emission-labeled wake transport derives the canonical direction and weight on regular support from the present fixed-speed wake ontology. The direction-only extrapolated construction is not the wake-surface normal, while a coherently moving extrapolated center changes the propagation law, causal support, and collapse weight. The counterfactual therefore cannot demote the canonical candidates unless the substrate wake postulates are changed.

The equilibrium test precedes every stability test. Because all extrapolated-direction tangential zeros in the searched domain have outward radial acceleration, none is a circular equilibrium and no linearized delay spectrum about those rows is meaningful. The stability result is therefore not applicable after acceleration-balance failure; it is not a measured instability.

Falsifiers are direct. A negative canonical self-hit radial projection on any admissible circular root refutes the radial-sign proposition. Failure of the principal tangential term to change sign between $\beta_f = 1.5$ and $\beta_f = 1.65$ refutes the threshold result. A missed root with chord residual below the declared tolerance refutes the census. Recomputing the complete canonical ledger without the algebraic zero near $\beta_f = 3.07036$ refutes the canonical measurement. Finding an extrapolated-direction tangential zero with negative radial coefficient inside $1 < \beta_f < 20$ refutes the counterfactual nonexistence measurement.

High-Speed-Ratio Partner and Self Circular Residual Status

The receiver-side partner branch has a clean high-speed asymptotic form. Let $\xi_p(\beta_f)$ solve

$$\cos \xi_p = \frac{\xi_p}{\beta_f}, \qquad 0 < \xi_p < \frac{\pi}{2}$$

and set

$$C = \frac{\kappa q^2}{4R^2}$$

Then

$$\xi_p = \frac{\pi}{2} - \frac{\pi}{2\beta_f} + O(\beta_f^{-2})$$

so the partner projections satisfy

$$a_\theta^{(\mathrm{part})} = \frac{4C}{\pi^2}\beta_f + O(C), \qquad a_r^{(\mathrm{part})} = -\frac{2C}{\pi} + O(C\beta_f^{-1})$$

The older residual constants

$$C\left(\frac{4}{\pi^2} - \frac{1}{12}\right)\beta_f, \qquad \frac{C}{\pi}\log\beta_f - \frac{2C}{\pi}, \qquad \frac{4C}{\pi^2}\beta_f, \qquad \frac{2C}{\pi}\log\beta_f - \frac{2C}{\pi}$$

belong to the formal simple-root transmitter-side chart. They remain useful for comparing root families, but they do not certify a global acceleration residual or a large-β_f circular exclusion until fold neighborhoods and coincident births share one accepted event convention. The complete unregularized simple-root sum has now been recomputed over $1 < \beta_f < 20$: the restricted principal-partner ledger stays tangentially positive, while the full partner-plus-self ledger has algebraic zeros after older partner-root births. The regulated chart must still be recomputed before either pattern is promoted to retained dynamics.

Thus the equal-magnitude bare circular chart remains an obstruction benchmark, not a closed no-go theorem. A retained constant-radius exclusion still requires positive transmitter-side floors, inactive gaps, finite memory depth, the receiver-side branch records, and signed radial/tangential residual closure on the same branch chart.

The circular self-hit and partner-hit formulas are kernel benchmarks. They are not the Noether braid model. The Noether braid model is the six-body branch chart containing self, partner, and inter-binary causal roots, with hierarchy averaging only where justified by separated scales and certified branch data.

Maximum-curvature binary (declared indexed-binary idealization)

For a declared **two-body** maximum-curvature orbit of binary a, we have:

- Two charges on roughly circular orbits about their COM,
- Both potentially with self-hit,
- Plus partner acceleration contributions with causal delay.

Analytic expectations:

- An *exact closed form* is very unlikely.
- But:
  - We can construct a controlled circular ansatz:
    - Assume perfectly circular orbits with fixed R, ω,
    - Compute partner acceleration including causal delay (as in Sub-Field-Speed Circular Orbit),
    - Compute self-acceleration (as in Self-Interaction (Self-Hit Dynamics)),
    - Demand that time-averaged radial acceleration gives exactly $\omega^2 R$,
    - Demand that time-averaged tangential acceleration vanish.
  - That gives us a **pair of algebraic conditions** in R and ω (or equivalently R and v).
  - Solving those algebraic conditions (perhaps numerically) defines a maximum-curvature solution family.

However, the circular benchmark still exposes a serious certification burden in the bare two-body kernel. The principal partner branch contributes positive tangential acceleration, but older signed partner sheets can contribute negatively. The self sector gives outward radial support while its tangential projection changes sign by sheet. On the current unregularized simple-root chart, the complete partner-plus-self sum does vanish at discrete algebraic points, beginning near $\beta_f = 3.07036$, where the net radial acceleration is inward. Exact constant-speed circular algebraic balance is therefore not excluded. No stable or retained circular branch follows until the fold-born roots share one accepted singular-event convention and pass the branch-history, wake-boundary, and return-map requirements.

This sharpens the maximum-curvature program into a concrete fork:

- the measured simple-root algebraic cancellations survive the finite-event and retained-history completion, after which stability still requires a separate delay-operator proof, or
- the cancellations disappear under that completion. The tested inertially extrapolated direction already removes them and supplies no replacement equilibrium on $1 < \beta_f < 20$, but it can decide the canonical branch only if a wake-state derivation promotes that direction and its accompanying weight.
- Analytically: we can reduce the existence question to algebraic conditions and asymptotic expansions, and in the bare circular ansatz we can identify the partner-positive/self-signed tangential balance that any closure certificate must satisfy.
- Dynamically: the stability question remains separate from the algebraic construction and requires numerical analysis of attractivity versus fine-tuned orbit families.

No stability verdict follows from the present algebraic record. Existence of a circular or maximum-curvature solution would only solve the acceleration-balance conditions

$$\overline{A}_{\mathrm{rad}}(R, v) = \omega^2 R, \qquad \overline{A}_{\tan}(R, v) = 0$$

Stability is a different question: linearizing the delayed dynamics about the candidate orbit gives a delay operator

$$L(\lambda)$$

and the characteristic equation

$$\det(\lambda I - L(\lambda)) = 0$$

Any root with

$$\operatorname{Re}\lambda > 0$$

is an unstable mode.

> **Target Proposition (MCB transverse stability diagnostic).**
> For any candidate bare two-body maximum-curvature binary, compute the linearized delay operator on radial and tangential perturbations. The null-separatrix self-hit wall may block the radial collapse channel but cannot supply centripetal acceleration on the circular chart. The complete unregularized circular partner-plus-self ledger has measured algebraic cancellation points, while the restricted principal-partner ledger remains tangentially positive on $1 < \beta_f < 20$. Thus a bare MCB should be treated as an uncertified organizing orbit in

$$> (R, v) >$$

> space until the net signed tangential balance and transverse eigenvalues are certified.

This is the intended dynamical interpretation. Stable particles in the Noether braid architecture are Noether braid assemblies; a bare MCB, if it exists, is a high-curvature component or limiting scaffold whose instability explains why additional locking structure is needed.

The resulting status would be an analytic scaffold with a numerical stability check, not a closed-form certification.

Symmetric delayed spiral (advanced non-circular benchmark)

The circular obstruction makes a non-circular benchmark worthwhile. A workable first ansatz is the symmetric logarithmic spiral

$$r(\theta) = R_0 e^{-a\theta}, \qquad T(\theta) = \frac{\theta}{\Omega}, \qquad \mathbf{X}_1(\theta) = r(\theta)\,\mathbf{e}_r(\theta), \qquad \mathbf{X}_2(\theta) = -r(\theta)\,\mathbf{e}_r(\theta)$$

with fixed pitch $a > 0$ and constant angular rate $\Omega > 0$.

The variable-pitch extension replaces the constant pitch by

$$p(\theta) \equiv -\frac{r'(\theta)}{r(\theta)}$$

At a transmitter angle $\theta_0 = \theta - \Delta$, write

$$p_0 \equiv p(\theta - \Delta), \qquad \omega_0 \equiv \dot{\theta}(\theta - \Delta), \qquad \rho \equiv \frac{r(\theta - \Delta)}{r(\theta)}$$

The logarithmic benchmark is the special case $p(\theta) = a$, $\omega_0 = \Omega$, and $\rho = e^{a\Delta}$. This extension is useful because a true minimum-radius event requires

$$\dot{r} = 0, \qquad \ddot{r} \geq 0$$

which in the pitch variable means

$$p(\theta_*) = 0, \qquad p'(\theta_*) \leq 0$$

when $\dot{\theta}(\theta_*) \neq 0$.

For a receiver event at angle θ and a partner emission at $\theta_0 = \theta - \Delta$ with $\Delta > 0$, define

$$\Lambda_p(\theta, \Delta) \equiv \sqrt{1 + \rho^2 + 2\rho \cos \Delta}$$

Then

$$\mathbf{r}_{12}(\theta; \theta_0) = r(\theta)\Big[(1 + \rho \cos \Delta)\mathbf{e}_r(\theta) - \rho \sin \Delta\, \mathbf{e}_\theta(\theta)\Big]$$

so the exact delayed-hit condition is

$$r(\theta)\, \Lambda_p(\theta, \Delta) = c_f\, (T(\theta) - T(\theta - \Delta))$$

For constant angular rate this reduces to

$$\Lambda_p(\theta, \Delta) = \frac{\Delta}{b(\theta)}, \qquad b(\theta) \equiv \frac{\Omega r(\theta)}{c_f}$$

which is the non-circular analogue of the circular partner equation $\cos \xi = \xi / \beta_f$.

The receiver Frenet frame for the variable-pitch spiral is

$$\hat{\mathbf{T}} = \frac{-p\, \mathbf{e}_r(\theta) + \mathbf{e}_\theta(\theta)}{\sqrt{1 + p^2}}, \qquad \hat{\mathbf{N}} = \frac{-\mathbf{e}_r(\theta) - p\, \mathbf{e}_\theta(\theta)}{\sqrt{1 + p^2}}$$

where $p = p(\theta)$ and $\hat{\mathbf{N}}$ points inward in the circular limit.
Using the branch unit vector

$$\hat{\mathbf{r}}_{12} = \frac{(1 + \rho \cos \Delta)\mathbf{e}_r(\theta) - \rho \sin \Delta\, \mathbf{e}_\theta(\theta)}{\Lambda_p}$$

the partner transmitter-velocity projection entering the Jacobian is

$$\mathbf{V}_2(\theta - \Delta) \cdot \hat{\mathbf{r}}_{12} = \frac{r(\theta) \rho\, \omega_0}{\Lambda_p}\Big[p_0(\cos \Delta + \rho) - \sin \Delta\Big]$$

Hence

$$J_{12} = 1 + \frac{r(\theta) \rho\, \omega_0}{c_f\, \Lambda_p}\Big[\sin \Delta - p_0(\cos \Delta + \rho)\Big]$$

The sign is fixed by the circular limit: when $p_0 = 0$ and $\rho = 1$, this gives $J_{12} = 1 + \beta_f \sin(\Delta/2)$.

Closed Transmitter-Side Spiral Factors

For acceleration contributions the transmitter-side factor fixes the transmitter-side weight. Define the current and transmitter-event dimensionless tangential speeds

$$b \equiv \frac{r(\theta)\dot{\theta}(\theta)}{c_f}, \qquad b_0 \equiv \frac{r(\theta) \rho \omega_0}{c_f}$$

Then the transmitter-side and receiver-side factors on the same retained partner root are available in closed form:

$$\frac{D_{t,p}}{c_f} = 1 + \frac{b_0}{\Lambda_p}\Big[\sin \Delta - p_0(\cos \Delta + \rho)\Big]$$

$$\frac{D_{r,p}}{c_f} = 1 + \frac{b}{\Lambda_p}\Big[p(1 + \rho \cos \Delta) + \rho \sin \Delta\Big]$$

Hence the exact partner acceleration weight is

$$W_p^{\mathrm{acc}}(\theta,\Delta) = \frac{1}{\left|1 + \dfrac{b_0}{\Lambda_p}\big[\sin\Delta - p_0(\cos\Delta + \rho)\big]\right|}$$

This expression is algebraic once a delayed root Δ is known. The receiver-side expression remains useful for signed root playback but does not enter this weight. In the uniform circular limit, $W_p^{\mathrm{acc}} = (1 + \beta_f \sin(\Delta/2))^{-1}$.

For opposite polarities, the branch acceleration is

$$\mathbf{A}_{12} = -\kappa|q_1 q_2| \frac{W_p^{\mathrm{acc}}(\theta,\Delta)}{r(\theta)^2 \Lambda_p^2}\, \hat{\mathbf{r}}_{12}$$

Projecting onto the variable-pitch Frenet frame gives

$$a_T^p = \kappa|q_1 q_2| \frac{W_p^{\mathrm{acc}}(\theta,\Delta)}{r(\theta)^2 \Lambda_p^3 \sqrt{1+p^2}} \Big[p(1+\rho\cos\Delta) + \rho\sin\Delta\Big]$$

$$a_N^p = \kappa|q_1 q_2| \frac{W_p^{\mathrm{acc}}(\theta,\Delta)}{r(\theta)^2 \Lambda_p^3 \sqrt{1+p^2}} \Big[1 + \rho\cos\Delta - p\rho\sin\Delta\Big]$$

The partner tangential numerator is therefore

$$S_T^p(\theta,\Delta) \equiv p(1+\rho\cos\Delta) + \rho\sin\Delta$$

The missing self-branch analogue uses

$$\Lambda_s(\theta,\Delta) \equiv \sqrt{1+\rho^2 - 2\rho\cos\Delta}$$

$$\hat{\mathbf{r}}_{11} = \frac{(1-\rho\cos\Delta)\mathbf{e}_r(\theta) + \rho\sin\Delta\,\mathbf{e}_\theta(\theta)}{\Lambda_s}$$

The self-hit delay equation is

$$r(\theta)\,\Lambda_s(\theta,\Delta) = c_f\,(T(\theta) - T(\theta-\Delta))$$

and the self-branch Jacobian is

$$J_{11} = 1 - \frac{r(\theta)\rho\,\omega_0}{c_f\,\Lambda_s}\Big[\sin\Delta + p_0(\rho - \cos\Delta)\Big]$$

Again the circular limit agrees with the uniform circular self-hit formula, $J_{11} = 1 - \beta_f\cos(\Delta/2)$.

The receiver projection on the same self line of action gives the companion closed-form records

$$\frac{D_{t,s}}{c_f} = 1 - \frac{b_0}{\Lambda_s}\Big[\sin\Delta + p_0(\rho - \cos\Delta)\Big]$$

$$\frac{D_{r,s}}{c_f} = 1 - \frac{b}{\Lambda_s}\Big[-p(1-\rho\cos\Delta) + \rho\sin\Delta\Big]$$

and therefore

$$W_s^{\mathrm{acc}}(\theta,\Delta) = \frac{1}{\left|1 - \dfrac{b_0}{\Lambda_s}\big[\sin\Delta + p_0(\rho - \cos\Delta)\big]\right|}$$

The uniform circular limit again gives $D_{r,s} = D_{t,s}$ for root playback, while
$W_s^{\rm acc} = 1/|J_{11}|$. Thus the transmitter-side calculation requires
evaluating the transmitter-side denominator on the retained root intervals and
recording D_r/D_t separately for continuation.

For self-hit, $\sigma_{11} = +1$, so

$$\mathbf{A}_{11} = \frac{\kappa q_1^2}{r(\theta)^2 \Lambda_s^2} W_{11}^{\rm acc}\, \hat{\mathbf{r}}_{11}$$

The self-branch tangential projection is

$$a_T^s = \frac{\kappa q_1^2 W_{11}^{\rm acc}}{r(\theta)^2 \Lambda_s^3 \sqrt{1+p^2}} \Big[-p(1-\rho\cos\Delta) + \rho\sin\Delta \Big]$$

so

$$S_T^s(\theta, \Delta) \equiv -p(1-\rho\cos\Delta) + \rho\sin\Delta$$

Closed Spiral-Direction Flow

The physical question is whether the binary's radius is shrinking or growing.
The delayed acceleration does two different jobs, and they must be kept separate. Its radial part changes the inward or outward motion. Its azimuthal part changes the rotation rate and angular momentum. A forward azimuthal push can spin the binary up while the radius is still shrinking, so the torque sign alone does not answer the spiral-direction question.

The geometry separates those jobs into two dimensionless sums. B_r is the net outward-radial contribution, while B_θ is the net forward-azimuthal contribution. For an equal-magnitude opposite-polarity binary, let $q^2 = |q_1 q_2| = q_1^2$, and define

$$B_r \equiv -\sum_{\rm part} \frac{W_p^{\rm acc}(1+\rho_p\cos\Delta_p)}{\Lambda_p^3} + \sum_{\rm self} \frac{W_s^{\rm acc}(1-\rho_s\cos\Delta_s)}{\Lambda_s^3}$$

$$B_\theta \equiv \sum_{\rm part} \frac{W_p^{\rm acc}\rho_p\sin\Delta_p}{\Lambda_p^3} + \sum_{\rm self} \frac{W_s^{\rm acc}\rho_s\sin\Delta_s}{\Lambda_s^3}$$

With $\omega = \dot\theta$, the exact polar equations are

$$\ddot r - r\omega^2 = \frac{\kappa q^2}{r^2} B_r, \qquad r\dot\omega + 2\dot r\,\omega = \frac{\kappa q^2}{r^2} B_\theta$$

and the angular-momentum record is

$$\frac{d}{dT}(r^2\omega) = \frac{\kappa q^2}{r} B_\theta$$

Thus $B_\theta > 0$ means that the wakes are adding angular momentum. It does not mean that the binary is moving outward. Radial direction is carried separately by the changing radius.

The signed pitch packages the direction into one number:

$$p \equiv -\frac{\dot r}{r\omega}, \qquad \Gamma \equiv \frac{r^3\omega^2}{\kappa q^2} > 0$$

for $\omega > 0$. The sign convention is simple: $p > 0$ means that the radius shrinks as the binary turns, while $p < 0$ means that the radius grows. Direct substitution into the polar equations gives the closed receiver-side pitch flow

$$\frac{dp}{d\theta} = -(1+p^2) - \frac{B_r + pB_\theta}{\Gamma}$$

$$\frac{d}{d\theta}\log\omega = 2p + \frac{B_\theta}{\Gamma}$$

together with $d\log r/d\theta = -p$. These identities are exact on any smooth retained spiral chart. The complicated path-history information is confined to the delayed roots inside B_r and B_θ. Once those roots are known, the equations directly evolve the spiral direction.

At a radial turning point, the binary is momentarily neither moving inward nor outward, so $p = 0$. The direction after that instant is decided by one balance:

$$\left.\frac{dp}{d\theta}\right|_{p=0} = -\frac{\Gamma + B_r}{\Gamma}$$

Therefore

$$\Gamma + B_r > 0 \quad \Longleftrightarrow \quad \text{minimum radius followed by outward motion}$$

while

$$\Gamma + B_r < 0 \quad \Longleftrightarrow \quad \text{maximum radius followed by inward motion}$$

In plain language, Γ is the outward centrifugal requirement and B_r is the signed radial wake contribution. If their sum is positive, the radius has reached a minimum and rebounds outward. If their sum is negative, the radius has reached a maximum and turns inward. The equality case is radially tangent and requires the next derivative. This is the closed-form in-versus-out decision rule.

The simplest proposed spiral assumes that its tightness and angular rate never change. In symbols, its signed pitch is constant, $p = p_\star$, and its angular rate is constant. Under those assumptions, the two compatibility conditions reduce to

$$B_r = (p_\star^2 - 1)\Gamma, \qquad B_\theta = -2p_\star\Gamma$$

or, after eliminating the positive scale Γ,

$$(p_\star^2 - 1)B_\theta + 2p_\star B_r = 0, \qquad \Gamma = -\frac{B_\theta}{2p_\star}$$

for $p_\star \neq 0$. The immediate conclusion is that a constant-rate inward spiral requires a net backward azimuthal contribution, $B_\theta < 0$. The principal partner root instead contributes forward, with $B_\theta > 0$. That single delayed partner wake therefore cannot produce the proposed constant-rate inward spiral by itself. Older signed roots, self roots, or a changing angular rate would have to alter the balance.

The stronger result concerns three assumptions taken together:

- the spiral keeps the same tightness;
- the angular rate stays constant;
- only the single principal partner root is active.

With no active self root, constant signed pitch gives

$$\rho = e^{p_\star \Delta}, \qquad \Lambda_p^2 = 1 + \rho^2 + 2\rho\cos\Delta, \qquad b = \frac{\Delta}{\Lambda_p}$$

and the branch-strength factor cancels from the pitch-compatibility equation. The remaining necessary condition is

$$(p_\star^2 - 1)\rho\sin\Delta - 2p_\star(1 + \rho\cos\Delta) = 0$$

For fixed $p_\star \neq 0$, the left-hand side is analytic in Δ and is not identically zero; its continuation to $\Delta = 0$ has value $-4p_\star$. Its zeros on a retained principal interval are therefore isolated. A continuous single-root history satisfying the compatibility equation must keep Δ constant. The delay equation then keeps b constant, and constant angular rate keeps r constant, contradicting $p_\star \neq 0$. Hence:

> **Proposition (single-principal-partner logarithmic-spiral no-go).** No exact nonzero constant-pitch, constant-angular-rate logarithmic spiral, inward or outward, exists over an open interval of the strictly sub-field, single-principal-partner receiver-side chart.

The proposition does not say that binaries cannot spiral. It says that the simple logarithmic picture is too rigid: a real spiral cannot preserve both its tightness and its angular rate while responding only to one delayed partner wake. At least one feature must evolve. The spiral can change tightness, change angular rate, acquire another delayed root, cross into the self-hit regime, or receive multi-body contributions.

The Frenet tangential sum used below is the same information in a rotated basis:

$$B_T = \frac{-pB_r + B_\theta}{\sqrt{1+p^2}}$$

so the polar pitch flow and the Frenet obstruction are equivalent statements, not separate tests.

The circular obstruction yields a branch-chart test. A non-circular spiral can beat the isolated circular tangential obstruction only if the certified active roots satisfy a negative weighted tangential sum on enough of the controlled cycle:

$$\sum_{\text{part}} |q_1 q_2| \frac{W_p^{\text{acc}} S_T^p}{\Lambda_p^3} + \sum_{\text{self}} q_1^2 \frac{W_s^{\text{acc}} S_T^s}{\Lambda_s^3} < 0$$

after the common positive factors are removed. Algebraic sign allowance is not enough; the delayed-root equations must actually admit those roots with positive transmitter-side floors, transmitter-side acceleration-weight intervals, and finite memory depth.

At a minimum-radius event θ_*, the pitch condition gives $p(\theta_*) = 0$. Therefore both tangential numerators reduce locally to

$$S_T^p(\theta_*, \Delta) = S_T^s(\theta_*, \Delta) = \rho\sin\Delta$$

Principal roots with $0 < \Delta < \pi$ still carry the same positive tangential sign as the circular benchmark. The only bare-kernel escape routes are therefore:

1. admissible older or wrapped roots with $\sin \Delta < 0$ and enough transmitter-side acceleration weight;
2. off-turn variable-pitch intervals where the p-terms dominate the positive principal branches;
3. additional medium, Noether braid, or multi-body structure outside the isolated two-body spiral ansatz.

The radial turn condition is equally explicit. Since

$$\ddot{r} = a_r + r\dot{\theta}^2$$

at a point with $\dot{r} = 0$, a minimum-radius turn requires

$$r_*\dot{\theta}_*^2 - \sum_{\text{part}} \frac{\kappa |q_1 q_2| \, W_p^{\text{acc}}(1 + \rho_p \cos \Delta_p)}{r_*^2 \Lambda_p^3} + \sum_{\text{self}} \frac{\kappa q_1^2 \, W_s^{\text{acc}}(1 - \rho_s \cos \Delta_s)}{r_*^2 \Lambda_s^3} > 0$$

This is a theorem target, not a closure proof. It supplies the concrete falsification gate: enumerate the admissible partner and self roots on a variable-pitch candidate, certify their transmitter-side floors and same-record transmitter-side acceleration-weight intervals, and test both the radial turn inequality and the weighted tangential sum. If all admissible roots keep the weighted tangential sum nonnegative on every candidate turn corridor, the bare isolated spiral does not beat the circular obstruction.

For a retained chart at a turn center, the radial record can be normalized by the common acceleration factor, but that normalization separates the branch sum from the independent acceleration ratio. In the equal-magnitude opposite-polarity case, one may write

$$\Gamma_{\text{rs}} \equiv \frac{r_*^3 \Omega^2}{\kappa q_1^2}, \qquad B_r^{\text{rec}}(\theta_*) = -\sum_{\text{part}} \frac{W_p^{\text{acc}}(1 + \rho_p \cos \Delta_p)}{\Lambda_p^3} + \sum_{\text{self}} \frac{W_s^{\text{acc}}(1 - \rho_s \cos \Delta_s)}{\Lambda_s^3}$$

so the normalized turn record is

$$\Gamma_{\text{rs}} + B_r^{\text{rec}}(\theta_*) > 0$$

The subscript rs identifies this retained-spiral benchmark. The retained branch chart must emit same-record D_t, D_r, transmitter-side acceleration weights, and signed root-playback records before B_r^{rec} exists as acceleration evidence. It does not determine Γ_{rs} from $b_* = \Omega r_*/c_f$, from the delayed-root offsets, or from a branch-sum threshold. A branch certificate must therefore either supply an independently derived acceleration-ratio interval after the transmitter-side branch sum exists or report the radial result as blocked.

A fixed retained-chart benchmark illustrates this burden without supplying canonical dynamics. Let $a_{\text{rs}} = 0.204$ be the prescribed pitch amplitude, $b_* = 7/2$ the prescribed turn-center speed ratio, and C_{rs} the complete fixed record consisting of those inputs, the interval $I_* = [-\pi/6, \pi/6]$, three retained partner-root tubes P_1, P_2, P_3, one retained self-root tube S_1, and the associated inactive-gap and finite-memory data. The labels P_k and S_1 identify those root tubes only; they are not particle or persistent-braid indices. Every equation below that consumes C_{rs}, a_{rs}, or b_* is a diagnostic for this prescribed benchmark, not a derived Master EOM result. Promotion requires same-record $c_f/|D_t|$ acceleration-weight intervals and D_r/D_t playback intervals on all four tubes.

If the same turn-center radial curve is allowed a variable angular rate, with $\omega_* = \dot{\theta}(0) > 0$ and $\alpha_* = \ddot{\theta}(0)$, then $r'(0) = 0$ and the local kinematic targets become

$$B_r^{\text{rec}}(C_{\text{rs}}; 0) = (a_{\text{rs}} - 1)\Gamma_*, \qquad B_\theta^{\text{rec}}(C_{\text{rs}}; 0) = \Gamma_* \frac{\alpha_*}{\omega_*^2}$$

where $\Gamma_* = r_*^3 \omega_*^2 / (\kappa q_1^2)$. This supplies only a local angular-deceleration target for a variable-angular-rate continuation. It does not by itself close such a continuation, because the delayed roots and transmitter-side acceleration weights must be recomputed for the nonconstant time law.

The stronger invariant form of the target is the angular slope of the time law,

$$\frac{d}{d\theta}\log\dot\theta\bigg|_{\theta=0} = \frac{\ddot\theta(0)}{\dot\theta(0)^2} = \frac{B_\theta^{\mathrm{rec}}(C_{\mathrm{rs}};0)}{\Gamma_*}$$

However, the delayed roots are controlled by a finite-memory integral, not by this local slope alone. If

$$H(\Delta) = \omega_* \int_{-\Delta}^{0} \frac{d\phi}{\dot\theta(\phi)}$$

then the turn-center root equation is $\Lambda_{P/S}(0,\Delta) = H(\Delta)/b_*$. Retaining a constant-rate root at the same offset would require $H(\Delta_\alpha) = \Delta_\alpha$, or

$$\int_{-\Delta_\alpha}^{0} \left(\frac{\omega_*}{\dot\theta(\phi)} - 1\right) d\phi = 0$$

Thus the variable-rate retained-spiral continuation is a finite-memory time-law problem: the local angular-deceleration target must be reconciled with inverse-rate averages over the delayed branch intervals and with the same-box transmitter-side acceleration contributions. Simple one-parameter extensions of the local slope are not evidence unless they preserve the retained roots and recompute $W^{\mathrm{acc}} = c_f/|D_t|$ on the resulting branch record.

This finite-memory condition is nevertheless not an algebraic no-go at the turn center. In past-lag coordinates $x = -\phi$, define

$$q(x) = \frac{\omega_*}{\dot\theta(-x)}$$

A retained-root profile must satisfy both moment and endpoint constraints,

$$\int_0^{\Delta_\alpha} \big(q(x) - 1\big)\, dx = 0, \qquad q(\Delta_\alpha) = 1$$

for each retained-spiral delay. Because the local target gives $q'(0) = B_\theta^{\mathrm{rec}}(C_{\mathrm{rs}};0)/\Gamma_* < 0$, the inverse-rate profile dips below 1 just behind the turn and must compensate by rising above 1 before the first retained delay. A positive retained-root inverse-rate profile can satisfy these constraints, keep the active transmitter-speed factors at their constant-rate values at the retained offsets, and make the same branch sums give the required local angular-rate slope.

The first off-center transport record is also fixed at the turn center. If $q_\theta(u) = \dot\theta(\theta)/\dot\theta(\theta - u)$ and $H(\theta,\Delta) = \int_0^\Delta q_\theta(u)\, du$, then the retained endpoint constraints imply

$$\partial_\theta H(\theta,\Delta_\alpha)|_{\theta=0} = k_*\Delta_\alpha, \qquad k_* = \frac{B_\theta^{\mathrm{rec}}(C_{\mathrm{rs}};0)}{\Gamma_*}$$

Since $b'(\theta)/b(\theta) = k_*$ at the turn center, the first θ-derivative of H/b cancels at the retained endpoints. Thus the retained-memory witness inherits the constant-chart first-order root-transport identity at $\theta = 0$. This is still only a branch-chart existence target, not an orbit certificate: the active roots, inactive gaps, transmitter-speed Jacobians, finite-memory depth, generalized root-transport residuals, and acceleration-balance records still have to be recomputed on a finite θ interval for the chosen nonconstant time law.

The finite-collar target can be stated without adding a new law. Let

$$Q(\theta) = \frac{\omega_*}{\dot\theta(\theta)}, \qquad \sigma(\theta) = \frac{r(\theta)}{r_*}, \qquad K_Q(\theta,\Delta) = \int_{\theta-\Delta}^{\theta} Q(\phi)\, d\phi$$

Then the transported retained-root equation is

$$F_{\alpha,Q}(\theta,\Delta)=\Lambda_\alpha(\theta,\Delta)-\frac{K_Q(\theta,\Delta)}{b_*\sigma(\theta)}=0$$

At each retained endpoint, $K_Q(0,\Delta_\alpha)=\Delta_\alpha$ and $\partial_\theta K_Q(0,\Delta_\alpha)=0$, so the first memory drift begins at second order in θ. The branch-chart certificate must bound that drift while satisfying the tangential transport equation for Q and the radial residual on the same active root ledger.

A local convergence diagnostic can sharpen this finite-collar target, but it does not by itself fix the full continuation class. After the tangential record is imposed on the retained ledger, the transported radial record should be tested through the leading one-sided jet of $\mathcal{R}_R^{\mathrm{tr}}(\theta)$ near $\theta=0$. For a specified tangential-transport profile, the jet coefficient is

$$\left(\mathcal{R}_R^{\mathrm{tr}}\right)'_+(0)=B'_+(0)-(3a_{\mathrm{rs}}-2)B_\theta^{\mathrm{rec}}(C_{\mathrm{rs}};0)$$

The retained endpoint and moment constraints do not yet fix all transmitter-side endpoint-slope data entering $B'_+(0)$. A nonzero sampled coefficient is therefore a local obstruction candidate for that profile, not a theorem that every positive C^2 variable-rate continuation fails.

A sampled endpoint-slope construction sharpens the same caution. By perturbing the retained past inverse-rate profile while preserving the retained endpoint values, moment records, compact C^2 tail, and center slope, one can cancel the leading affine radial jet at sampled level and still keep a positive retained past profile with the expected $3+1$ active-root ledger after tangential transport. This does not certify retained-spiral closure. It moves the theorem-grade burden to finite-collar control after endpoint-slope cancellation: positivity, inactive gaps, Jacobian floors, transmitter-side acceleration weights, finite memory, tangential transport, and the full radial residual must all be bounded on the same branch chart. Provenance note: this sampled construction and the adjacent prescribed benchmark record currently name no instrument or archived computation artifact; until one is linked, both carry construction-note grade, not measured grade, and they license no dynamical inference.

Effective Continuum Limits

Another class of analytic work appears only after coarse-graining the microscopic DDE:

Homogeneous, isotropic Noether Sea

Assume:

- Very large number of architrinos,
- Statistically homogeneous and isotropic distribution,
- Global neutrality.

Then, at coarse-grained level:

- Conditional on a declared convergent summation prescription for the infinite-transmitter wake sum (the convergence burden stated under Superposition above), symmetry dictates the net acceleration on a test architrino at rest is zero.
- Small perturbations can be analyzed by linearizing around the homogeneous background.

The targets are to:

- derive an effective wave equation for small perturbations in density or potential diagnostics,
- show that disturbances propagate at an emergent channel speed tied to c_f and medium response,
- recover Maxwell-like or acoustic-like behavior as effective continuum behavior.

These are field-theory-style analytic solutions (plane waves, Green's functions) of the **coarse-grained** equations, not of the micro DDEs. They are useful only when the continuum variables are explicitly derived from the master equation by a declared coarse-graining limit.

This regime is analytically tractable and important for:

- Emergent electromagnetism,
- Emergent metric propagation (gravitational-wave analogues),
- Stability of the Noether sea itself.

Analytic footholds and remaining targets

Several analytic checks provide footholds for the remaining closure targets. Root-existence, inactive-gap, and transmitter-side transversality records remain usable as topology inputs; radial/tangential acceleration balance, action, power, and finite-window conservation records must be recomputed with W_{ij}^{acc} before they can be promoted.

1. **Partner-only circular orbit with causal delay ($v < c_f$)** has explicit radial and tangential components, including the positive tangential-drive obstruction for a bare constant-speed circle.
2. **Uniform circular self-hit ($v > c_f$)** has principal-root onset asymptotics, signed higher-winding branch birth, branchwise radial/tangential projections, transmitter-side diagnostic large-β_f estimates, and a same-record acceleration-recomputation target for promoted sums.
3. **Variable-pitch spiral retained-chart benchmarks** expose both branch-chart records and prescribed-history compatibility records. The fixed retained-spiral constant-Ω history has active-root, inactive-gap, transmitter-side Jacobian-floor, finite-memory, and root-transport records, but its acceleration-balance and outward-constant records require transmitter-side acceleration-weight intervals on the same branch cells before they can act as closure evidence. The retained spiral is therefore a prescribed-history diagnostic, not an acceleration-balance no-go, until the retained chart is recomputed with W_{ij}^{acc}.

The remaining analytic targets are sharper:

1. build the maximum-curvature branch certificate from active roots, inactive gaps, transmitter-side Jacobian floors, transmitter-side acceleration-weight intervals, finite memory, root transport, returned-section residuals, radial/tangential balance, and the independent acceleration-ratio record;
2. coarse-grain the master equation around a homogeneous Noether sea and extract the linear response and dispersion relation $\omega(k)$;
3. prove which regularized energy diagnostic is actually induced by a symmetry-preserving action-level regularization.

These targets keep the bridge between the formal law and the broader closure program mathematical: a branch chart, a conserved charge, or a response equation must be supplied before a stability or mass claim is promoted.

Analytic Summary

- **General N-body analytic solution:** No; the structure is too complex (DDE with state-dependent delays and self-hit multiplicity).
- **Idealized / symmetric cases:** Yes, in several important classes:
    - 1D radial two-body,
    - sub-c_f circular orbit,
    - uniform circular self-hit,
    - algebraic maximum-curvature conditions,
    - continuum/wave limits of the Noether sea.

Energy, Symmetry, and Conservation

Energy, Lagrangian, and Hamiltonian Structure of the Architrino Dynamics

In this section we outline how **energy** and **variational structure** are handled in $\mathbb{AAA}$, given the Master Equation of Motion:

$$\frac{d^2\mathbf{X}_i}{dT_r^2} = \sum_j \sum_{T_t \in \mathcal{C}_{ij}(T_r)} \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2(T_r;T_t)} W_{ij}^{\mathrm{acc}}(T_r;T_t)\, \hat{\mathbf{r}}_{ij}(T_r;T_t)$$

where each contribution comes from a **causal wake intersection** at reception time T_r between receiver i and a wake emitted by transmitter j at emission time T_t. The set $\mathcal{C}_{ij}(T_r)$ encodes all such emission times selected by the causal constraint

$$\|\mathbf{X}_i(T_r) - \mathbf{X}_j(T_t)\| = c_f(T_r - T_t), \quad T_t < T_r$$

Once any internal binary reaches the $v > c_f$ regime at some stage in its curved history, **self-hit** becomes a live branch candidate and must be checked explicitly in realistic energy accounting. Completed assemblies cannot be assigned a “no self-hit” energy record merely from current sub-field-speed motion; the retained path history must show that same-transmitter roots are absent or inactive with a certified branch gap.

We organize the discussion into four pieces:

1. Aggregate kinetic energy for a finite, isolated set of architrinos,
2. An action-level nonlocal Noether energy charge compatible with path-history dynamics,
3. A nonlocal Lagrangian scaffold whose variations reproduce the Master Equation only when the constraint residual closes,
4. A corresponding Hamiltonian / total energy functional, with energy exchange only at $T = \mathrm{now}$ between architrinos.

Aggregate Kinetic Energy

We work with **absolute time** T and Euclidean 3-space. For each architrino i, define:

- Position $\mathbf{X}_i(T)$,
- Velocity $\mathbf{V}_i(T) = d\mathbf{X}_i/dT$,
- Optional universal bookkeeping constant μ_{arch} when a quadratic kinetic proxy is desired.

We do **not** a priori assign energy to any continuous field; energy is carried by architrinos and their assemblies and is updated only at the instants where wake surfaces intersect receivers.

Definition (Quadratic kinetic bookkeeping proxy). For a finite isolated set of architrinos $\{i = 1, \dots, N\}$,

$$K_\mu(T) \equiv \sum_{i=1}^{N} \frac{1}{2}\mu_{\mathrm{arch}} \|\mathbf{V}_i(T)\|^2$$

Remarks:

- This is a bookkeeping choice for analysis, numerics, and Noether-style energy accounting. The substrate law itself remains acceleration-first.
- Because μ_{arch} is universal, it can be absorbed into units or into an overall normalization of force-like quantities if desired.
- For assemblies (binaries, Noether braids), one defines an effective assembly mass M_{assembly} as

$$M_{\mathrm{assembly}} = \frac{1}{V_{\mathrm{CM}}} \frac{d}{dV_{\mathrm{CM}}} (\text{total kinetic} + \text{interaction energy of internal motion})$$

where V_{CM} is the center-of-mass speed. In practice, this is computed from the internal architrino motions (e.g., the tight indexed-binary self-hit orbit plus its interaction with partner binaries).

Thus kinetic energy splits naturally into:

- **Internal kinetic energy** of bound assemblies (setting rest mass),
- **Center-of-mass kinetic energy** of assemblies relative to the Noether sea.

Action-Level Nonlocal Noether Energy

With finite-speed causal wakes and path-history dependence, an instantaneous position-only potential is not fundamental. Time-translation symmetry of a symmetry-preserving nonlocal action model supplies the corresponding nonlocal Noether charge. The formulas in this subsection therefore belong to the action-derived delayed model, not to every regularized implementation of the Master Equation.

For the dual-mollified local 1D collinear model, the same conservation language should be read more carefully: the causal-surface mollifier δ_η and core mollifier ϵ_c support a finite local vector field and a tractable return-map theorem program, but exact Noether-charge statements transfer automatically only if that dual mollification is itself derived from a time-translation-invariant action-level regularization of the causal kernel.

Energy exchange per causal hit

Consider a single contribution to the acceleration of receiver i at reception time T_r from a causal hit emitted by transmitter j at time $T_t \in \mathcal{C}_{ij}(T_r)$. The acceleration contribution is:

$$\mathbf{A}_{ij}(T_r;T_t) = \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\text{acc}}(T_r;T_t)\, \hat{\mathbf{r}}_{ij}$$

The instantaneous power delivered to architrino i by this hit is:

$$P_{ij}(T_r;T_t) = \mu_{\text{arch}}\, \mathbf{A}_{ij} \cdot \mathbf{V}_i = \mu_{\text{arch}}\, \kappa\, \sigma_{ij}\, \frac{|q_i q_j|}{r_{ij}^2} W_{ij}^{\text{acc}}(T_r;T_t)\, V_{r,ij}$$

where $V_{r,ij} = \mathbf{V}_i(T_r) \cdot \hat{\mathbf{r}}_{ij}$ is the radial component of the receiver's velocity along the line of action. This is the **only instant** when the interaction can change the kinetic energy of i. Between hits, $\mathbf{A}_{ij}$ from this specific emission is zero.

Summing over all contributing transmitters and all causal emission times at a given T_r,

$$\frac{dK_\mu}{dT_r}(T_r) = \sum_i \sum_j \sum_{T_t \in \mathcal{C}_{ij}(T_r)} P_{ij}(T_r;T_t)$$

with the understanding that for self-hit we include $j = i$ as well.

Action-Level Wake-Energy Functional at a Time Boundary

Let $\mathcal{K}_{ij}(T_1, T_t)$ denote the causal-delay interaction kernel appearing in the nonlocal action scaffold below:

$$\mathcal{K}_{ij}(T_1,T_t) = \mu_{\text{arch}} \kappa\, \sigma_{ij}\, |q_i q_j|\, \Theta(T_1 - T_t)\, \frac{\delta\big(\tilde{g}_{ij}(T_1,T_t)\big)}{r_{ij}(T_1,T_t)}, \qquad \tilde{g}_{ij}(T_1,T_t) = T_1 - T_t - \frac{r_{ij}(T_1,T_t)}{c_f}$$

The tilde marks this as the time-normalized action constraint. The length-valued
Master Equation constraint remains $g_{ij} = r_{ij} - c_f(T_r - T_t)$.
Because $[\delta(\tilde{g})] = T^{-1}$, the prefactor
$\mu_{\text{arch}}\kappa$ gives this kernel the required energy-per-time
dimension. A κ/c_f prefactor would not.

For an isolated system, the nonlocal Noether charge associated with $T \mapsto T + T_{\text{shift}}$ is

$$E_{\text{tot}}(T) = K_\mu(T) + E_{\text{wake}}(T)$$

with

$$E_{\text{wake}}(T) = -\frac{1}{2}\sum_{i,j}\int_{-\infty}^{T} dT_t \int_{T}^{\infty} dT_1\, \partial_{T_1}\mathcal{K}_{ij}(T_1, T_t)$$

The outer minus sign follows the convention that the interaction enters the action as $-\frac{1}{2}\sum S_{ij}$. It also makes the sharp static like-polarity interaction charge positive, as required by the work integral.

Plainly: one action convention now fixes the interaction units, the static sign, and the boundary charge together.

For $i = j$, the same rule applies with the trivial coincidence branch ($T_1 = T_t$) excluded, matching the self-hit convention used throughout this chapter.

Interpretation: the double integral measures interaction links that cross the absolute-time boundary T (past emission side $T_t \le T$ and future reception side $T_1 \ge T$). This is the exact “in-flight” interaction contribution in the nonlocal theory.

For exact solutions of the causal action, nonlocal Noether's theorem gives

$$\frac{d}{dT}\Big(K_\mu(T) + E_{\text{wake}}(T)\Big) = 0$$

No separate spatial field-energy ontology is required; conservation is encoded directly in worldline geometry and the causal kernel.

For proof and simulation, the same statement can be written as a residual balance. Let

$$\mathbf{R}_i^{(\eta)}(T) = \mu_{\text{arch}}\mathbf{A}_i(T) - \mathbf{F}_{i,\text{act}}^{(\eta)}(T)$$

be the Euler-Lagrange residual of the symmetry-preserving regularized action, where $\mathbf{F}_{i,\text{act}}^{(\eta)}$ includes the scale term and any nonzero constraint-variation residual from the action. Let $\mathcal{B}_E^{(\eta)}(T)$ collect energy flux through finite history-window endpoints, period cuts, and excluded self-coincidence boundaries. Then the action-level energy balance is

$$\frac{d}{dT}\left(K_\mu(T) + E_{\text{wake}}^{(\eta)}(T)\right) = \sum_i \mathbf{V}_i(T)\cdot\mathbf{R}_i^{(\eta)}(T) + \mathcal{B}_E^{(\eta)}(T)$$

For isolated compactly supported or period-matched histories, $\mathbf{R}_i^{(\eta)} = \mathbf{0}$ and $\mathcal{B}_E^{(\eta)} = 0$ give the exact conserved charge. A nonzero residual identifies a real failure mode: branch-chart loss, nonsymmetric regularization, leakage through the finite memory window, or an unaccounted derivative-of-delta counterterm.

Equivalent work-integral form

For direct trajectory evaluation, one may reconstruct a compatible interaction contribution through the accumulated power exchange along the realized trajectory:

$$U(T) = U_* - \int_{T_*}^{T}\sum_i \mu_{\text{arch}}\,\mathbf{A}_i(T')\cdot\mathbf{V}_i(T')\,dT'$$

This work-integral form is a practical trajectory-level reconstruction when the same action-derived acceleration law and boundary convention are used. It should not be treated as an independent off-shell Noether functional; outside the symmetry-preserving action model it is a diagnostic bookkeeping quantity rather than a proved conserved charge.

In short-delay effective limits, E_{wake} reduces to an approximate instantaneous pair form

$$E_{\text{wake}}(T) \approx \sum_{i<j} U_{ij}\big(\mathbf{X}_i(T), \mathbf{X}_j(T)\big)$$

with leading $1/r_{ij}$ behavior plus geometry-dependent self-hit corrections.

Exact Nonlocal Lagrangian

Transmitter-side action target. A scalar-action scaffold is closure-relevant only if its variation produces the transmitter-side target $W_{ij}^{\text{acc}}\hat{\mathbf{r}}_{ij}/r_{ij}^2$ on the retained branch chart with $W_{ij}^{\text{acc}} = c_f/|D_{t,ij}|$. The signed playback factor D_r/D_t is retained for root continuation but is not multiplied into the acceleration or action target.

To connect with variational methods and with later continuum approximations, it is useful to exhibit the **action principle** for the delayed dynamics. Because the interactions depend on path history via causal wakes, the action is necessarily nonlocal in time.

Exact causal-delay Fokker-type interaction term

For the focused scalar causal-locus statistic (definitions, theorem spine, and circular branch-count benchmark), see Causal Action Functional. That chapter's scalar action-counting functional is not an acceleration/action record unless it is rebuilt with W_{ij}^{acc}/r^2. It is not automatically identical to the exact Fokker-type variational action below, whose $1/r$ causal kernel must be tested against the transmitter-side branch law after variation.

Let the worldline of architrino i be $\mathbf{X}_i(T)$. For the action-scaffold discussion, the same universal bookkeeping constant may be inserted in the quadratic kinetic term:

$$S[\{\mathbf{X}_i\}] = \sum_i \int dT\, \frac{1}{2}\mu_{\text{arch}}\|\mathbf{V}_i(T)\|^2 \;-\; \frac{1}{2}\sum_{i\neq j} S_{ij}$$

with interaction contributions

$$S_{ij} = \mu_{\text{arch}}\kappa\, \sigma_{ij}\, |q_i q_j| \int dT \int dT'\, \Theta(T-T')\, \frac{\delta\big(\tilde{g}_{ij}(T,T')\big)}{r_{ij}(T,T')}$$

where

$$\tilde{g}_{ij}(T,T') \equiv T - T' - \frac{r_{ij}(T,T')}{c_f}, \qquad r_{ij}(T,T') = \|\mathbf{X}_i(T) - \mathbf{X}_j(T')\|$$

Key points:

- $\Theta(T-T')$ enforces the purely past-causal branch ($T' \le T$).
- $\delta(\tilde{g}_{ij})$ restricts support to the characteristic causal surface $r_{ij} = c_f(T-T')$.
- The sharp action scaffold contains no fundamental mollifier: η is a regularization parameter used to test branch limits.

At a receiver event $T = T_r$, integrating out the delta via the delay-map Jacobian gives the branch-resolved form:

$$\delta\big(\tilde{g}_{ij}(T_r,T')\big) = \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \frac{\delta(T'-T_t)}{|\partial_{T'}\tilde{g}_{ij}(T_r,T_t)|}, \qquad \partial_{T'}\tilde{g}_{ij} = -1 + \frac{\hat{\mathbf{r}}_{ij}(T_r;T_t)\cdot\mathbf{V}_j(T_t)}{c_f}$$

Hence

$$S_{ij} = \mu_{\text{arch}}\kappa\, \sigma_{ij}\, |q_i q_j| \int dT_r \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \frac{1}{r_{ij}(T_r;T_t)\; |1 - \hat{\mathbf{r}}_{ij}(T_r;T_t)\cdot\mathbf{V}_j(T_t)/c_f|}$$

This branch-resolved form is written per reception time after the transmitter-time delta has been integrated out. On a retained smooth root $T_t = T_{t,\ell}(T_r)$, the causal constraint also gives

$$\frac{dT_{t,\ell}}{dT_r} = \frac{c_f - \hat{\mathbf{r}}_{ij}(T_r;T_{t,\ell})\cdot\mathbf{V}_i(T_r)}{c_f - \hat{\mathbf{r}}_{ij}(T_r;T_{t,\ell})\cdot\mathbf{V}_j(T_{t,\ell})}$$

This derivative is required for root continuation and change-of-reception-time calculations. It does not create a second acceleration weight. An action, wake-history state, or conservation account that uses D_r as an instantaneous strength must therefore be recomputed. Records may retain D_r/D_t as playback evidence while using $c_f/|D_t|$ for acceleration.

Variation and line-of-action acceleration law

This subsection is the bridge from the causal-hit rule to an action-style account. The physical rule has already said what a receiver feels: delayed line-of-action hits with transmitter-side acceleration weight. The variation below asks whether the same rule can be obtained from one regularized action ledger, so that acceleration, power, and conservation bookkeeping come from the same functional rather than from separate matching rules.

The branch law targeted by the action-level variation is:

$$\frac{d}{dT_r}\left(\mu_{\mathrm{arch}}\mathbf{V}_i(T_r)\right) = \sum_j \mathbf{F}_{ij}(T_r)$$

and the branch-resolved acceleration is

$$\mathbf{F}_{ij}(T_r) = \mu_{\mathrm{arch}}\,\kappa\,\sigma_{ij}\,|q_i q_j| \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \frac{W^{\mathrm{acc}}_{ij}(T_r;T_t)\,\hat{\mathbf{r}}_{ij}(T_r;T_t)}{r^2_{ij}(T_r;T_t)}$$

The inverse-square factor follows in the theorem sketch from the variation of the scale-invariant kernel. On a simple-root chart, the interaction density is

$$\frac{1}{r_{ij}}\delta(\tilde{g}_{ij}), \qquad \tilde{g}_{ij} = T - T' - \frac{r_{ij}}{c_f}$$

Varying the receiver position gives

$$\delta r_{ij} = \hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_i, \qquad \delta\left(\frac{1}{r_{ij}}\right) = -\frac{\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_i}{r^2_{ij}}$$

The variation of

$$\delta(\tilde{g}_{ij})$$

is the remaining distributional part of the proof. After the transmitter-side variation, integration by parts on the root-selected chart, and boundary terms are accounted for, the target branch-resolved Euler-Lagrange term is proportional to

$$\frac{W^{\mathrm{acc}}_{ij}\hat{\mathbf{r}}_{ij}}{r^2_{ij}}$$

This $1/r^2$ scaling is not an added ansatz in the accepted proof route: it is the pull-back expected from a scale-invariant causal-cone constraint in 3D when varying a $1/r$ Fokker kernel. The full proof now also requires deriving the transmitter-side acceleration weight and controlling the derivative-of-delta term under the same symmetry-preserving regularization.

The derivative-of-delta term has a useful exact reduction on any transversal branch. Since

$$\partial_{T'}\tilde{g}_{ij}(T,T') = -J_{ij}(T;T')$$

one has

$$\delta'_\eta(\tilde{g}_{ij}) = -\frac{1}{J_{ij}}\partial_{T'}\delta_\eta(\tilde{g}_{ij})$$

Thus the root-constraint variation can be integrated by parts in the transmitter time T':

$$\int dT'\,\Theta(T-T')\frac{\delta'_\eta(\tilde{g}_{ij})}{c_f r_{ij}}\hat{\mathbf{r}}_{ij} = \mathcal{B}^{(\eta)}_{ij}(T) + \int dT'\,\delta_\eta(\tilde{g}_{ij})\partial_{T'}\left[\Theta(T-T')\frac{\hat{\mathbf{r}}_{ij}}{c_f r_{ij} J_{ij}}\right]$$

The first term is an endpoint or excluded-coincidence contribution; the second is the root-chart interior derivative that must be accounted for before the pure scalar kernel can be claimed to derive any branch-resolved acceleration law. Therefore the action proof does not license dropping $\delta'_\eta(\tilde{g}_{ij})$ by fiat. It requires the symmetry-preserving regularization to make this interior derivative vanish, become a boundary/transmitter-side contribution under the allowed variations, or be cancelled by an explicit counterterm. In the canonical Master EOM the branch-resolved target is $W^{\mathrm{acc}}_{ij}\hat{\mathbf{r}}_{ij}/r^2_{ij}$, so this residual must be rebuilt inside the receiver-side proof rather than reused as closure evidence.

The transmitter-side variation narrows the issue further. Holding the receiver point fixed and varying the emission point gives

$$\delta r_{ij} = -\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_j(T'), \qquad \delta\tilde{g}_{ij} = \frac{1}{c_f}\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_j(T')$$

so

$$\delta_{\mathrm{src}}\left(\frac{\delta_\eta(\tilde{g}_{ij})}{r_{ij}}\right) = \left[\frac{\delta_\eta(\tilde{g}_{ij})}{r^2_{ij}} + \frac{\delta'_\eta(\tilde{g}_{ij})}{c_f r_{ij}}\right]\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_j(T')$$

Selecting the future reception time as the root gives

$$\partial_T\tilde{g}_{ij}(T,T') = 1 - \frac{\hat{\mathbf{r}}_{ij}(T,T')\cdot\mathbf{V}_i(T)}{c_f}$$

and hence the transmitter-side derivative-of-delta term integrates by parts as

$$\int dT\,\Theta(T-T')\frac{\delta'_\eta(\tilde{g}_{ij})}{c_f r_{ij}}\hat{\mathbf{r}}_{ij} = \tilde{\mathcal{B}}^{(\eta)}_{ij}(T') - \int dT\,\delta_\eta(\tilde{g}_{ij})\partial_T\left[\Theta(T-T')\frac{\hat{\mathbf{r}}_{ij}}{c_f r_{ij}\left(1-\hat{\mathbf{r}}_{ij}\cdot\mathbf{V}_i(T)/c_f\right)}\right]$$

This is a coefficient of $\delta\mathbf{X}_j(T')$, not of $\delta\mathbf{X}_i(T)$. For arbitrary compactly supported interior variations, the receiver and transmitter variations are independent. The transmitter-side term therefore does not generically cancel the receiver-side root-chart derivative in the Euler-Lagrange equation for $\mathbf{X}_i(T)$. Noether boundary terms control endpoint contributions and global time-translation, spatial-translation, and rotation charges; they do not remove an interior coefficient under compact variations.

In the sharp positive-delay transmitter-time-collapse limit,

$$\int dT'\,\delta_\eta(\tilde{g}_{ij})\partial_{T'}\left[\Theta(T-T')\frac{\hat{\mathbf{r}}_{ij}}{c_f r_{ij} J_{ij}}\right] \longrightarrow \frac{1}{|J_{ij}(T_r;T_t)|}\,\partial_{T'}\left[\frac{\hat{\mathbf{r}}_{ij}(T,T')}{c_f r_{ij}(T,T')J_{ij}(T;T')}\right]\Bigg|_{T'=T_t}$$

Thus the scalar $1/r$ causal kernel produces the inverse-square scale term as a receiver-side proof ingredient only if the admitted branch also satisfies the residual-vanishing condition

$$\partial_{T'}\left[\frac{\hat{\mathbf{r}}_{ij}(T,T')}{r_{ij}(T,T')J_{ij}(T;T')}\right]\Bigg|_{T'=T_t} = \mathbf{0}$$

or if the action is supplemented by an explicit regularized counterterm whose receiver Euler derivative cancels this residual interior vector. Such a counterterm must come from an invariant action-level mechanism, not from fitting the already accepted acceleration law. Under the transmitter-side law this is not a completed derivation; it is a warning that the pure scalar $1/r$ Fokker-type action is only a partial variational scaffold until the W_{ij}^{acc} target is derived.

Equivalently, define the direct scale term

$$\mathbf{F}_{ij,\mathrm{scale}}^{(\eta)}(T)=\int_{-\infty}^{T} dT' \,\frac{\hat{\mathbf{r}}_{ij}(T,T')}{r_{ij}^{2}(T,T')}\,\delta_\eta(\tilde{g}_{ij}(T,T'))$$

and the constraint residual

$$\mathbf{C}_{ij}^{(\eta)}(T)=\mathbf{C}_{ij,r}^{(\eta)}(T)+\mathbf{C}_{ij,t}^{(\eta)}(T)+\mathbf{C}_{ij,\mathrm{bdry}}^{(\eta)}(T)$$

where $\mathbf{C}_{ij,r}^{(\eta)}$ is the receiver-side interior derivative displayed above, $\mathbf{C}_{ij,t}^{(\eta)}$ is the transmitter-side coefficient on $\delta\mathbf{X}_j(T')$, and $\mathbf{C}_{ij,\mathrm{bdry}}^{(\eta)}$ is the boundary contribution. On a regularized chart the action-derived equation has the diagnostic form

$$\mu_{\mathrm{arch}}\mathbf{A}_i(T)=\sum_j \kappa\,\sigma_{ij}|q_iq_j|\left(\mathbf{F}_{ij,\mathrm{scale}}^{(\eta)}(T)+\mathbf{C}_{ij}^{(\eta)}(T)\right)$$

The canonical branch law is recovered on a tested window W in the weak simple-root limit only if

$$\lim_{\eta\to0^+}\int_W \left\|\sum_j \kappa\,\sigma_{ij}|q_iq_j|\mathbf{C}_{ij}^{(\eta)}(T)\right\| dT=0$$

with the same branch floors and boundary convention used to define the action. This windowed residual condition is the minimal proof obligation for upgrading the variational scaffold to an exact action derivation of the Master EOM.

Decision (pure scalar action). The pure scalar $1/r$ Fokker-type scaffold remains unpromoted. The receiver-factor obstruction has been removed from its target, but the local derivative-of-delta residual and the future-reception boundary problem still must be resolved on the same causal retained-history update.

Equivalently, on an admissible branch with $r_{ij}>0$ and $|J_{ij}|>J_{\min}>0$,

$$\partial_{T'}\left[\frac{\hat{\mathbf{r}}_{ij}(T,T')}{r_{ij}(T,T')J_{ij}(T;T')}\right]\Bigg|_{T'=T_t}\neq\mathbf{0}$$

is a certificate that the pure scalar scaffold leaves a nonzero receiver-acceleration residual on that branch. This falsifies the universal claim “the scalar $1/r$ action by itself is the exact action for the Master EOM.” It does not falsify the transmitter-side Master Equation or the possibility of a later causal wake-state action. It means the action proof must close the residual, retained-history update, and conserved accounts without reintroducing receiver velocity into the arriving acceleration.

No-go scaffold (same-support local scalar counterterm). The clean local scalar counterterm route is closed under the following restricted assumptions: the added term has the same causal-surface support as the $1/r$ kernel, uses only $\tilde{g}_{ij}$, r_{ij}, and J_{ij} on the existing branch chart, introduces no new variables, adds no off-surface support, and is not fitted after the acceleration law is already known. Suppressing the common coupling and sign factors, the allowed branch-pair form is

$$S_{\mathrm{ct},ij}^{(\eta)}=\int dT\,dT'\,\Theta(T-T')\,a(r_{ij},J_{ij})\,\delta_\eta(\tilde{g}_{ij})$$

For receiver variation,

$$\delta r_{ij}=\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_i,\qquad \delta\tilde{g}_{ij}=-\frac{1}{c_f}\hat{\mathbf{r}}_{ij}\cdot\delta\mathbf{X}_i$$

Before any optional J_{ij}-variation is included, the radial part of the counterterm variation contains

$$\delta_{\mathbf{X}_i} S^{(\eta)}_{\mathrm{ct},ij} \supset \left[\partial_{r_{ij}} a\, \delta_\eta(\tilde g_{ij}) - \frac{a}{c_f}\delta'_\eta(\tilde g_{ij})\right] \hat{\mathbf{r}}_{ij}\cdot \delta\mathbf{X}_i$$

The optional J_{ij}-dependence can add transverse and transmitter-velocity terms, but it does not remove the scalar radial coefficient that must cancel the original derivative-of-delta residual. Cancelling that coefficient for all admitted receiver variations requires

$$a(r_{ij}, J_{ij}) = -\frac{1}{r_{ij}}$$

This choice necessarily adds

$$\partial_{r_{ij}} a\, \delta_\eta(\tilde g_{ij}) = \frac{\delta_\eta(\tilde g_{ij})}{r_{ij}^2}$$

which changes the accepted inverse-square scale term. Any further same-support scalar correction that removes this scale change reintroduces a derivative-of-delta coefficient. A $\tilde g_{ij}$-antiderivative of $\delta_\eta(\tilde g_{ij})$ would move support away from the causal wake surface and is outside the assumptions. Therefore no same-support local scalar counterterm built only from $\tilde g_{ij}$, r_{ij}, and J_{ij} is admissible under this restricted route.

The obstruction also survives a finite local delta-jet extension. Let

$$K^{(\eta)}_{\mathrm{ct}}(r,g) = \sum_{n=0}^{N} a_n(r)\delta^{(n)}_\eta(g), \qquad D_{ij} \equiv \partial_r - \frac{1}{c_f}\partial_g$$

The direct kernel $K^{(\eta)}_0 = \delta_\eta(g)/r$ has

$$D_{ij} K^{(\eta)}_0 = -\frac{\delta_\eta(g)}{r^2} - \frac{\delta'_\eta(g)}{c_f r}$$

Cancelling only the derivative-of-constraint residual would require

$$D_{ij} K^{(\eta)}_{\mathrm{ct}} = \frac{\delta'_\eta(g)}{c_f r}$$

without adding another $\delta_\eta(g)/r^2$ scale term. For $N \geq 1$, the highest derivative coefficient is $-a_N(r)\delta^{(N+1)}_\eta(g)/c_f$, so $a_N = 0$; descending through the jet order forces $a_n = 0$ for every $n \geq 1$. The remaining $N = 0$ case requires $a_0(r) = -1/r$, but then $\partial_r a_0 = 1/r^2$, so the counterterm again changes the inverse-square scale term it was supposed to preserve.

The conclusion is narrow but decisive for local repairs: no finite same-support local scalar or delta-jet counterterm cancels the scalar-kernel residual while leaving the canonical branch strength intact. A viable action-level repair must instead be nonlocal along the (r, g) characteristic, or must use a richer velocity/history-dependent invariant action. Either route changes the action ontology enough that it should be discussed explicitly before canonization.

The terminal common-center inter-layer chart gives a concrete obstruction to the remaining per-branch stationarity route. In that specialization, stationarity of $\hat{\mathbf{r}}/(rJ)$ forces the transmitter tangent to be parallel to the transmitter-receiver separation. The scalar part then reduces to $\rho_\delta(1-\rho_\delta) = 0$, where ρ_δ denotes the branch value of $\partial_\delta \rho_b$: the first factor collapses a positive-delay branch when the transmitter speed is nonzero, and the second factor is $J = 0$, a grazing branch excluded by the Jacobian floor. Thus terminal inter-layer charts should not expect the scalar scaffold to close by per-branch stationarity. The remaining local target is branch-summed residual closure for a scalar scaffold or a different action candidate derived from Architrino primitives.

For the transmitter-side branch target, the branch-summed residual target is the vanishing of the signed receiver-side interior Euler derivative after the direct inverse-square term is removed:

$$\sum_{b:\, o_b=i} \kappa\ \mathrm{sign}(q_{j_b} q_i)\, |q_{j_b} q_i|\, \mathbf{C}_b^{(0)}(T) = \mathbf{0}$$

with the same positive-delay, Jacobian-floor, and boundary convention used by the branch chart. This is not the Master EOM acceleration residual and not the Noether conservation ledger. It is the additional condition needed for the scalar action scaffold to have no leftover interior Euler derivative on that receiver. If the signed sum is nonzero, the scalar action candidate fails on that chart; the residual does not become a new acceleration term.

Nonlocal characteristic repair target. The least invasive remaining action-level route is to solve the counterterm equation before imposing causal-surface support. In the reduced scalar variables, the required receiver-gradient correction has the form

$$D_{ij} K_{\mathrm{ct}}^{(\eta)}(r, g) = \frac{\delta_\eta'(g)}{c_f r}, \qquad D_{ij} = \partial_r - \frac{1}{c_f}\partial_g$$

The characteristics of D_{ij} preserve

$$u = g + \frac{r}{c_f}$$

Thus a formal characteristic solution is

$$K_{\mathrm{ct}}^{(\eta)}(r, g) = H_{\mathrm{ct}}^{(\eta)}\left(g + \frac{r}{c_f}\right) + \int_{r_*}^{r} \frac{1}{c_f \rho}\, \delta_\eta'\left(g + \frac{r-\rho}{c_f}\right) d\rho$$

with $H_{\mathrm{ct}}^{(\eta)}$ and the lower characteristic endpoint r_* fixed by the history-window, core-regularization, or boundary convention. This expression is invariant under time translation, spatial translation, and spatial rotation because it depends only on the causal scalar g, the Euclidean separation r, and declared scalar endpoints. It is not a same-support wake-surface term: it carries a characteristic tail in (r, g) and therefore changes the action scaffold.

This gives a concrete proof target rather than a completed replacement action. A candidate nonlocal action may be promoted only if its endpoint convention preserves $H(0) = 0$, its Euler derivative cancels the residual above without changing the accepted inverse-square branch term, and its Noether boundary terms close the same energy, momentum, and angular-momentum ledger used by the Master EOM.

The endpoint calculation sharpens that target. The lower-endpoint form above is only the formal characteristic integral. A delayed-interior tail should instead be oriented toward an outgoing endpoint:

$$K_{\mathrm{ct},+}^{(\eta)}(r, g) = H_+^{(\eta)}\left(g + \frac{r}{c_f}\right) - \int_{r}^{R_+} \frac{1}{c_f \rho}\, \delta_\eta'\left(u - \frac{\rho}{c_f}\right) d\rho, \qquad u = g + \frac{r}{c_f}$$

with $R_+ \geq r$ on the retained finite history chart, or with an explicitly controlled $R_+ = \infty$ limit. A characteristic endpoint is the special case $R_+ = R_+(u)$. Since $D_{ij} u = 0$, differentiation gives

$$D_{ij} K_{\mathrm{ct},+}^{(\eta)} = \frac{\delta_\eta'(g)}{c_f r} - \frac{D_{ij} R_+}{c_f R_+}\, \delta_\eta'\left(u - \frac{R_+}{c_f}\right)$$

Thus the desired interior cancellation holds without an extra endpoint contribution only when R_+ is itself a characteristic endpoint, $D_{ij} R_+ = 0$.

Endpoint-ledger decision. The displayed endpoint term is not automatically a Noether boundary term. Its support is

$$u = \frac{R_+}{c_f}, \qquad g = \frac{R_+ - r}{c_f}$$

which is generally an interior tail surface of the retained delayed chart, not the primary arrival surface $g = 0$. If $D_{ij} R_+ \neq 0$, compact receiver variations inside the retained chart see

$$-\frac{D_{ij}R_+}{c_f R_+}\,\delta'_\eta\left(u-\frac{R_+}{c_f}\right)$$

as an Euler coefficient. Moving that term into the Noether wake-history ledger would hide an acceleration-law change unless the endpoint is a declared fixed history boundary whose variation is held fixed. Therefore the characteristic-tail repair preserves the accepted Master EOM branch acceleration only under one of the following conditions:

$$D_{ij}R_+ = 0, \qquad \text{or} \qquad \lim_{\eta\to 0^+}\int_W \left\|\frac{D_{ij}R_+}{c_f R_+}\,\delta'_\eta\left(u-\frac{R_+}{c_f}\right)\right\| dT = 0$$

for the declared branch chart and fixed endpoint convention. In that admissible case the endpoint contributes only a boundary wake-history flux, not a new receiver acceleration. In the generic non-characteristic case, the repair is a no-go for the canonical Master EOM because it adds an extra interior action-level acceleration.

In the sharp-support limit, the outgoing form is supported on

$$0 \le g \le \frac{R_+ - r}{c_f}$$

so it is a causal interior tail behind the arriving wake surface, not a same-support surface density. Conversely, a lower endpoint $r_* < r$ supports a tail with $g \le 0$ and is not delayed-interior causal support unless the boundary convention supplies a separate interpretation. This proves a useful but limited result: the characteristic-tail equation can cancel the scalar scaffold's interior derivative residual at the level of the Euler derivative, but it does so by adding a nonlocal tail and endpoint ledger obligation. It is not yet an exact action for the Master EOM.

A nondegenerate characteristic endpoint gives the cleanest candidate. On a retained chart choose

$$R_+(u) = c_f(u + h_+), \qquad h_+ > 0$$

or take the controlled $R_+ = \infty$ limit. Since $R_+ = R_+(u)$ and $D_{ij}u = 0$, the endpoint is characteristic and the Euler leakage term proportional to $D_{ij}R_+$ vanishes. The outgoing counterterm can then be written, after the change of variable $s = u - \rho/c_f$, as

$$K^{(\eta)}_{\mathrm{ct},+}(r,g) = H^{(\eta)}_+(u) - \int_{-h_+}^{g} \frac{\delta'_\eta(s)}{c_f(u-s)} ds$$

Integrating by parts gives

$$\frac{\delta_\eta(g)}{r} + K^{(\eta)}_{\mathrm{ct},+}(r,g) = H^{(\eta)}_+(u) + \frac{\delta_\eta(-h_+)}{c_f(u+h_+)} + \int_{-h_+}^{g} \frac{\delta_\eta(s)}{c_f(u-s)^2} ds$$

The finite-endpoint clearance condition is therefore

$$\mathcal{B}^{(\eta)}_+(u,h_+) \equiv \frac{\delta_\eta(-h_+)}{c_f(u+h_+)} = 0$$

for a compactly supported mollifier with h_+ outside the support, or $\mathcal{B}^{(\eta)}_+ \to 0$ in the declared weak limit for a Gaussian mollifier. If finite-η endpoint clearance is not exact, the characteristic gauge must be fixed by

$$H^{(\eta)}_+(u) = -\mathcal{B}^{(\eta)}_+(u,h_+)$$

before the kernel is treated as a normalized action object. This condition is invisible to the receiver Euler derivative because it depends only on u, but it is visible to the Noether wake-history charge.

With the endpoint-clear normalization imposed, the delayed-interior effective kernel is

$$K^{(\eta)}_{\mathrm{eff},h_+}(r,g)=\int_{-h_+}^{g}\frac{\delta_\eta(s)}{c_f(u-s)^2}ds,\qquad u=g+\frac{r}{c_f}$$

In the infinite-endpoint form,

$$K^{(\eta)}_{\mathrm{eff}}(r,g)=\int_{-\infty}^{g}\frac{\delta_\eta(s)}{c_f(u-s)^2}ds$$

Both forms satisfy the receiver-gradient identity

$$D_{ij}K^{(\eta)}_{\mathrm{eff}}=-\frac{\delta_\eta(g)}{r^2}$$

with the finite form using the same identity after endpoint clearance. Thus the delayed-interior characteristic-tail kernel cancels the derivative-of-constraint residual without adding a second inverse-square scale term. The accompanying Noether boundary terms for energy, momentum, and angular momentum must be taken from the same normalized kernel, as below; replacement of a diagnostic inverse-square adapter on any concrete branch still requires the branch-chart residual and conservation checks.

Noether boundary increments for the normalized tail. With the endpoint-clear normalization imposed, there is no remaining free $H^{(\eta)}_+(u)$ gauge term that can shift the wake-history charge. Define the weighted effective action kernel

$$\mathcal{K}^{(\eta)}_{ij,\mathrm{eff}}(T_1,T_t)=\mu_{\mathrm{arch}}\kappa\,\sigma_{ij}|q_iq_j|\Theta(T_1-T_t)K^{(\eta)}_{\mathrm{eff}}(r_{ij}(T_1;T_t),\tilde g_{ij}(T_1,T_t))$$

with the same finite-endpoint version when the chart uses $h_+<\infty$. For a time cut T_*, let

$$X_{ij}(T_*)=\{(T_1,T_t):T_t\le T_*<T_1,\ T_1>T_t\}$$

with the trivial self-coincidence branch excluded when $i=j$. The normalized characteristic-tail wake increments are

$$E^{(\eta)}_{\mathrm{wake,eff}}(T_*)=-\frac{1}{2}\sum_{i,j}\int_{X_{ij}(T_*)}\partial_{T_1}\mathcal{K}^{(\eta)}_{ij,\mathrm{eff}}(T_1,T_t)\,dT_t\,dT_1$$

$$\mathbf{P}^{(\eta)}_{\mathrm{wake,eff}}(T_*)=-\frac{1}{2}\sum_{i,j}\int_{X_{ij}(T_*)}\nabla_{\mathbf{X}_i(T_1)}\mathcal{K}^{(\eta)}_{ij,\mathrm{eff}}(T_1,T_t)\,dT_t\,dT_1$$

and

$$\mathbf{J}^{(\eta)}_{\mathrm{wake,eff}}(T_*)=-\frac{1}{2}\sum_{i,j}\int_{X_{ij}(T_*)}\mathbf{X}_i(T_1)\times\nabla_{\mathbf{X}_i(T_1)}\mathcal{K}^{(\eta)}_{ij,\mathrm{eff}}(T_1,T_t)\,dT_t\,dT_1$$

The minus signs in the spatial charges follow the sign convention that the interaction contribution appears with a minus sign in the action. The receiver-gradient identity gives

$$\nabla_{\mathbf{X}_i(T_1)}K^{(\eta)}_{\mathrm{eff}}=\hat{\mathbf{r}}_{ij}D_{ij}K^{(\eta)}_{\mathrm{eff}}=-\frac{\delta_\eta(\tilde g_{ij})}{r_{ij}^2}\hat{\mathbf{r}}_{ij}$$

while the transmitter-end gradient is the opposite. Therefore a global spatial translation or rotation of both endpoints changes no interior action density, and a step translation or step rotation across T_* exposes exactly the boundary increments above. The characteristic endpoint condition $D_{ij}R_+=0$, together with endpoint clearance, is the local reason these increments are wake-history boundary terms rather than a hidden extra receiver acceleration.

This closes the local kernel-normalization and Noether-increment definition for the delayed-interior characteristic-tail repair. It does not by itself certify any proposed branch, terminal label, or Noether braid attractor: a branch chart must still show vanishing Euler residual, finite memory depth, positive transmitter-side Jacobian floors, retained same-record transmitter-side acceleration-weight records, and closure of $K_\mu + E^{(\eta)}_{\text{wake,eff}}$, $\mathbf{P}_{\text{mech}} + \mathbf{P}^{(\eta)}_{\text{wake,eff}}$, and $\mathbf{J}_{\text{mech}} + \mathbf{J}^{(\eta)}_{\text{wake,eff}}$ over the same retained branch set.

Branch-chart conservation pullback. Let $\mathfrak{B}(\Gamma, \mathcal{S}; h, \eta, \epsilon_c)$ be a retained branch chart with active causal-root records $\mathcal{R}^{\text{act}}$, positive inactive-root gaps, positive transmitter-side Jacobian floor, a retained transmitter-side acceleration-weight floor ν_{rec}, finite memory depth, and declared endpoint convention. For a time cut T_*, define the chart-restricted crossing domain

$$X^{\mathfrak{B}}_{ij}(T_*) \equiv X_{ij}(T_*) \cap \{(T_1, T_t) : (i, j, T_1, T_t) \text{ lies on a retained record of } \mathcal{R}^{\text{act}}\}$$

with trivial self-coincidence excluded when $i = j$. The pulled-back wake-history charges are the same Noether boundary terms above, restricted to $X^{\mathfrak{B}}_{ij}(T_*)$:

$$E^{(\eta)}_{\text{wake,eff},\mathfrak{B}}(T_*) = -\frac{1}{2}\sum_{i,j}\int_{X^{\mathfrak{B}}_{ij}(T_*)} \partial_{T_1}\mathcal{K}^{(\eta)}_{ij,\text{eff}}(T_1, T_t)\, dT_t\, dT_1$$

$$\mathbf{P}^{(\eta)}_{\text{wake,eff},\mathfrak{B}}(T_*) = -\frac{1}{2}\sum_{i,j}\int_{X^{\mathfrak{B}}_{ij}(T_*)} \nabla_{\mathbf{X}_i(T_1)}\mathcal{K}^{(\eta)}_{ij,\text{eff}}(T_1, T_t)\, dT_t\, dT_1$$

and

$$\mathbf{J}^{(\eta)}_{\text{wake,eff},\mathfrak{B}}(T_*) = -\frac{1}{2}\sum_{i,j}\int_{X^{\mathfrak{B}}_{ij}(T_*)} \mathbf{X}_i(T_1) \times \nabla_{\mathbf{X}_i(T_1)}\mathcal{K}^{(\eta)}_{ij,\text{eff}}(T_1, T_t)\, dT_t\, dT_1$$

The matching mechanical charges on the same chart are

$$K_{\mu,\mathfrak{B}}(T) = \sum_{i\in\mathfrak{B}}\frac{1}{2}\mu_{\text{arch}}\|\mathbf{V}_i(T)\|^2, \qquad \mathbf{P}_{\text{mech},\mathfrak{B}}(T) = \sum_{i\in\mathfrak{B}}\mu_{\text{arch}}\mathbf{V}_i(T)$$

$$\mathbf{J}_{\text{mech},\mathfrak{B}}(T) = \sum_{i\in\mathfrak{B}}\mathbf{X}_i(T) \times \mu_{\text{arch}}\mathbf{V}_i(T)$$

For a retained window $W = [T_a, T_b]$, the branch-chart conservation test is

$$\Delta_W\left(K_{\mu,\mathfrak{B}} + E^{(\eta)}_{\text{wake,eff},\mathfrak{B}}\right) = \int_W \sum_i \mathbf{V}_i(T)\cdot\mathbf{R}^{(\eta)}_{i,\text{eff},\mathfrak{B}}(T)\, dT + \int_W \mathcal{B}^{(\eta)}_{E,\mathfrak{B}}(T)\, dT$$

$$\Delta_W\left(\mathbf{P}_{\text{mech},\mathfrak{B}} + \mathbf{P}^{(\eta)}_{\text{wake,eff},\mathfrak{B}}\right) = \int_W \sum_i \mathbf{R}^{(\eta)}_{i,\text{eff},\mathfrak{B}}(T)\, dT + \int_W \mathcal{B}^{(\eta)}_{P,\mathfrak{B}}(T)\, dT$$

$$\Delta_W\left(\mathbf{J}_{\text{mech},\mathfrak{B}} + \mathbf{J}^{(\eta)}_{\text{wake,eff},\mathfrak{B}}\right) = \int_W \sum_i \mathbf{X}_i(T)\times\mathbf{R}^{(\eta)}_{i,\text{eff},\mathfrak{B}}(T)\, dT + \int_W \mathcal{B}^{(\eta)}_{J,\mathfrak{B}}(T)\, dT$$

The theorem-level branch claim requires the three residual balances to converge to zero with $\epsilon^{(\eta)}_{\text{var}}(W) \to 0$, vanishing declared endpoint or period-cut leakage, stable branch floors, and the same retained record set in the acceleration residuals and in the three wake-history charges. A work-integral reconstruction $U(T)$ or a projected torque increment is only a numerical diagnostic unless it is derived from this same action kernel, endpoint convention, and retained branch chart.

For a finite spatial window, the energy boundary record can be read as the wake-escapement flux defined in Energy. In that notation, a theorem-level conservation packet should be able to rewrite the energy balance in the form

$$\frac{dE_W}{dT} = -\Phi_{\text{wake},\partial W}(T) + P_{\text{ext},W}(T) + \mathcal{R}_{E,W}(T), \qquad \Phi_{\text{wake},\partial W}(T) = \frac{d}{dT}\sum_{\alpha\in\mathcal{E}_{\text{esc}}(W)} E^{\text{emit}}_\alpha.$$

This does not add a second energy channel. It identifies the endpoint and boundary term of the delayed action with the causal-wake history that exits the retained window without a retained receiver. The same boundary object is the entropy-arrow theorem target in Entropy: energy flux, wake escapement, and observer-window entropy production are three projections of one finite-window path-history defect.

Self-interaction ($i = j$) is included by adding S_{ii} with the same kernel, but explicitly excluding the trivial coincidence $T' = T$ (no instantaneous self-push at the moment of emission). Self-hit corresponds to nontrivial roots $T_t < T_r$ where the worldline re-intersects its own causal isochrons, which are captured naturally by the same double-integral structure.

Thus:

- The scalar $1/r$ action above is a nonlocal variational scaffold for the delayed dynamics under the stated branch and regularization assumptions,
- It becomes an exact action derivation of the Master EOM only on branch charts where the constraint residual vanishes or is cancelled by an invariant action-level counterterm,
- A finite same-support local scalar or delta-jet counterterm has been ruled out because it cancels the derivative residual only by disturbing the inverse-square scale term,
- The currently minimal known action repair is the delayed-interior characteristic-tail kernel above; its receiver Euler derivative has the desired inverse-square identity, and its normalized wake-history boundary increments are explicit,
- Without such closure, the pure scalar action is falsified as the universal exact action for the Master EOM and should be treated as a diagnostic scaffold,
- Any δ_η replacement must preserve the symmetries that supply the Noether charges if conservation claims are to remain exact.

Trajectory Work Reconstruction and Total-Energy Target

Given the kinetic energy definition, the next object separates a realized-trajectory identity from a genuine Noether charge.

General structure

Along any realized trajectory, define the diagnostic reconstruction

$$H_U[\{\mathbf{X}_i(\cdot)\}, \{\mathbf{V}_i(\cdot)\}; T] \equiv K_\mu(T) + U(T)$$

with $U(T)$ reconstructed along the realized trajectory by:

$$U(T) = U_* - \int_{T_*}^{T} \sum_i \mu_{\text{arch}}\, \mathbf{A}_i(T') \cdot \mathbf{V}_i(T')\, dT'$$

where U_* is a fixed reference and $\mathbf{A}_i$ is the actual acceleration given by the Master Equation (including self-hit and partner contributions). Then:

$$\frac{dH_U}{dT} = \frac{dK_\mu}{dT} + \frac{dU}{dT} = \sum_i \mu_{\text{arch}}\, \mathbf{A}_i \cdot \mathbf{V}_i - \sum_i \mu_{\text{arch}}\, \mathbf{A}_i \cdot \mathbf{V}_i = 0$$

This constancy is true by construction and is not independent conservation evidence. The reconstruction is not a local function only of $(\mathbf{X}_i(T), \mathbf{P}_i(T))$, but neither does it become an off-shell Noether charge merely by retaining history.

The theorem-grade total-energy target is instead

$$E_{\text{tot}}(T) = K_\mu(T) + E_{\text{wake}}(T),$$

where E_{wake} must arise as the boundary charge of the same symmetry-preserving delayed action whose interior variation reproduces the Master EOM. Only that derivation, together with closed boundary flux, promotes conservation beyond the trajectory identity $dH_U/dT = 0$.

Local canonical form in effective limits

In regimes where:

- Internal binaries are in tight, quasi-stationary maximum-curvature orbits (giving approximately fixed internal energies),
- Wake travel times across the system are short compared to dynamical timescales of the center-of-mass motion of assemblies,
- Self-hit contributions primarily renormalize the internal energies (rest masses),

we can introduce **effective assemblies** with:

- Effective masses M_A,
- Positions $\mathbf{X}_A$,
- Momenta $\mathbf{P}_A = M_A\, d\mathbf{X}_A/dT$,
- An approximate instantaneous interaction potential $U_{\text{eff}}(\{\mathbf{X}_A\})$,

and write a **local canonical Hamiltonian**:

$$H_{\text{eff}}(\{\mathbf{X}_A\},\{\mathbf{P}_A\}) = \sum_A \frac{\|\mathbf{P}_A\|^2}{2M_A} + U_{\text{eff}}(\{\mathbf{X}_A\})$$

which:

- Approximates the full history-aware energy functional when assemblies are well separated and slowly varying,
- Recovers familiar particle-mechanics structure for many emergent phenomena (orbital motion, scattering, bound states) without ever attributing energy to a continuous field.

Summary

- **Kinetic energy** is defined in the usual way at the architrino level, with internal kinetic energy of tightly bound self-hit binaries contributing to assembly rest masses.
- **Interaction energy** is not primitive as an instantaneous position function; it is encoded in the nonlocal causal charge E_{wake} and may be reconstructed from the work-integral form U.
- A **nonlocal variational scaffold** is available under the regularity and boundary assumptions stated above: a multi-time Lagrangian whose kernel enforces the causal isochron geometry and targets the Master EOM with its transmitter-side inverse-square law, becoming an exact action derivation only when the constraint residual vanishes or is explicitly cancelled.
- The theorem-grade **total energy** is the action-derived history charge $K_\mu + E_{\text{wake}}$; the realized-trajectory quantity $K_\mu + U$ is a diagnostic identity. In suitable limits the former reduces to a canonical $H_{\text{eff}} = \sum \mathbf{P}^2/2M + U_{\text{eff}}$ for effective assemblies, with no separate "field energy" ontology.

All energy accounting remains localized to **architrinos and their assemblies** and is only updated at the instants when **causal wake surfaces intersect receivers** at $T = \text{now}$. The action-derived conserved charge is written as $K_\mu(T) + E_{\text{wake}}(T)$; a work-integral reconstruction $K_\mu(T) + U(T)$ is compatible only along realized trajectories after the same boundary convention and acceleration law have been declared.

Symmetry, Conservation, and Lyapunov Functionals

Introduction

The Master Equation is a state-dependent delay system: acceleration at time T depends on the path-history segment over $[T-h, T]$. In this setting, conservation laws are not functions of the instantaneous state $(\mathbf{X}, \mathbf{V})$ alone. Instead, they are **functionals on path history** that track "in-flight" wake contributions.

The comparison to delay-equation theory should therefore be read literally but narrowly. A finite-propagation two-body law is not an ordinary present-state ODE: a valid update needs a retained history segment, the active causal-root ledger, and the same receiver/transmitter branch records used by the acceleration law. In standard terminology, a reduced chart whose delayed dependencies reach only positions and velocities resembles a state-dependent delay differential equation, while a chart that retains delayed accelerations or highest-derivative constraints is closer to a neutral delay differential equation. That classification is only a mathematical comparison; the native burden remains the same-record causal-root, D_t, D_r, $W^{\rm acc}$, and wake-history ledger.

This section makes the symmetry group explicit and states the corresponding conserved functionals for isolated systems with $\eta > 0$.

Fundamental Symmetry Group

Definition (Fundamental symmetry group). The substrate and interaction kernel are invariant under

$$G_{\rm fund} = E(3) \times \mathbb{R}_{\rm time}$$

where $E(3) = \mathbb{R}^3 \rtimes O(3)$ acts by spatial translations and rotations, and $\mathbb{R}_{\rm time}$ acts by time translation.

Theorem (Invariance of the Master Equation). If $\mathbf{X}(T)$ is a solution, then:

1. **Time translation:** $\mathbf{Y}(T) = \mathbf{X}(T + T_{\rm shift})$ is a solution for any $T_{\rm shift} \in \mathbb{R}$.
2. **Spatial isometry:** $\mathbf{Y}(T) = R\mathbf{X}(T) + \mathbf{b}$ is a solution for any $R \in O(3)$ and $\mathbf{b} \in \mathbb{R}^3$.

Proof sketch. The causal constraint depends only on Euclidean distances and time differences. Both are invariant under $G_{\rm fund}$. The line-of-action vector $\hat{\mathbf{r}}_{ij}$ transforms covariantly under rotations, so the per-hit acceleration retains the same form.

This symmetry statement applies to the background, the interaction kernel, and the transformed full histories. It does not license arbitrary architrino flips or permutations after provenance has been assigned. Let H_i^T denote the path-history/provenance record of architrino i up to time T. A label permutation P is an exact symmetry only on the restricted histories for which

$$H^T_{P(i)} = P(H_i^T)$$

for every i, with the same transformation also preserving all causal-root relations $\mathcal{C}_{ij}(T_r)$. For generic states this condition fails, so effective indistinguishability must be treated as coarse-grained observer bookkeeping rather than substrate identity.

Generalized Momentum and Angular Momentum

The delayed theory separates ordinary mechanical motion from the causal-wake history that is still in flight. For an action-derived delayed model with translation and rotation symmetry, the full Noether charges are history functionals: the particle-only quantities need not be conserved by themselves, but the particle-plus-wake totals are. In regularized or numerical variants, the same expressions should be treated as conserved diagnostics only when the chosen regularization preserves those symmetries.

Definition (Mechanical momentum).

$$\mathbf{P}_{\rm mech}(T) = \sum_i \mu_{\rm arch} \mathbf{V}_i(T)$$

Because the accelerations are delayed, $d\mathbf{P}_{\rm mech}/dT$ is generally nonzero.

Definition (Wake momentum functional). For an isolated system, define

$$\mathbf{P}_{\rm wake}(T) = \mathbf{P}_{\rm wake}(T_*) - \int_{T_*}^{T} \sum_i \mathbf{F}_i(T')\, dT'$$

with $\mathbf{F}_i = \mu_{\rm arch}\mathbf{A}_i$ from the Master Equation.

Validation condition (total momentum).

$$\mathbf{P}_{\mathrm{tot}}(T) \equiv \mathbf{P}_{\mathrm{mech}}(T) + \mathbf{P}_{\mathrm{wake}}(T)$$

is constant in time for isolated solutions of the symmetry-preserving nonlocal action. With the integral definition above, constancy along one realized trajectory is true by construction; independent conservation evidence requires $\mathbf{P}_{\mathrm{wake}}$ to be derived as the spatial-translation boundary charge of that same action. For working regularized models it remains a validation condition.

Definition (Mechanical angular momentum).

$$\mathbf{L}_{\mathrm{mech}}(T) = \sum_i \mathbf{X}_i(T) \times \mu_{\mathrm{arch}} \mathbf{V}_i(T)$$

Definition (Wake angular momentum functional).

$$\mathbf{L}_{\mathrm{wake}}(T) = \mathbf{L}_{\mathrm{wake}}(T_*) - \int_{T_*}^{T} \sum_i \mathbf{X}_i(T') \times \mathbf{F}_i(T')\, dT'$$

Conservation target (total angular momentum).

$$\mathbf{L}_{\mathrm{tot}}(T) \equiv \mathbf{L}_{\mathrm{mech}}(T) + \mathbf{L}_{\mathrm{wake}}(T)$$

is the angular-momentum decomposition associated with rotational invariance of the nonlocal causal action. For isolated solutions of the symmetry-preserving action model it is conserved. For working regularized models, conservation of $\mathbf{L}_{\mathrm{tot}}$ is a validation condition rather than an automatic consequence.

Remark. These definitions mirror the energy decomposition used earlier: the apparent “missing” momentum and angular momentum are assigned to in-flight causal-wake geometry. The total quantities are therefore functionals of the path history, not functions of the instantaneous particle state alone.

Energy Functional and No-Runaway Criterion

Time-translation invariance implies a conserved history functional, which we write as

$$E_{\mathrm{tot}}(T) = K_\mu(T) + E_{\mathrm{wake}}(T)$$

where K_μ is the quadratic kinetic bookkeeping proxy and E_{wake} denotes the exact nonlocal interaction charge. In direct trajectory evaluation, U may be used as a compatible reconstruction up to a constant offset when it is derived from the same action-level acceleration law and boundary convention.

This statement is exact for the action-based delayed theory discussed in this section. For regularized working models, especially the dual-mollified local collinear recapture model, it should be interpreted as exact only when the regularization preserves the same symmetry structure; otherwise it is the natural history-aware bookkeeping candidate rather than a proved invariant.

There is an important independence limit. If E_{wake} or U is defined only by integrating the same realized acceleration power $-\sum_i \mu_{\mathrm{arch}} \mathbf{A}_i \cdot \mathbf{V}_i$, then constancy of $K_\mu + E_{\mathrm{wake}}$ is true by construction. That reconstruction cannot independently detect a persistent same-sign tangential acceleration: it merely books the kinetic change into the opposite wake entry. An independent no-runaway or circular-closure test therefore needs the action-derived time-translation boundary charge, or another separately derived finite-window wake account, rather than the work integral alone.

Lemma (Bounded work rate under regularization). If $\eta > 0$ and the mollified kernel bounds the per-hit acceleration, then there exists $F_{\max}(\eta)$ such that

$$\left| \frac{dK_\mu}{dT} \right| \le \sum_i \|\mathbf{F}_i\|\, \|\mathbf{V}_i\| \le N\, F_{\max}(\eta)\, V_{\max}(T)$$

Theorem target (No-runaway criterion). For an isolated system with fixed $\eta > 0$, if the action-derived interaction charge $E_{\rm wake}(T)$, or a compatible realized-trajectory reconstruction $U(T)$, is bounded below on the admissible history class (for example, by enforcing a minimum separation within the regularized kernel support), then $K_\mu(T)$ is bounded for all times where the solution exists. In particular, a runaway $V_{\max}(T) \to \infty$ is only possible if the corresponding interaction term tends to $-\infty$, which requires a collapse toward the singular regime or a breakdown of the regularized assumptions.

Interpretation. Self-hit repulsion can transfer energy between U and K, but it cannot generate unbounded kinetic energy without a corresponding unbounded decrease in U. This is the core conservation argument for excluding unphysical runaway acceleration in the regularized model.

Simulation Diagnostics (Symmetry and Conservation)

In addition to the convergence checks in Numerical Implementation Notes, track these conserved functionals in any isolated run:

- **Total energy**: $H_{\rm tot}(T) = K_\mu(T) + E_{\rm wake}(T)$, or a declared compatible reconstruction $K_\mu + U$, should remain constant within the chosen numerical tolerance.
- **Total momentum**: $\mathbf{P}_{\rm tot}(T)$ should be constant; monitor $\|\mathbf{P}_{\rm tot}(T) - \mathbf{P}_{\rm tot}(T_{\rm init})\|$.
- **Total angular momentum**: $\mathbf{L}_{\rm tot}(T)$ should be constant; in planar runs, the unit axis $\hat{\mathbf{n}} = \mathbf{L}_{\rm tot}/\|\mathbf{L}_{\rm tot}\|$ should remain fixed.
- **Binary symmetry defect** (for symmetric initial data):

$$\Delta_{\rm sym}(T) = \|\mathbf{X}_1(T) + \mathbf{X}_2(T)\|$$

A secular drift indicates numerical asymmetry or a symmetry-breaking perturbation.

These diagnostics operationalize the symmetry constraints and provide early warning of numerical artifacts or model inconsistencies.

Closure Interface: Coarse-Graining Gate to Effective Quantum Envelope

For integration with the quantum closure program, the master equation provides the microscopic gate:

$$\frac{d^2\mathbf{X}_i}{dT_r^2} = \text{delayed causal-hit sum over } \mathcal{C}_{ij}(T_r)$$

The required next reduction is a controlled map to mesoscopic density dynamics:

$$f(T, \mathbf{X}, \mathbf{V}) \Longrightarrow (\rho, \mathbf{u}, S) \Longrightarrow \psi = \sqrt{\rho}\, e^{iS/\hbar_{\rm eff}}$$

Closure condition for this interface:

- the same coarse-graining window that preserves validated dynamical invariants must recover the effective Schrödinger limit in the non-relativistic, weak-field, fixed-particle-number regime;
- residual non-Markovian terms must be explicitly retained as correction operators, not absorbed into uncontrolled fitting.

Return-map symplectic residual for action-derived branch promotion. When a replayable branch chart is promoted to an action-derived reduced Hamiltonian chart, the section return map must preserve the reduced symplectic structure. Let $z = (Q^a, \Pi_a)$ be local reduced coordinates after the retained root constraints and section condition have been solved, let

$$\mathcal{P}_\mathcal{S} : z_n \mapsto z_{n+1}, \qquad M_\mathcal{S} = D\mathcal{P}_\mathcal{S}$$

and let $\Omega_\mathcal{S}$ be the pulled-back symplectic matrix on the reduced section. Define

$$\mathcal{R}_\Omega \equiv \left\| M_\mathcal{S}^T \Omega_\mathcal{S} M_\mathcal{S} - \Omega_\mathcal{S} \right\|, \qquad \mathcal{R}_{\rm vol} \equiv |\det M_\mathcal{S} - 1|$$

For an exact finite-dimensional Hamiltonian reduction, $\mathcal{R}_\Omega = 0$ and therefore $\mathcal{R}_{\rm vol} = 0$. For the delayed Master EOM these are not automatic consequences of a small orbit residual: they are closure diagnostics for the claim that the retained branch chart has captured the missing path-history degrees of freedom well enough to behave like a canonical return map. A nonzero $\mathcal{R}_\Omega$ means at least one of the following remains unresolved: omitted causal-root records, window-boundary wake flux, an action-level residual, or a reduction that is not actually Hamiltonian. Thus a local master-equation closure claim still uses $\mathfrak{B}(\Gamma, \mathcal{S}; h, \eta, \epsilon_c)$ as defined above, while the stronger Hamiltonian claim must additionally report $\mathcal{R}_\Omega \le \epsilon_\Omega$.

Standard charged-particle comparison target. In ordinary electromagnetic mechanics, a charged particle can be described by

$$L_{\rm EM} = \frac{1}{2} m\, \gamma^{\rm eff}_{ij} \frac{dx^i_{\rm eff}}{dt_{\rm eff}} \frac{dx^j_{\rm eff}}{dt_{\rm eff}} - e\phi_{\rm eff}(x^i_{\rm eff}, t_{\rm eff}) + e\, \frac{dx^i_{\rm eff}}{dt_{\rm eff}} A^{\rm eff}_i(x^i_{\rm eff}, t_{\rm eff}), \qquad p_{i,{\rm can,eff}} = m\gamma^{\rm eff}_{ij} \frac{dx^j_{\rm eff}}{dt_{\rm eff}} + eA^{\rm eff}_i$$

The velocity-coupled one-form shifts canonical momentum and yields the effective Lorentz-force law. Under

$$\phi_{\rm eff} \mapsto \phi_{\rm eff} - \partial_{t_{\rm eff}}\chi, \qquad A^{\rm eff}_i \mapsto A^{\rm eff}_i + \partial_{x^i_{\rm eff}}\chi$$

the Lagrangian changes only by $e\, d\chi/dt_{\rm eff}$, so the effective equations are unchanged. In $\mathbb{AAA}$ this is a comparison structure, not substrate ontology: the primitive kernel still contains only radial causal hits. The corresponding closure target is to extract an assembly-level effective one-form

$$\mathcal{A}_{\rm eff} = A^{\rm eff}_a(Q, t_{\rm eff})\, dQ^a - \phi_{\rm eff}(Q, t_{\rm eff})\, dt_{\rm eff}$$

from coarse-grained causal-root geometry, then show that the observer-level residual

$$\mathcal{R}_{\rm EM}(W) = \int_W \left\| \mu_A a^i_{A,{\rm eff}}(t_{\rm eff}) - e_A \left(E^i_{\rm eff}(x^i_{A,{\rm eff}}, t_{\rm eff}) + \epsilon^i{}_{jk} V^j_{A,{\rm eff}}(t_{\rm eff}) B^k_{\rm eff}(x^i_{A,{\rm eff}}, t_{\rm eff}) \right) \right\| dt_{\rm eff}$$

vanishes in the stated approximation while the underlying branch ledger remains a sum of line-of-action contributions. Failure of this residual is a magnetic-emergence failure, not evidence for inserting an intrinsic cross-product term into the Master EOM.

Constrained branch-multiplier formulation. A constrained action is an active evidence record only if its branch kernel carries transmitter-side acceleration weight. On a fixed retained branch chart, the causal roots may still be represented as constrained variables rather than solved away immediately. Let $T_{t,ij,\ell}(T)$ be the emission time assigned to retained record ℓ and define

$$G_{ij,\ell}(T) \equiv r_{ij,\ell}(T) - c_f \big(T - T_{t,ij,\ell}(T)\big), \qquad r_{ij,\ell}(T) = \|\mathbf{X}_i(T) - \mathbf{X}_j(T_{t,ij,\ell}(T))\|$$

The transmitter-side target uses

$$\mathcal{K}^{{\rm rec},\eta}_{ij,\ell}(T) \equiv \frac{w^{(\eta)}_{ij,\ell}(T)\, W^{\rm acc}_{ij,\ell}(T)}{r_{ij,\ell}(T)}, \qquad W^{\rm acc}_{ij,\ell}(T) = \frac{c_f}{|D_{t,ij,\ell}(T)|}$$

where $D_t = c_f - \hat{\mathbf{r}} \cdot \mathbf{V}_j(T_t)$. The receiver-side quantity $D_r = c_f - \hat{\mathbf{r}} \cdot \mathbf{V}_i(T)$ remains in signed root playback, not in this action-kernel target. A branch-reduced constrained scaffold on a window W must therefore be recomputed in the form

$$S^{(\eta)}_{\mathfrak{B}} = \int_W \left[\sum_i \frac{1}{2} \mu_{\rm arch} \|\mathbf{V}_i(T)\|^2 - \sum_{(i,j,\ell) \in \mathcal{R}^{\rm act}} \tilde{\alpha}_{ij} \mathcal{K}^{{\rm rec},\eta}_{ij,\ell}(T) + \sum_{(i,j,\ell) \in \mathcal{R}^{\rm act}} \lambda_{ij,\ell}(T) G_{ij,\ell}(T) \right] dT$$

where $\tilde{\alpha}_{ij}$ carries the coupling and polarity convention, $w^{(\eta)}_{ij,\ell}$ carries the retained mollified branch and cutoff convention, and $\lambda_{ij,\ell}$ is a Lagrange multiplier for the causal-root constraint. Variation with respect to $\lambda_{ij,\ell}$ enforces $G_{ij,\ell} = 0$. Variation with respect to the root variable gives the branch-record equation

$$0 = \partial_{T_{t,ij,\ell}} \left[-\tilde{\alpha}_{ij} \mathcal{K}^{{\rm rec},\eta}_{ij,\ell} + \lambda_{ij,\ell} G_{ij,\ell} \right]$$

provided the record has no explicit $dT_{t,ij,\ell}/dT$ dependence after the chosen reduction. Variation with respect to the receiver position exposes the constraint contribution

$$\delta_{\mathbf{X}_i} \int_W \lambda_{ij,\ell} G_{ij,\ell}\, dT = \int_W \lambda_{ij,\ell}(T)\, \hat{\mathbf{r}}_{ij,\ell}(T) \cdot \delta \mathbf{X}_i(T)\, dT$$

Thus the multiplier term is not a new substrate acceleration. It is the finite-dimensional record of the work required to keep the retained branch record on the causal-root surface while the surrounding path history is varied. The unconstrained branch action is recovered only when these multiplier contributions are either solved into the same invariant action-level counterterm used above, converted into legitimate boundary wake-history terms, or shown to vanish in the branch-summed residual:

$$\mathcal{R}_{\lambda,i}(W) \equiv \int_W \left\| \sum_{\ell:\, o_\ell = i} \lambda_\ell(T) \hat{\mathbf{r}}_\ell(T) - \sum_j \kappa\, \sigma_{ij} |q_i q_j| \mathbf{C}_{ij}^{(\eta)}(T) \right\| dT \longrightarrow 0$$

Here o_ℓ denotes the receiver index of branch record ℓ. This is the delayed-action analogue of ordinary holonomic constraint handling: one may solve constraints into generalized coordinates, or retain them with multipliers, but the multiplier ledger must not be hidden inside a claimed exact acceleration law.

Noether history-functional balance target. Let $S_{\mathfrak{B}}^{(\eta)}$ be a symmetry-preserving regularized action on a retained branch chart, and let a one-parameter transformation have infinitesimal generator $\boldsymbol{\xi}_i(T)$ on each worldline. If the action changes only by endpoint terms,

$$\delta_\xi S_{\mathfrak{B}}^{(\eta)} = \left[B_\xi^{(\eta)}(T) \right]_{T_a}^{T_b}$$

after the retained causal-root constraints, endpoint convention, and excluded self-coincidence convention are applied, then the corresponding history charge at a cut T_* has the form

$$Q_\xi^{(\eta)}(T_*) = \sum_i \mu_{\mathrm{arch}} \mathbf{V}_i(T_*) \cdot \boldsymbol{\xi}_i(T_*) + Q_{\xi,\mathrm{wake}}^{(\eta)}(T_*) - B_\xi^{(\eta)}(T_*)$$

Its finite-window balance is

$$\frac{dQ_\xi^{(\eta)}}{dT} = \sum_i \boldsymbol{\xi}_i(T) \cdot \mathbf{R}_i^{(\eta)}(T) + \mathcal{B}_\xi^{(\eta)}(T)$$

where $\mathbf{R}_i^{(\eta)}$ is the Euler residual of the same action and $\mathcal{B}_\xi^{(\eta)}$ collects leakage through finite memory endpoints, period cuts, omitted branch records, and non-characteristic tail endpoints. Exact conservation follows only when both terms vanish. Time translation, spatial translation, and rotation are the special cases that produce energy, momentum, and angular momentum above. This is the delayed version of the standard symmetry-to-conservation statement, with the crucial difference that the conserved object is a particle-plus-wake history functional rather than an equal-time particle function.

Energy

In $\mathbb{AAA}$, energy accounting begins with moving architrinos and the causal wakes recorded by their motion. A wake is not a hidden fuel, a vacuum reservoir, or a second substance in the Euclidean void. It is the source-dependent causal-isochron record of an architrino's emissions. Motion changes the wake geometry, branch timing, and received potential; it does not turn the wake into an independent material thing.

This chapter answers four linked questions. What kinetic bookkeeping is allowed for a single architrino? How does work occur when a receiver crosses delayed causal wakes? How do assemblies hide or expose internal energy? How can Noether sea coupling make energy, inertia, and effective geometry appear at larger scales?

The chapter underwrites Particle Masses, A1 Dynamics, Noether Braid, Noether Sea Pro/Anti Coupling, Emergent Metric, and the constructive delay-energy standard in Delay Dynamics Energy.

All such dynamics unfold on a fixed ontological background: absolute time plus the Euclidean void. Accelerations and motion arise from **delayed causal hits from causal isochrons**, with line-of-action direction and transmitter-side acceleration weight, on this fixed background. Derivations keep c_f symbolic so the primitive-speed dependence remains visible; numerical instantiations use normalized units with $c_f = 1$.

The chapter keeps four levels separate. At the substrate level, kinetic and potential terms are architrino and causal-wake records on absolute time and the Euclidean void. At the dynamical level, energy changes through receiver-side causal hits and radial power. At the effective level, assemblies acquire inertia, apparent energy, and effective metric response through Noether sea coupling. At the inference level, scalar masses, thermodynamic records, and cosmological inventories are accepted only after a window, boundary record, and residual are declared.

Spacetime in this framework belongs to the effective level, not the ontological one. The ambient Noether sea is built from dense populations of neutral Noether braid assemblies occupying the Euclidean void. Its energetic state and configuration control how energy, inertia, and effective geometry appear at larger scales.

Kinetic Energy and Momentum of a Single Architrino

An architrino in motion possesses kinetic energy and momentum.

- **Kinetic Energy** E_k

  A scalar quantity representing the energy of motion. For a single architrino a with velocity $\mathbf{V}_a(T)$, we write

$$E_{k,a}(T) = K(s_a), \qquad s_a = \|\mathbf{V}_a(T)\|,$$

where s_a denotes the speed argument and K is a strictly convex, monotonically increasing function with $K(0) = 0$. If an effective saturation proxy is being used, $K'(s_a) \to \infty$ at the saturation scale; in the primitive limit, K grows unboundedly. K is left unspecified because mass is emergent from interactions between assemblies, especially the Noether braids in the Noether sea. Strict convexity ensures a one-to-one mapping between kinetic energy and speed magnitude. Because a free architrino has no intrinsic speed limit in the micro-model, E_k is, in principle, unbounded as $\|\mathbf{V}_a\| \to \infty$. **Scaffold-grade:** at this stage $K(s)$ is an unconstrained functional degree of freedom; it must eventually be fixed by back-solution consistency across certified branches, and inconsistent back-solved μ_K across certified branches would falsify this kinetic-scalar scaffold.

- **Momentum** $\mathbf{p}_a$

  The vector counterpart of kinetic energy:

$$\mathbf{p}_a(T) = P\big(\|\mathbf{V}_a(T)\|\big)\,\hat{\mathbf{V}}_a(T), \quad \hat{\mathbf{V}}_a = \frac{\mathbf{V}_a}{\|\mathbf{V}_a\|},$$

where P is a speed-dependent magnitude. Its detailed form is not postulated at the architrino level; it emerges from matching to assembly behavior.

If this momentum is treated as the conjugate momentum for the primitive kinetic scalar and $\mathbf{F} = d\mathbf{p}/dT$ is used in the work-energy relation, then P and K are not independent. For arbitrary nonzero velocity and acceleration, consistency requires

$$P'(s) = \frac{K'(s)}{s} = \mu_K(s), \qquad P(s) = \int_0^s \frac{K'(u)}{u}\,du$$

after choosing $P(0) = 0$. If this condition is not imposed, $\mathbf{p}$ should be read as a momentum-like bookkeeping vector rather than the canonical momentum of K.

Kinetic-scalar / closure compatibility. The conjugacy relation above also prevents a hidden second speed scale. If the primitive kinetic scalar is modeled with a finite saturation scale c_K, meaning $K'(s) \to \infty$ as $s \to c_K^-$, then any effective assembly closure using a signal speed c_{eff} is admissible on the declared comparison window only when

$$\left|\frac{c_{\text{eff}}}{c_K} - 1\right| \le \epsilon_{cK}$$

with ϵ_{cK} declared before the comparison is promoted. If K is instead kept in the primitive unbounded-speed limit, then c_{eff} is wholly a Noether sea response quantity and no substrate-level particle speed cap may be invoked in the energy or mass-shell argument.
This is the Legendre-compatibility condition for the kinetic scalar: once K is chosen, the canonical radial momentum magnitude is fixed by the same generating function. A later effective mass-shell closure may introduce c_{eff} only as the declared sea-response scale, or as the same finite scale already present in K to the stated tolerance; it may not carry an unrelated second speed limit.

No fundamental mass:

In this model, there is no **particle-specific substrate mass** assigned to individual architrinos. We do **not** assume $E_k = \frac{1}{2}m\|\mathbf{V}\|^2$ or $\mathbf{p} = m\mathbf{V}$ at the substrate level for distinct architrino species. Instead:

- Kinetic energy and momentum are **primitive kinematic quantities** of architrinos.
- The substrate law is written in **acceleration-first** form.
- If force-like or quadratic-kinetic bookkeeping is needed, one may introduce a single universal conversion constant μ_{arch}, but this is not a particle-specific inertial mass.
- “Mass” in the usual observer sense appears **only at the assembly level** as a derived property of how a large internal energy distribution responds to external forcing in the Noether sea.

Work–Energy Relation and Per-Hit Power

Kinetic-energy accounting is controlled by the acceleration-first master law, but the familiar quadratic work-energy form applies only after a kinetic proxy has been chosen. For a general primitive kinetic scalar with $s_a = \|\mathbf{V}_a\|$,

$$\frac{dE_{k,a}}{dT} = K'(s_a)\frac{\mathbf{V}_a \cdot \mathbf{A}_a}{s_a} = \mu_K(s_a)\,\mathbf{A}_a \cdot \mathbf{V}_a, \qquad \mu_K(s) \equiv \frac{K'(s)}{s}$$

If one introduces the optional universal bookkeeping constant μ_{arch} and defines $\mathbf{F}_a \equiv \mu_{\text{arch}}\mathbf{A}_a$, then the quadratic bookkeeping proxy $K_{\mu,a} = \frac{1}{2}\mu_{\text{arch}}\|\mathbf{V}_a\|^2$ satisfies

$$\frac{dK_{\mu,a}}{dT} = \mathbf{F}_a(T) \cdot \mathbf{V}_a(T)$$

Here $\mathbf{F}_a$ is the optional force-like bookkeeping quantity associated with the net acceleration from all causal hits; it is not a particle-specific substrate mass law.

From the canonical per-hit law

$$\mathbf{A}_{ij}(T;T_t) = \kappa\,\sigma_{ij}\,\frac{|q_i q_j|}{r_{ij}^2}W_{ij}^{\text{acc}}(T;T_t)\,\hat{\mathbf{r}}_{ij}$$

where

$$D_{t,ij}(T;T_t) \equiv c_f - \mathbf{V}_j(T_t)\cdot\hat{\mathbf{r}}_{ij}, \qquad D_{r,ij}(T;T_t) \equiv c_f - \mathbf{V}_i(T)\cdot\hat{\mathbf{r}}_{ij}, \qquad W_{ij}^{\text{acc}}(T;T_t) \equiv \frac{c_f}{|D_{t,ij}(T;T_t)|}$$

is the transmitter-side acceleration weight. Here r_{ij} and $\hat{\mathbf{r}}_{ij}$ are evaluated on the same retained causal branch. The transmitter-side factor D_t

sets root transversality and acceleration density; D_r/D_t separately records signed root playback.

Decompose the receiver's velocity into radial and transverse components:

$$\mathbf{V}_i = V_r \hat{\mathbf{r}}_{ij} + \mathbf{V}_\perp, \quad V_r = \mathbf{V}_i \cdot \hat{\mathbf{r}}_{ij}.$$

Because $\mathbf{A}_{ij} \parallel \hat{\mathbf{r}}_{ij}$:

- The **instantaneous work rate** from this hit is

$$\left.\frac{dK_\mu}{dT}\right|_{\text{hit}} = \mu_{\text{arch}} \mathbf{A}_{ij} \cdot \mathbf{V}_i = \mu_{\text{arch}} \kappa\, \sigma_{ij}\, |q_i q_j| \frac{W_{ij}^{\text{acc}}(T;T_t)}{r_{ij}^2} V_r$$

Only V_r contributes to instantaneous quadratic-proxy power. For the primitive scalar K, replace μ_{arch} by $\mu_K(\|\mathbf{V}_i\|)$.

- A hit only changes the **along-the-line** component of velocity; sideways motion $\mathbf{V}_\perp$ is unchanged instantaneously.

Potential Energy and Causal-Wake Potential

Potential energy arises from the interaction of an architrino with the **net causal-wake potential** generated by all architrinos, including in some regimes its own past emissions.

Net Causal-Wake Potential

At a point $\mathbf{X}$ and time T, the net potential is the **superposition** of contributions from all sources:

$$\Phi_{\text{net}}(\mathbf{X}, T) = \sum_o \Phi_o(\mathbf{X}, T).$$

Each Φ_o is built from the expanding causal isochrons emitted by source o, using the measure-valued or mollified emission density described in the architrino section. In the mollified representation with causal-surface width $\eta > 0$, Φ_{net} is a smooth function of $(\mathbf{X}, T)$; in the ideal limit $\eta \to 0$ it becomes a measure-valued distribution supported on causal isochrons.

Potential Availability Is Geometric

The phrase "an architrino emits potential" should not be read as a transmitter continually spending an internal fuel. The emission is the causal-wake geometry of the architrino itself: at each emission time, an expanding causal isochron is added to the transmitter's path history. That causal structure can later participate in work, but it is not a material energy substance stored inside the Euclidean void.

Potential energy is therefore relational. It is assigned when a receiver is placed in a transmitter's path-history causal-wake record and its trajectory intersects the relevant causal wake surfaces. The receiver's energy accounting depends on the active causal roots, their inverse-square distance factors, their polarity signs, the transmitter-side root denominator, the transmitter-side acceleration weight, and the receiver's radial motion through the line of action. In the general per-hit law the transmitter-side factor is

$$D_{t,ij}(T;T_t) = c_f - \mathbf{V}_j(T_t) \cdot \hat{\mathbf{r}}_{ij}$$

and the receiver-side factor is

$$D_{r,ij}(T;T_t) = c_f - \mathbf{V}_i(T) \cdot \hat{\mathbf{r}}_{ij}.$$

The branch strength is $W^{\text{acc}} = c_f/|D_t|$, while the instantaneous power delivered to the receiver is controlled by

$$\mathbf{A}_{ij} \cdot \mathbf{V}_i = \|\mathbf{A}_{ij}\|\, V_r$$

On an affine partner chart, the transmitter-side factor and receiver-side factor must both be tracked. The simple branch expression $J_p = 1 + (dX/dT)/c_f$ is only a transmitter-side topology expression unless the receiver-side factor is also present on the same chart.

Thus the potential to do work is broadly available wherever causal wakes pass, but work is realized only through an actual receiver trajectory. A quiet region is not a region with no causal activity; it is a region where the active wake contributions sum to negligible net acceleration and negligible net power for the assemblies present there.

Potential Energy

For a receiver architrino i with polarity q_i at position $\mathbf{X}_i(T)$, the potential energy $U_i(T)$ is the fixed-history bookkeeping value assigned to the current configuration against the causal path-history wake record:

$$U_i(T) = q_i\,\Phi_{\mathrm{net}}[\mathrm{history}]\big(\mathbf{X}_i(T), T\big).$$

The sign of Φ_{net} is not a sign on total energy. A negative causal-wake potential contribution from an electrino source is a polarity-signed interaction record; it becomes energy bookkeeping only after the receiver polarity, active causal root, line-of-action geometry, transmitter-side factor, transmitter-side acceleration weight, and receiver radial motion are specified. Work can therefore occur relative to a negative potential without introducing a negative-energy substance or a negative total-energy reservoir.

Unlike electrostatics, Φ_{net} is not a function of instantaneous source positions but a functional of their past worldlines intercepted by the backward causal-wake record of $\mathbf{X}_i(T)$. The gradient $\nabla\Phi_{\mathrm{net}}$ is taken with respect to the receiver's spatial coordinates on the fixed background, holding the causal history fixed. In the idealized picture, Φ is a distribution supported on causal isochrons, not a smooth continuum field.

When we work with the mollified effective potential Φ_η, we can also write the fixed-history, force-like relation:

$$\mathbf{F}_i(T) = -\nabla_{\mathbf{X}_i} U_i(T) = -q_i \nabla_{\mathbf{X}_i} \Phi_\eta[\mathrm{history}]\big(\mathbf{X}_i(T), T\big),$$

and this is required to be equivalent to the Master Equation in the quasi-static, resolved-in-time limit after the same force normalization, such as $\mathbf{F}_i = \mu_{\mathrm{arch}}\mathbf{A}_i$ or the appropriate $\mu_K \mathbf{A}_i$, has been declared; the recovery is graded a target in the Master Equation chapter.
The force-as-gradient identity is valid only when taking the gradient at fixed causal history; the fundamental acceleration law remains the per-hit sum of the Master EOM.

Macroscopic Cancellation and Localized Resonance

Constant causal emission by many architrinos does not imply a large random macroscopic force. The net causal-wake potential is a superposition, and in a large, incoherent population the leading gradients arrive with many signs, distances, phases, and line-of-action directions. For a receiver sampling such a population, macroscopic quietness is a two-moment condition, not only a mean-zero statement:

$$\|\langle \nabla\Phi_{\mathrm{net}}\rangle_W\| \le \epsilon_{\mathrm{mean}}, \qquad \frac{\mathrm{Var}_W(\nabla\Phi_{\mathrm{net}})}{\left\|\nabla\Phi^{\mathrm{bound}}_{\mathrm{coh}}\right\|^2} \le \epsilon_{\mathrm{var}}$$

Both bounds must use the same horizon, screening, and summation prescription that makes the many-source wake sum converge. The variance bound is the load-bearing part: incoherent fluctuation must remain small compared with the coherent bound-state gradient that phase-locked assemblies preserve. This cancellation is one reason the Noether sea can be densely active while remaining macroscopically quiet. What standard prose may call a vacuum state is not empty Euclidean void; it is the effective limit in which the local Noether sea assemblies and their causal wakes balance so well that only small residual gradients remain available to ordinary probes.

Mean-zero wake potential is therefore not zero total energy. A statistically neutral $50/50$ electrino/positrino inventory can make the large-scale potential gradient and received power nearly vanish while still carrying kinetic energy, local correlated interaction energy, retained wake-history content, and Noether sea organization. The conserved quantity for an isolated exact trajectory is the history-aware total ledger, not "initial kinetic energy plus a naive instantaneous potential" evaluated after the wake record has been discarded.

For energy accounting, cancellation is applied only after transmitter identity, polarity, emission time, active causal root, branch Jacobian, line-of-action geometry, and receiver radial power have been retained. A net-zero scalar potential channel is therefore a projection of a richer transmitter-tagged ledger, not proof that no wake-history energy, internal branch energy, or coherent work opportunity remains available to a receiver whose branch resolves the contributing rows.

Phase-locked bound states are the important exception. In a localized assembly, nearby constituents do not sample random phases; their active causal roots are correlated, and the $1/r^2$ distance factor lets the nearest coherent branches dominate over the far incoherent background. A collinear breather, for example, is precisely a reduced setting in which two opposite-polarity architrinos can form a localized, non-canceling causal resonance: instead of averaging away, the partner-hit and self-hit branches stay phase organized enough to exchange kinetic and potential energy across a bounded cycle.

Energy Conservation and Exchange

In the exact causal theory, energy conservation is enforced through exchange between kinetic motion and the causal-history interaction content encoded by wakes. This wake term should not be read as an independent material reservoir that drains from the transmitter with every unreceived isochron; it is the nonlocal bookkeeping required by the same delayed causal action that generates the hits. For mollified working models, the strongest exact conservation claims remain conditional on the regularization being derived from the same time-translation-invariant causal action rather than inserted only at the equation-of-motion level.

Classical virial language is recovered only at branch level. The familiar comparison form $\langle 2K - pU \rangle = 0$ is admissible after a retained branch chart supplies a branch-local potential, homogeneity degree, and proof that the same acceleration contribution used by the Master EOM is generated by that potential over the declared window. Standard mechanics often writes T for kinetic energy in this formula; here K avoids collision with absolute time T. Until those rows close, virial behavior remains a diagnostic on the causal-root ledger rather than a primitive substrate axiom; see the branch-virial target in Analytic Baselines.

For a single architrino:

$$\Delta E_k = \int \mathbf{F} \cdot d\mathbf{X} = -\Delta U$$

(when we restrict attention to its interactions with a fixed set of sources). For an **isolated system** of architrinos and their wakes, the total energy is:

$$E_{\text{total}} = \sum_a E_{k,a} + U_{\text{int}} + E_{\text{wake}},$$

and is constant in time for exact isolated solutions of the causal action. In mollified working models, this same bookkeeping should be treated as exact only when the mollified kernel inherits that action-level time-translation symmetry; otherwise it remains the natural candidate history functional to monitor, but not yet an established exact invariant.

- U_{int} is an optional effective decomposition of near-field interaction energy.
- E_{wake} accounts for the exact nonlocal interaction content carried by wake structures and any radiation-like transport through the Noether sea.

The same distinction governs cosmological redshift. Because the Euclidean void does not expand and absolute time supplies the comparison parameter, a transparent redshift branch cannot treat the photon's missing energy as a bookkeeping disappearance. At the universe-state level, the conservation target is a scalar ledger of architrino kinetic/configuration energy, causal-wake energy in flight, and Noether sea constitutive energy:

$$E_{\text{tot}}(T) = E_{\text{arch}}(T) + E_{\text{wake}}(T) + E_{\text{sea}}(T), \qquad \frac{dE_{\text{tot}}}{dT} = 0$$

This global target requires the total energy on the constant-T leaf to be finite or convergently summable. For an unbounded or observationally truncated cosmology, the safe conservation statement is local continuity,

$$\partial_T \rho_E + \nabla_{\mathbf{X}} \cdot \mathbf{S}_E = 0$$

tested through finite windows and boundary fluxes. In the pure transparent-path limit, after source, recoil, remnant, and boundary terms have been separated, a bundle redshifted by $1+z$ carries the deficit

$$\Delta E_\gamma = E_{\text{emit}} - E_{\text{obs}} = E_{\text{emit}} \frac{z}{1+z}, \qquad \Delta E_\gamma + \Delta E_{\text{sea,path}} = 0$$

If the Noether sea update needed to close this row is nonlocal, re-radiating, path-history inconsistent, or incompatible with image sharpness and CMB blackbody preservation, the fixed-void redshift branch has failed the energy ledger rather than solved cosmological redshift.

Consistency rule: either use E_{wake} alone for all interaction energy, or, if a U_{int} pairwise term is retained as an effective decomposition inside assemblies, then E_{wake} must explicitly omit the corresponding near-field content to prevent double counting.

For a hybrid decomposition, the omission must be checkable on the same finite window. Let the near/far split be made with the same coarse-graining window W_ℓ used in the matter-to-sea source $S^{(\ell)}_{\text{mat}\to\text{sea}}$. Define the partition-overlap residual

$$\mathcal{R}_{\text{dbl},W} = \frac{\left| E^{(\eta)}_{\text{wake},W} - \left(E^{\text{far}}_{\text{wake},W} + E^{\text{near}}_{\text{wake},W} \right) \right| + \left| U_{\text{int},W} - E^{\text{near}}_{\text{wake},W} \right|}{\left| E^{(\eta)}_{\text{wake},W} \right| + |U_{\text{int},W}| + \varepsilon_E}$$

with $\varepsilon_E > 0$ a declared denominator floor. A retained $U_{\text{int}} + E_{\text{wake}}$ decomposition is admissible only when $\mathcal{R}_{\text{dbl},W} \to 0$ under refinement of the same window, boundary record, and regularized causal action.

Conservation Status

The conservation claim is a level-specific statement. For an isolated branch whose acceleration law comes from a time-translation-invariant causal action,

$$\frac{d}{dT} E_{\text{total}}(T) = 0, \qquad E_{\text{total}}(T) = \sum_a E_{k,a}(T) + U_{\text{int}}(T) + E_{\text{wake}}(T)$$

This is not a claim that $\sum_a E_{k,a}$ is constant on Σ_T, nor that a finite simulation window conserves its particle-only ledger. Delayed hits move energy between mechanical motion and causal-wake history, and finite windows must also name boundary flux, external work, and residuals. A calculation that omits one of those terms has not established energy nonconservation; it has exposed an incomplete retained record.

For the time-normalized constraint $\tilde{g} = T_r - T_t - r/c_f$, dimensional consistency requires the scalar action kernel coefficient $\mu_{\text{arch}}\kappa$, not κ/c_f. The corresponding regularized interaction diagnostic is proportional to $\delta_\eta(\tilde{g})/r$; simple-root collapse produces W^{acc}/r once. An inverse-square acceleration density with a manually inserted W^{acc} is not an energy functional. With the polarity convention that like signs repel, the sharp like-polarity interaction charge is positive and the boundary derivative inherits the outer minus sign declared in the action.

Plainly: the wake-energy row must come from the same $1/r$ action kernel as the acceleration derivation. Reusing the $1/r^2$ acceleration formula as energy gives the wrong units and double-counts the root weight.

In working models the exact claim is conditional. If the mollifier, history window, self-branch cutoff, or characteristic-tail repair is inserted only at the equation-of-motion level, then the same expression is a diagnostic to monitor, not a proved Noether charge. Exact conservation is promoted only when the same regularized action supplies both the acceleration contribution and the energy row, and when the energy residual in this section vanishes under refinement. The formal construction routes, crosswalk residual, and promotion conditions for E_{wake} are isolated in Delay Dynamics Energy.

The finite-η pathology theorem target in Master Equation uses this conservation status in a restricted way. The no-runaway conclusion is available only when the action-derived $E^{(\eta)}_{\text{wake}}$, or a compatible realized-trajectory reconstruction, has a declared lower bound on the same admissible branch chart. If the lower bound is absent, the run is not promoted as a closed solution; it is routed to the continuation boundary where collapse, missing wake-history bookkeeping, regulator dependence, or endpoint leakage must be resolved.

For reaction or radiation events, energy can leave the source assembly as photon output, recoil, medium excitation, remnant excitation, wake-carried exchange, or handoff terms, but those are named outputs rather than hidden losses. The event-level version is the componentwise ledger closure in Reaction Ledger.

Wake Escapement

This is a boundary-accounting idea, not a new energy reservoir. If a wake leaves the chosen local window before any retained receiver crosses it, the local work ledger cannot spend that wake internally. The accounting must therefore mark it as escaped flux, recoil, boundary exchange, or another declared handoff rather than hiding it inside the local assembly.

For a finite local window $W \subset \Sigma_T$, **wake escapement** is the subset of emitted causal isochrons that exit the retained window without intersecting any retained receiver inside that window. More explicitly, if architrino a emits at T_t, define the causal isochron at later time T by

$$C_a(T; T_t) = \{\mathbf{Y} \in \Sigma_T : \|\mathbf{Y} - \mathbf{X}_a(T_t)\| = c_f(T - T_t)\}$$

The emitted isochron belongs to the escapement set $\mathcal{E}_{\text{esc}}(W)$ when it has a first retained boundary crossing

$$C_a(T_{\partial W}; T_t) \cap \partial W \neq \varnothing$$

and there is no retained receiver hit before that crossing:

$$\nexists\, b, T_r \quad \text{with} \quad T_t < T_r < T_{\partial W}, \quad \mathbf{X}_b(T_r) \in W, \quad \mathbf{X}_b(T_r) \in C_a(T_r; T_t)$$

Wake escapement is therefore a finite-window boundary classification, not a new substance in the Euclidean void. It names the portion of causal-wake history that cannot be balanced by local receiver work because no local receiver intercepted it. In a contracting binary, the persistent positive tangential drive identified in Binary Dynamics should be read against this boundary ledger: particle kinetic gain, local interaction-energy change, recoil, and escaped wake flux are parts of one balance law.

For a finite spatial window $W \subset \Sigma_T$, conservation is a balance law rather than a claim that the window is isolated. This is the conservation-law upgrade relative to instantaneous mechanics: energy, momentum, and angular momentum are not generally conserved equal-time particle snapshots, but finite-window history functionals whose apparent deficits must be carried by causal-wake fluxes or by an explicit residual. Write

$$E_W(T) = \sum_{a:\mathbf{X}_a(T) \in W} K_a(T) + U_{\text{int},W}(T) + E_{\text{wake},W}(T)$$

where the terms include only the kinetic, interaction, and wake-history content retained by the declared window record. The finite-window energy balance should take the residual form

$$\frac{dE_W}{dT} + \int_{\partial W} \mathbf{J}_E \cdot \hat{\mathbf{n}}\, dA = P_{\text{ext},W} + \mathcal{R}_E(\eta, \Delta T, W)$$

Here $\mathbf{J}_E$ is the boundary flux of causal-wake energy bookkeeping, including any wake escapement through ∂W; $P_{\text{ext},W}$ is declared external work through sources or controls not included in W; and $\mathcal{R}_E$ records mollifier, timestep, and omitted-boundary-history error. A finite-window conservation claim is mature only when $\mathcal{R}_E \to 0$ under the same regularized causal action used for the local equation of motion.

The characteristic-tail repair target in Master Equation inherits this same rule. If the outgoing tail kernel $K^{(\eta)}_{\mathrm{ct},+}$ is used, its endpoint contribution may be counted as a Noether wake-history boundary flux only when the endpoint is characteristic, or when it is a declared fixed history boundary whose leakage residual vanishes:

$$\mathcal{B}^{(\eta)}_{E,+} \sim \frac{D_{ij}R_+}{c_f R_+}\,\delta'_\eta\left(u-\frac{R_+}{c_f}\right) \longrightarrow 0$$

on the retained branch chart. If $D_{ij}R_+ \neq 0$ and this residual does not vanish, the endpoint is an interior Euler source rather than a conservation-boundary term. In that case the characteristic-tail action changes the accepted branch acceleration and cannot be used to close exact energy conservation for the canonical Master EOM.

The analogous momentum and angular-momentum closures must also remain tied to the same window and boundary data. The finite-window momentum functional P^i_W contains the mechanical momentum retained in W plus the retained wake-history momentum record:

$$\frac{dP^i_W}{dT} + \int_{\partial W} \Pi^{ij}\hat{n}_j\,dA = F^i_{\mathrm{ext},W} + \mathcal{R}^i_P(\eta,\Delta T,W)$$

For a declared origin $\mathbf{X}_0$, the corresponding angular-momentum history functional has the schematic form

$$\mathbf{L}_W(T) = \sum_{a:\mathbf{X}_a(T)\in W} \big(\mathbf{X}_a(T)-\mathbf{X}_0\big)\times \mathbf{p}_a(T) + \mathbf{L}_{\mathrm{wake},W}(T)$$

where $\mathbf{p}_a$ is the declared mechanical momentum proxy for the chosen kinetic bookkeeping. Its finite-window balance target is

$$\frac{dL^i_W}{dT} + \int_{\partial W} \Lambda^{ij}\hat{n}_j\,dA = \tau^i_{\mathrm{ext},W} + \mathcal{R}^i_L(\eta,\Delta T,W)$$

Here Π^{ij} and Λ^{ij} are finite-window flux diagnostics for retained causal wakes and assembly crossings, not new substrate fields. $\tau^i_{\mathrm{ext},W}$ is the external torque about the same origin $\mathbf{X}_0$. If the energy, momentum, and angular-momentum residuals can be made small only by changing the window measure, boundary wake record, or regularization separately for each observable, the calculation has fitted separate summaries rather than demonstrated one causal-history conservation law.

Cosmological inventory comparisons add one more finite-window caution. A gravitational binding contribution is negative relative to dispersed matter in the declared window, but the sign is meaningful only after the boundary and coarse-graining are fixed. In this chapter, G_{eff} in the binding line is a provisional external comparison input until the mass map and Noether sea response tensor independently derive it. For a component inventory over W,

$$E^{\mathrm{grav}}_{\mathrm{bind},W} = -\frac{1}{2}\int_W\int_W \frac{G_{\mathrm{eff}}(\theta;x^i_{\mathrm{eff}},y^i_{\mathrm{eff}})\,\rho_{\mathrm{eff}}(x^i_{\mathrm{eff}})\rho_{\mathrm{eff}}(y^i_{\mathrm{eff}})}{\|\mathbf{x}_{\mathrm{eff}}-\mathbf{y}_{\mathrm{eff}}\|}\,dV_{x_{\mathrm{eff}}}\,dV_{y_{\mathrm{eff}}} + \mathcal{B}_{\partial W}$$

where $\mathcal{B}_{\partial W}$ records boundary and embedding terms. The corresponding inventory residual is

$$\mathcal{R}_{\mathrm{grav\ bind},W} = \frac{\left|E^{\mathrm{grav}}_{\mathrm{bind},W}-E^{\mathrm{obs}}_{\mathrm{bind},W}\right|}{\epsilon_{\mathrm{bind}}} + \frac{|\mathcal{B}_{\partial W}|}{\epsilon_{\partial W}}$$

The circularity check is the post-handoff residual

$$\mathcal{R}_{G\text{-consist},W} = \frac{\left|G^{\mathrm{bind}}_{\mathrm{eff}}-G^{(\zeta,\mathcal{M})}_{\mathrm{eff}}\right|}{\left|G^{(\zeta,\mathcal{M})}_{\mathrm{eff}}\right|+\varepsilon_G} \le \epsilon_G$$

where $G^{\mathrm{bind}}_{\mathrm{eff}}$ is the value used in the inventory comparison and $G^{(\zeta,\mathcal{M})}_{\mathrm{eff}}$ is the value derived from shielding, exposed response, and the Noether sea response tensor. Until $\mathcal{R}_{G\text{-consist},W}$ is reported on the same window, the cosmological binding line is comparison bookkeeping only, not a derived inventory contribution. This keeps gravitational binding from

being used as an adjustable bookkeeping sign that can repair the cosmic energy inventory without specifying the same window, boundary wake history, and effective G_{eff} used by the rest of the cosmology branch.
The stronger same-record requirement is that $G_{\text{eff}}^{(\zeta,\mathcal{M})}$, the response-speed tensor that supplies c_{eff}, and the ruler/metric response consumed by the effective geometry chapter all be read from one Noether sea response record. If those quantities require separate sea records or separately tuned response tensors, the gravity, clock, and ruler sectors have been fitted independently rather than derived from one exposed-energy and medium-response ledger.

Theorem target (center of response). The standard center-of-mass theorem depends on equal-time internal force cancellation. In delayed causal dynamics that cancellation is not available as a particle-only statement on Σ_T: the reciprocal hit generally belongs to a different emission time, a different causal-root branch, or a boundary wake record not retained by the finite window. For an assembly window $W_A(T)$, the replacement target is to prove that there is a response center $\mathbf{X}_{\text{resp}}(T)$ and an assembly response tensor M_A^{ij} such that the finite-window momentum balance reduces, over resolved windows, to

$$\frac{d}{dT}\left(M_A^{ij}\frac{dX_{\text{resp},j}}{dT}\right) = F^i_{\text{ext},W_A} - \int_{\partial W_A} \Pi^{ij}\hat{n}_j\, dA + \mathcal{R}^i_{\text{resp}}(\eta, \Delta T, W_A)$$

The pair $(\mathbf{X}_{\text{resp}}, M_A^{ij})$ is not free to be chosen after the balance is fitted. The response center must be pinned independently by the exposed internal-energy ledger,

$$X^i_{\text{resp}}(T) \equiv \frac{\int_{W_A(T)} X^i\, \zeta_{\text{loc}}(\mathbf{X},T)\, e_{\text{internal}}(\mathbf{X},T)\, dV}{\int_{W_A(T)} \zeta_{\text{loc}}(\mathbf{X},T)\, e_{\text{internal}}(\mathbf{X},T)\, dV}$$

whenever the denominator is positive and the window contains the exposed assembly record on the native slice Σ_T. The tensor M_A^{ij} must then reduce to the independently extracted response tensor I_A^{ij} on the same branch chart. Only when these independently defined objects satisfy the balance with $\mathcal{R}^i_{\text{resp}} \to 0$ does it reduce to the familiar center-of-mass form. A non-vanishing irreducible residual means the exposed-energy center is not the inertial response center for that branch, rather than a license to redefine the center. Until that theorem is closed, a center-of-mass trajectory is an effective readout of the assembly response, not a substrate-level proof that internal delayed forces cancel instantaneously.
Equivalently, $\mathbf{X}_{\text{resp}}$ and the inertial-response center are two different moment maps on the same retained assembly record: one weights exposed internal energy, while the other is inferred from momentum response. Their coincidence is a theorem target, not a definition. The obstruction is the finite-window wake-momentum flux across ∂W_A; if that boundary record has a secular or nonrecurrent component, the two centers can differ even when the equal-time particle picture looks nearly balanced. This is the center-of-response version of the memory-boundary recurrence condition used by the effective-Lagrangian symplectic-promotion row.

In practice, finite systems or simulation domains should monitor $E_W(T)$, $P^i_W(T)$, and $L^i_W(T)$ together with their boundary fluxes and residuals. $E_{\text{total}}(T)$ is the isolated-system limit when the declared window contains the full wake-history record and the boundary terms vanish.

Entropy, Free Energy, and Coarse Residuals

Entropy and free-energy language belongs to coarse-grained records, not to empty Euclidean void. It is useful when a simulation or continuum reduction groups many microhistories into the same retained macrostate. For a declared coarse map $\mathcal{Q} : S(T) \mapsto z$ with cell probabilities p_α over the retained histories, the entropy diagnostic is

$$S_{\mathcal{Q}} = -k_B \sum_\alpha p_\alpha \log p_\alpha$$

When a temperature-like channel $T_{\mathcal{Q}}$ is declared by the same record, the Helmholtz-style free-energy diagnostic is

$$F_{\mathcal{Q}} = E_{\mathcal{Q}} - T_{\mathcal{Q}} S_{\mathcal{Q}}$$

This is not an added thermodynamic postulate. It is a test that the chosen coarse variables have retained enough state counting to make relaxation and response claims reproducible.

The distinction matters because energy conservation does not by itself measure work availability. Two records with the same total energy can have different free-energy diagnostics when one retains a concentrated heat, chemical, photon-channel, or potential-gradient channel and the other has dispersed the same energy into unresolved thermal, boundary, or wake-history records. A finite-window calculation must therefore close the energy ledger and the entropy ledger on the same retained record before claiming that energy remained useful, became waste heat, or crossed the boundary as low-grade radiation.

For an isolated finite window, the minimum coarse thermodynamic gate is the same-record entropy-production residual

$$\mathcal{R}_{S,W} = \frac{\left[-\Delta_W S_Q + \int_W \frac{\mathcal{D}_Q}{T_Q+\varepsilon_T}\, dT'\right]_+}{|\Delta_W S_Q| + \int_W \left|\frac{\mathcal{D}_Q}{T_Q+\varepsilon_T}\right| dT' + \varepsilon}$$

where $[x]_+ = \max(x,0)$ and $\mathcal{D}_Q$ is the declared coherent-to-incoherent transfer rate, including viscous, thermal, wake-boundary, or Noether sea response channels retained by the packet. Passing this gate means only that the selected coarse record has not made entropy decrease after unresolved boundary leakage is accounted for. It does not prove a fundamental stochastic substrate.

For the consolidated mapping from legacy entropy formulas into $\mathbb{AAA}$ record projections, see Entropy.

In near-equilibrium comparison runs, response and fluctuation must also come from one record. The fluctuation-dissipation map may be invoked only after that same retained record supplies an admissible temperature channel. Concretely, the record θ_W that supplies χ''_{AB} and S^{meas}_{AB} must pass $\mathcal{R}_{S,W}$ and must yield consistent temperatures from at least two independent observable pairs:

$$\mathcal{R}_{T,W} = \frac{\left|T_Q^{(AB)} - T_Q^{(A'B')}\right|}{\left|T_Q^{(AB)}\right| + \left|T_Q^{(A'B')}\right| + \varepsilon_T} \le \epsilon_T$$

If this sea-temperature admissibility check fails, the packet may report the dissipative response χ''_{AB} alone, but it may not use an equilibrium fluctuation-dissipation map as closure evidence. If an observable O_A has response kernel $\chi_{AB}(\omega)$ to a controlled source coupled to O_B, the causal-response check is that the dissipative part and the equilibrium fluctuation spectrum $S_{AB}(\omega)$ obey a declared classical or quantum fluctuation-dissipation row. A dimensionless packet residual can be written as

$$\mathcal{R}_{\text{FD}}(A,B) = \frac{\|S^{\text{meas}}_{AB}(\omega) - \mathcal{F}_T(\chi''_{AB}(\omega))\|_\omega}{\|S^{\text{meas}}_{AB}(\omega)\|_\omega + \|\mathcal{F}_T(\chi''_{AB}(\omega))\|_\omega + \varepsilon}$$

Here $\mathcal{F}_T$ is the packet's chosen fluctuation-dissipation map, and χ''_{AB} is the imaginary, dissipative response. A passing value supports the coarse response chart; a failing value means the noise, dissipation, and energy ledger have been fitted separately.

Noether Sea, Effective Spacetime, and Energy Storage

At the fundamental level, the Euclidean void is an empty container. **Effective spacetime** is the observer-level summary of a **sea of high-energy Noether braid assemblies**. The following size and energy statements are hypotheses awaiting a certified Noether braid and scale map:

- These Noether braids are extremely small compared to ordinary particles (electrons, protons, etc.).
- Each Noether braid is itself a tightly bound architrino assembly with very high internal kinetic and potential energy; A1 is the best-developed Family-A member, not the definition of the sea.

- As a sea, they form a **dense population of coupled assemblies** occupying the Euclidean void. This ambient Noether sea content carries non-zero assembly density and internal stress. It provides the constitutive relations (permittivity, permeability, and medium-dressed inertial response) that deform the primitive architrino dynamics into effective relativistic kinematics, providing the bridge-level spacetime medium for:
    - Emergent inertia and mass,
    - Effective causal-cone behavior and Lorentz-like behavior,
    - Effective gravitational coupling (emergent geometry at large scales).

Energy in this picture is distributed across:

1. **Unbound Architrinos** (rare at low energies),
2. **Standard Model assemblies** (electrons, nucleons, etc.),
3. The **Noether sea** and, in bridge prose, the spacetime medium.

Assemblies: Internal vs Apparent Energy

For composite systems such as Standard Model particles, nuclei, and composite bound states formed from architrinos and embedded in the Noether sea, we distinguish:

- **Total internal energy**: energy retained by the assembly and by its immediate Noether braid environment,
- **Apparent energy**: what leaks out as a long-range wake signature and governs how the assembly interacts with the outside world.

Internal Energy of an Assembly

For an assembly A (e.g., Noether braid or higher structure), let $i \in A$ run over its constituent architrinos. Then:

$$E_{\text{internal}}(A) = \sum_{i \in A} E_{k,i} + \frac{1}{2} \sum_{\substack{i,j \in A \\ i \neq j}} U_{ij} + E_{\text{coupling to sea}}(A),$$

where:

- $E_{k,i}$ is the kinetic energy of architrino i,
- U_{ij} is mutual potential energy of pair (i, j),
- $E_{\text{coupling to sea}}$ accounts for how the assembly deforms and polarizes the surrounding Noether sea, that is, the local Noether sea environment (or in bridge prose, the local spacetime medium).

Hypothesis. The internal energy can be much larger than the externally exposed energy. Any comparison to the Planck scale or a higher scale remains a benchmark-level possibility until a certified branch fixes the native energy map.

Apparent Energy and Shielding

The surrounding Noether sea, and the arrangement of positive- and negative-polarity architrinos inside an assembly, can **shield** internal energy from the external world through:

- **Polarity cancellation**: positive- and negative-polarity architrinos within the assembly (and in surrounding Noether braids) emit wakes that interfere destructively at larger distances.
- **Phase-structured far-field cancellation**: the geometry of internal orbits and Noether braid polarization patterns generates cancellation of most multipoles at scales $r \gg$ assembly size.
- **Indexed support shielding**: in candidate multi-tier fermion braid scaffolds, source-record support indices can partially screen other rows from the surrounding sea. Generation shifts are hypothesized to reflect loss of declared support rows, not a fixed outer-to-inner identity or only a loss of constituent count.

At the reference-attractor level, define the **shielding (leakage) factor** as the leading isotropic projection of a larger far-field wake ledger:

$$\zeta(A_0) \equiv \frac{\|\Pi_0 \mathcal{L}_{\text{wake}}(A_0)\|}{\|\mathcal{L}_{\text{naive}}(A_0)\|}, \qquad \mathcal{L}_{\text{aniso}}(A_0) \equiv \mathcal{L}_{\text{wake}}(A_0) - \Pi_0 \mathcal{L}_{\text{wake}}(A_0)$$

evaluated in a regime where the assembly appears as an effective point source. Here Π_0 extracts the monopole/isotropic component of the far-field wake ledger and $\mathcal{L}_{\text{aniso}}$ retains anisotropic leakage instead of hiding it inside a scalar error term. For a strongly shielded, neutral Noether braid in the Noether sea, we expect $\zeta \ll 1$.
Operationally, extract $\zeta(A)$ from a far-field fit of Φ_{net} (or hit amplitude) at $r \gg \text{size}(A)$: $\zeta \equiv A_{\text{measured}}/A_{\text{naive}}$, the ratio of the leading $1/r^2$ (or multipole) coefficient to the naive constituent sum, with anisotropic residuals reported separately.
The scalar shielding summary is admissible only when anisotropic leakage is small enough for the comparison being made, for example

$$\frac{\|\mathcal{L}_{\text{aniso}}(A_0)\|}{\|\mathcal{L}_{\text{naive}}(A_0)\|} \leq \epsilon_{\text{aniso}}$$

with ϵ_{aniso} declared before the branch is promoted to a scalar mass-facing result.

The scalar apparent-energy proxy that influences other assemblies at large distances is then:

$$E_{\text{apparent}}(A) \sim \zeta(A)\, E_{\text{internal}}(A),$$

This is a roadmap relation, not a substrate identity; proportionality constants must be fixed by matching to effective low-energy theory (e.g. mapping to mc^2).

The exposed energy cannot be counted twice as both the direct probe readout and the sea-retuning source. On a declared comparison window, split the exposed ledger into a probe channel and a sea-coupled channel:

$$\zeta(A)E_{\text{internal}}(A) = E_{\text{probe}}(A) + E_{\text{sea-coupled}}(A) + E_{\text{unresolved}}(A), \qquad E_{\text{probe}}(A) + E_{\text{sea-coupled}}(A) \leq \zeta(A)E_{\text{internal}}(A)$$

with partition residual

$$\mathcal{R}_{\text{part}}(A) = \frac{|\zeta(A)E_{\text{internal}}(A) - E_{\text{probe}}(A) - E_{\text{sea-coupled}}(A) - E_{\text{unresolved}}(A)|}{|\zeta(A)E_{\text{internal}}(A)| + \varepsilon_{\text{part}}}$$

The mass map couples distant probes to E_{probe} through the retuned Noether sea; the matter-to-sea source uses $E_{\text{sea-coupled}}$. A calculation that uses the raw $\zeta E_{\text{internal}}$ in both roles must report $\mathcal{R}_{\text{part}}$ as unresolved rather than treating the two uses as independent evidence.
This is an exactness condition on one forgetting map. The full internal ledger is first projected to the exposed ledger $\zeta E_{\text{internal}}$, and the probe, sea-coupled, and unresolved channels are further projections of that same exposed ledger. The residual $\mathcal{R}_{\text{part}}$ measures whether those fibers close back to the once-projected total; it is therefore an anti-double-count rule, not an optional accounting convention.

Define the probe-channel share

$$\zeta_{\text{probe}}(A) \equiv \frac{E_{\text{probe}}(A)}{E_{\text{internal}}(A)}$$

when $E_{\text{internal}}(A) > 0$. The raw far-field scalar $\zeta(A)$ names the total exposed ledger before the probe, sea-coupled, and unresolved split. The probe-channel scalar $\zeta_{\text{probe}}(A)$ names only the trace part consumed by the inertial probe formulas below.

Emergent Inertia (Mass) from Shielded Energy

Inertia is not fundamental; it is the externally exposed response of an assembly’s closed internal causal-history ledger, shielding factor, and Noether sea coupling to changes in bulk motion.

Operational Definition of Inertial Mass

For an assembly A, define its inertial mass $m_{\text{inertial}}(A)$ operationally via:

- Apply a small external wake potential (from a distant test source) that exerts a known net force $\mathbf{F}_{\text{ext}}$ on A,
- Measure the resulting acceleration of the response center; in regimes where the effective center-of-mass readout has been justified, denote this acceleration by $\mathbf{A}_{\text{cm}}$,
- Define:

$$m_{\text{inertial}}(A) \equiv \frac{\|\mathbf{F}_{\text{ext}}\|}{\|\mathbf{A}_{\text{cm}}\|}.$$

Because the external wake couples mainly to the probe-facing exposed energy, not the full internal circulation, the scalar roadmap limit is:

$$m_{\text{inertial}}(A) \approx \alpha_{\text{m}} \frac{E_{\text{probe}}(A)}{c_{\text{eff}}^2}.$$

The tensor handoff is more precise. In the formulas below, $\mathcal{Z}_A^{ab}$ is the probe-channel exposure tensor after the exposed-energy partition has been declared; the sea-coupled channel enters through $S^{(\ell)}_{\text{mat}\to\text{sea}}$ and the resulting Noether sea response, not as a second direct inertial source. For a small center-of-mass velocity $V_{\text{cm},b}$ through a declared Noether sea response record,

$$p^a_{\text{int}} \approx \alpha_{\text{m}}\, \zeta_{\text{probe}}(A) E_{\text{internal}}(A)\, \mathcal{M}^{ab}_{\text{sea}}\, V_{\text{cm},b}$$

with homogeneous isotropic limit

$$\mathcal{M}^{ab}_{\text{sea}} \to \frac{h^{ab}}{c_{\text{eff}}^2}$$

A more complete first-order handoff keeps the scalar and trace-free exposure pieces visible. Write

$$\mathcal{Z}_A^{ab} = \zeta_{\text{probe}}(A) h^{ab} + \mathcal{Z}_{\text{tf}}^{ab}(A), \qquad h_{ab}\mathcal{Z}_{\text{tf}}^{ab}(A) = 0$$

and split the local Noether sea response as

$$\mathcal{M}^{ab}_{\text{sea}} = \frac{1}{c_{\text{eff},0}^2}\left[(1+\delta\mathcal{M}_0)h^{ab} + \delta\mathcal{M}_{\text{tf}}^{ab}\right]$$

Then the exposed inertial-response tensor is

$$\mathsf{I}_A^{ab} = \frac{\alpha_{\text{m}} E_{\text{internal}}(A)}{2}\left(\mathcal{Z}^a_{A\,c}\mathcal{M}^{cb}_{\text{sea}} + \mathcal{Z}^b_{A\,c}\mathcal{M}^{ca}_{\text{sea}}\right), \qquad p^a_{\text{int}} \approx \mathsf{I}_A^{ab} V_{\text{cm},b}$$

Its rotational scalar trace is

$$m_{\text{tr}}(A) \equiv \frac{1}{3} h_{ab}\mathsf{I}_A^{ab} = \alpha_{\text{m}} \frac{E_{\text{internal}}(A)}{c_{\text{eff},0}^2}\left[\zeta_{\text{probe}}(A)(1+\delta\mathcal{M}_0) + \frac{1}{3}\mathcal{Z}_{\text{tf},ab}(A)\delta\mathcal{M}_{\text{tf}}^{ab}\right]$$

Only in the homogeneous isotropic limit does the scalar mass formula above follow. The trace formula gives a stricter diagnostic: pure exposure anisotropy does not shift scalar mass in an isotropic medium, and pure trace-free medium response does not shift scalar mass for scalar exposure. A scalar mass shift from anisotropy appears only through the contraction $\mathcal{Z}_{\text{tf},ab}\delta\mathcal{M}_{\text{tf}}^{ab}$; otherwise the residue remains directional inertia in I_A^{ab}. Here E_{internal} names the large internal energy circulation, while $\zeta_{\text{probe}}(A)$ names the probe-facing share of the small external leakage that survives cancellation and Noether sea shielding. The formula therefore explains weak long-range gravitational and inertial footprints without making the internal energy small: ordinary probes couple to the leaked pattern, not to every internal exchange branch.

The trace-free exposure tensor is also the mass-side carrier of orientation and framing leakage. Clock-orientation leakage, Hughes-Drever-style matter anisotropy, and scalar-mass anisotropy should therefore be compared as different contractions of the same branch-emitted trace-free exposure record against different probe or medium-response tensors. If $\mathcal{Z}_{\rm tf}^{ab}=0$ for an accepted branch in a homogeneous response record, all of these trace-free leakage channels vanish at this order; if it is nonzero, scalar mass remains protected only when the retained medium response has no matching trace-free component.

This scalar trace is admissible as a positive inertial mass only inside the shielding window

$$\zeta_{\rm probe}(A)(1+\delta\mathcal{M}_0)>\frac{1}{3}\left|\mathcal{Z}_{{\rm tf},ab}(A)\delta\mathcal{M}_{\rm tf}^{ab}\right|$$

with the comparison sea state declared. If a certified A_0 branch reports $\zeta_{\rm probe}$ so small that this inequality fails for plausible $\delta\mathcal{M}_{\rm tf}^{ab}$ in the accepted environment, the shielded-energy mass map is falsified for that branch. Thus deep probe-channel shielding is a constrained exposure window, not an unconstrained way to suppress all long-range response.
When $1+\delta\mathcal{M}_0>0$, a conservative sufficient lower bound is

$$\zeta_{\rm probe}(A)>\frac{\|\mathcal{Z}_{\rm tf}(A)\|_h\,\|\delta\mathcal{M}_{\rm tf}\|_h}{3(1+\delta\mathcal{M}_0)}$$

on the same window. More anisotropic exposure therefore permits less deep scalar shielding before the trace response can become zero or negative. Highly anisotropic branches must either reduce their trace-free exposure, keep the medium response nearly isotropic, or leave the scalar-mass regime.

At the matter-to-medium interface, a Standard Model fermion assembly should therefore be treated as a localized source of exposed response, not as an unshielded transfer of all internal energy into the surrounding Noether sea. For a coarse cell Ω_ℓ, the source supplied by stable matter assemblies can be written schematically as

$$S^{(\ell)}_{\rm mat\to sea}(\mathbf{X},T)=\sum_{A\subset\Omega_\ell}W_\ell(\mathbf{X}-\mathbf{X}_A(T))\,E_{\text{sea-coupled}}(A)+S^{(\ell)}_{\rm aniso}(\mathbf{X},T)$$

where W_ℓ is the coarse-graining window, $\mathbf{X}_A$ is the assembly center, and $S^{(\ell)}_{\rm aniso}$ records exposed tensor, orientation, spin, or wake-history residue that cannot be collapsed into the scalar shielding factor. This source then perturbs the local Noether sea state through a constitutive response map,

$$\delta\theta^{(\ell)}_{\rm sea}=\mathcal{C}_{\rm mat\to sea}\left(S^{(\ell)}_{\rm mat\to sea},\lambda_A,\xi_A,\mathcal{H}_A,\theta^{(\ell)}_{\rm sea,0}\right)$$

with $\delta\theta^{(\ell)}_{\rm sea}$ projecting into n, $\chi_{\rm sea}$, Γ_N, strain, orientation, cadence, and envelope-scale variables. In this language, saying that neighboring Noether braids absorb the exposed potential means that they retune their branch state. Depending on the accepted branch, that retuning may appear as higher cadence, changed strain, stronger alignment, envelope-scale shift, or altered coupling to nearby Noether braids; it should not be compressed into a generic statement that the braids simply gain energy and expand.

This is the same shielding-based logic developed more directly in Particle Masses. The matching factor $\alpha_{\rm m}$ should be fixed only after a calibration-free reference attractor has supplied $E_{\rm internal}$, raw ζ, $E_{\rm probe}$ or $\zeta_{\rm probe}$, the exposed-energy partition, and the medium-response map; it should not be fitted separately to each particle species. Universality is a cross-species invariant, not a notation choice. For any certified assembly A, define the back-solved value

$$\alpha_{\rm m}(A)\equiv\frac{m_{\rm tr}(A)c^2_{\rm eff,0}}{E_{\rm internal}(A)\left[\zeta_{\rm probe}(A)(1+\delta\mathcal{M}_0)+\frac{1}{3}\mathcal{Z}_{{\rm tf},ab}(A)\delta\mathcal{M}_{\rm tf}^{ab}\right]}$$

on branches that pass the positivity gate above. For any pair A,A' in the mass-map test set, require

$$\mathcal{R}_\alpha(A,A')\equiv\frac{|\alpha_{\rm m}(A)-\alpha_{\rm m}(A')|}{|\alpha_{\rm m}(A)|+|\alpha_{\rm m}(A')|}\le\epsilon_\alpha$$

with ϵ_α declared before promotion. If this residual cannot be held small without per-species tuning, the universality claim fails and the parameter count must be raised explicitly.
On a connected family of realized assembly branches, this is a flatness condition for α_{m} over the retained moduli. An irreducible jump in the back-solved α_{m} across different assembly topological charge sectors would not be hidden inside the same symbol; it would mark either a disconnected mass-map family or a failed universality claim for the compared species.

Thermodynamic or entropic derivations of gravitational force are therefore comparison benchmarks for this chapter, not replacements for the mass mechanism. They may sharpen the observer-level equation-of-state target for gravity, but $m_{\mathrm{inertial}}(A)$ is not closed until the same assembly ledger supplies its closed internal causal-history record, shielding extraction, Noether sea response tensor, and acceleration response.

The immediate hand-off is the A_0 reference attractor gate. The energy chapter owns the internal-energy and apparent-energy definitions that A_0 must report: layer energies, interaction and wake terms, total $E_{\mathrm{internal}}(A_0)$, far-field wake coefficients, $E_{\mathrm{probe}}(A_0)$, $E_{\text{sea-coupled}}(A_0)$, and $\mathcal{R}_{\mathrm{part}}(A_0)$. Those outputs are still closure targets until a stable branch, shielding extraction, and response tensor are computed. Compact finite-coordinate no-go records and branch-chart checker results cannot be consumed as energy-accounting inputs: a rejection blocks the chart path, and a clearance authorizes only a rerun candidate until Tier 2 shielding exists on an accepted branch.

The multi-scale status of A_0 matters for this accounting. Fast internal corrections should not be removed until they are classified. Nonresonant motion on a measured fast binary may average out of the leading apparent-energy fit, but corrections that change self-hit counts, the branch Jacobian near c_f, or the leakage tensor can change $E_{\mathrm{internal}}(A_0)$, $\zeta(A_0)$, or both. Apparent energy is therefore downstream of closure and stability, not an input used to force a convenient branch.

Noether Sea and Effective Relativistic Behavior

The Noether sea adds an additional layer:

- Moving assemblies must retune their internal causal ledger and reorganize local Noether sea coupling.
- The proposed mechanism is that the effective resistance to high center-of-mass speed (near the relevant internal Noether braid causal-wake propagation scale) increases steeply, producing an emergent saturation speed scale c_{eff} at which assemblies effectively saturate. This presupposes stable sea-coupled assemblies, none of which has yet been derived. Its identification with the photon-channel speed is a separate closure.

Thus:

- At low center-of-mass speeds $v_{\mathrm{CM}} \ll c_{\mathrm{eff}}$, the effective readout recovers $E_k \approx \frac{1}{2} m_{\mathrm{inertial}} v_{\mathrm{CM}}^2$ for assemblies.
- At high center-of-mass speeds approaching c_{eff}, internal coupling to the Noether sea and self-hit effects yield a relativistic-like $E_k \sim m_{\mathrm{inertial}} c_{\mathrm{eff}}^2 (\gamma_{\mathrm{eff}} - 1)$, with $\gamma_{\mathrm{eff}} = 1/\sqrt{1 - v_{\mathrm{CM}}^2 / c_{\mathrm{eff}}^2}$, as an **effective law**.
- Near c_{eff}, axial architrino stripping and oblation are failure channels or branch-transition hypotheses to test, not assumed parts of the mass mechanism.

The details of this emergent relativistic law arise from the combined dynamics of the assembly and the Noether sea; they are not postulated but must be confirmed by coefficient extraction, simulation, and matching to known particle kinematics. Ordinary dissipative drag is a failure channel for this program, not the mass mechanism. The mass-side integration and quantitative derivation path is tracked in Particle Masses.

Effective Energy-Momentum Closure

For assembly center-of-mass motion in the Lorentz-suppressed regime, impose the relativistic mass-shell relation as an **effective closure test** (not a substrate postulate):

$$E_{\mathrm{CM}}^2 = p_{\mathrm{CM}}^2 c_{\mathrm{eff}}^2 + M_0^2 c_{\mathrm{eff}}^4$$

Here:

- M_0 is the assembly rest/internal invariant extracted at $v_{\mathrm{CM}} = 0$ in a locally homogeneous sea.
- E_{CM} and p_{CM} are the total center-of-mass energy and momentum measured from trajectory dynamics.
- c_{eff} is the isotropic projection of the local Noether sea response-speed record. In weak-field homogeneous and neutral conditions that also pass the two-moment quietness condition above, $c_{\mathrm{eff}} \to c_\infty$, with $c_\infty = c_0$ by observer calibration. The relation between c_0 and the primitive wake speed c_f remains the declared hierarchy question in the speed-role table; the active Bell route requires $c_f > c_0$ rather than silently identifying them.

More precisely, the response-speed tensor may be written schematically as

$$\left(c_{\mathrm{eff}}^2\right)^{ab} = c_0^2\left[(1+\delta c_0)h^{ab} + \delta c_{\mathrm{tf}}^{ab}\right], \qquad c_{\mathrm{eff}}^2 \equiv \frac{1}{3}h_{ab}\left(c_{\mathrm{eff}}^2\right)^{ab}$$

The scalar mass-shell closure is admissible only when the anisotropic propagation correction is bounded,

$$\|\delta c_{\mathrm{tf}}\| \leq \epsilon_{c,\mathrm{tf}}$$

on the same comparison window. The scalar offset $\delta c_0 \to 0$ is not assumed by isotropy language alone; it must follow from the same homogeneous neutral summation and screening conditions that make the Noether sea macroscopically quiet.

Equivalent parameterization:

$$E_{\mathrm{CM}} = \gamma_{\mathrm{eff}} M_0 c_{\mathrm{eff}}^2, \qquad p_{\mathrm{CM}} = \gamma_{\mathrm{eff}} M_0 v_{\mathrm{CM}}, \qquad \gamma_{\mathrm{eff}} = \frac{1}{\sqrt{1 - v_{\mathrm{CM}}^2/c_{\mathrm{eff}}^2}}$$

This parameterization must keep rest, motion, and null transport separate. The rest term is the exposed internal ledger $M_0 c_{\mathrm{eff}}^2$, not a velocity-dependent rest mass. Motion changes the center-of-mass readout through γ_{eff} and p_{CM}, while the massless photon-channel limit is a separate null closure,

$$E_\gamma = c_\gamma \|\mathbf{p}_\gamma\|$$

after the photon channel and its speed record have been declared. A calculation that uses the same scalar mass-shell formula to explain a massive assembly, a moving massive assembly, and a photon without naming these three records has collapsed distinct observer-level closures into one slogan.

Consistency requirement: if this closure fails in regimes where emergent Lorentz behavior is claimed, the mass-loading and medium-response model is incomplete.

Cross-links:

- Proper-time closure test
- SR mapping entry

Energy and Self-Hit in the Noether Sea

In the **super-field-speed** regime ($\|\mathbf{V}_a\| > 1$ somewhere along the relevant path-history interval), architrinos and assemblies can intersect their own past isochrons (self-hit). In the presence of the Noether sea:

- Self-hit repulsion supplies an internal **outward floor** against collapse in Noether braids and more complex assemblies. On the uniform-circular chart it cannot supply centripetal support, and its tangential contribution is signed, so stability requires the other retained branch and wake-boundary entries.
- Energy represented in an architrino's causal wake and local Noether sea response can be partially routed back through delayed self-interaction. At the bookkeeping level, this is an exchange between internal kinetic energy and wake/medium energy associated with the local Noether braid configuration.

At the exact causal-action level, global energy is conserved: self-hit just routes energy along more complex paths (architrino → causal isochron → local Noether sea → back to architrino/assembly). In dual-mollified local theorem models, the same statement should be read conditionally unless the mollified kernel is explicitly tied to an action-level regularization.

Intuition (Plain Language)

Inside an assembly, large internal causal-history energy can circulate through many branch channels. Outside the assembly, distant probes couple only to the portion of that ledger that survives phase cancellation, shielding, and Noether sea response.

Architrinos and their assemblies are where the energy bookkeeping lives. The Noether sea is a dense population of high-energy Noether braid assemblies whose net long-range wake response is usually quiet because incoherent contributions cancel and shielded internal rows leak only weakly. In candidate indexed fermion source records, declared support rows screen other rows from the ambient Noether sea. The small residual exposure is what the mass and gravitational-response program must derive; no screening order follows from the persistent indices.

Summary and Role in the Larger Theory

- **At the architrino level:**

  Kinetic energy and potential energy are defined via the Master EOM. Exact global conservation belongs to the exact causal-action theory; in mollified working models it is the target bookkeeping structure and is exact only when the regularization preserves the underlying time-translation symmetry. The substrate law is acceleration-first; no particle-specific fundamental mass is assigned to architrinos, and speeds are unbounded in principle.
  Potential availability is geometric rather than fuel-like: causal wakes are emitted as path-history structure, while work appears only when a receiver intersects active wake branches with nonzero radial power.

- **At the assembly level:**

  Large internal energies, plus coupling to the Noether sea, generate:

  - Effective inertia (mass),
  - Shielded external wake signatures (tiny apparent energy compared to internal),
  - Generation dependence through which declared support rows remain active and how their shielding map changes,
  - An emergent speed scale c_{eff} and relativistic-like behavior.
    Macroscopic quietness follows from superposition and shielding: incoherent populations cancel statistically, while phase-locked assemblies such as collinear breathers preserve localized, non-canceling wake structure.

- **For spacetime and gravity:**

  The sea of small, high-energy Noether braids forms the Noether sea and, at coarse-grained level, the effective spacetime medium whose energy density and stress give rise to an emergent metric. The shielding factors and internal energies of both Noether braids in the Noether sea and “matter” assemblies contribute to:

  - The effective Newton constant G,
  - The cosmological Noether sea energy density,
  - How strongly observer-level effective metric response is reconstructed from different kinds of energy.

  Density-driven oblation is a candidate contribution to the effective gravitational-coupling closure: as the Noether sea encounters denser matter, local Noether braids may scale down and oblate, creating a compliance gradient that must be mapped through the Noether sea response tensor before it can be read as part of G.

Appendix A: Energy Zero and Bookkeeping

$\mathbb{AAA}$ uses a **binding-energy convention** that fixes the zero of potential energy at the **inner turning point** of an accepted bound branch (the maximum-curvature binary (MCB) radius when that branch has been certified). This choice is operational: on a branch with a self-hit lower boundary, the deepest accessible state supplies the reference. The present circular simple-root ledger supplies measured algebraic MCB candidates, not an accepted inner turning point. Until one candidate passes finite-event, retained-history, and stability certification, the energy gauge must use another explicitly declared reference event or radius and may not be described as a derived ground-state zero.

Cosmology inventory prose uses the same convention only after declaring the comparison window. Positive component entries such as matter, radiation, dark-sector bookkeeping, and thermal reservoirs are mass-equivalent or energy-density terms measured relative to that window, while gravitational binding is a negative finite-window contribution. Mixing a local branch convention with a cosmological inventory convention without naming the window and boundary term risks double counting the same retained wake-history energy.

Physical Setup and Why a New Zero is Needed

For an accepted attractive bound branch (opposite polarities), the inward motion accelerates until it reaches a **minimum radius** $r_{\min}$ where the certified self-hit and curvature records prevent further collapse. The motion then rebounds or orbits. Unlike a pure Coulomb potential, this branch has a lower bound on radius (and hence on accessible energy states).

Because a lower bound exists, the natural reference is **not** “infinite separation” but the **ground configuration** at $r_{\min}$.

The Bookkeeping Convention

We adopt a **singular-boundary gauge**: on a certified branch chart with a declared self-hit lower boundary $r_{\min}$, we fix the potential gauge at this wall. If an MCB branch is later certified, its lower boundary is one candidate realization of this reference. Without such a certified wall, choose and name a conventional reference radius r_{ref} instead; that gauge supports comparisons within the declared ledger cell but carries no claim that r_{ref} is a physical minimum.

$$U(r_{\min}) \equiv 0.$$

In this gauge, $U(r)$ represents the **accumulated work** performed to separate the binary from its ground state to radius r. Total energy is thus partitioned into *kinetic* (motion) and *deformation* (separation) components, with fully separated (unbound) pairs carrying maximal deformation energy $U_{\max} \equiv B_{\max}$.

When the active causal-root ledger changes, this gauge must be indexed by the branch ledger. For ledger cell b,

$$U^{(b)}(r) \equiv B^{(b)}_{\max} - B^{(b)}(r), \qquad B^{(b)}_{\max} = B^{(b)}\left(r^{(b)}_{\min}\right)$$

so a separator crossing that changes the effective inner wall cannot be counted once as a gauge-origin jump and again as an independent h-like energy quantum. At a crossing radius r_* between ledger cells b and b', the physical bookkeeping must satisfy

$$[E_{\mathrm{total}}]_{b\to b'} = K^{(b)}(r_*) + U^{(b)}(r_*) = K^{(b')}(r_*) + U^{(b')}(r_*) + \Delta_{\mathrm{ledger}}$$

where Δ_{ledger} is the declared root-change energy routed through the table entries such as ε_3, ε_w, and the binary-2 adjustment. The visible step is the ledger/gauge matching term; it is not additional to that matching.
Thus $U^{(b)}$ is a ledger-indexed potential, and the zero-section can jump when the active causal-root cell changes. A globally consistent energy ledger requires the Δ_{ledger} increments to glue around overlaps of ledger cells; otherwise the local potential gauges are individually consistent but the global binding-energy record is multivalued.

Binding Energy and Total Energy

Let $B(r)$ denote the **binding energy** at radius r, with

$$B(r_{\min}) = B_{\max}.$$

Define

$$U(r) = B_{\max} - B(r).$$

Then total energy bookkeeping is:

$$E_{\text{total}} = K(r) + U(r), \qquad U(r) \geq 0.$$

At the minimum radius:

$$E_{\text{total}} = K_{\max}, \quad U(r_{\min}) = 0.$$

All available mechanical energy is kinetic at the inner turning point. Moving outward converts kinetic energy into potential energy (the rebound / climb-out phase).

Effective Potential Language

If an effective potential is used, the centrifugal term and the self-hit barrier both contribute:

$$V_{\text{eff}}(r) = V(r) + \frac{L^2}{2m_{\text{eff}}r^2} + V_{\text{self-hit}}(r).$$

Here m_{eff} is an **effective inertial scale** (a bookkeeping proxy for mass in the coarse-grained description), not a primitive architrino mass.

The convention above fixes:

$$V_{\text{eff}}(r_{\min}) = 0.$$

This does **not** change dynamics; it sets a physically meaningful reference.

Self-Hit Echo and Discrete Steps (Working Note)

In this picture, the self-hit region is **not** assumed to change the local acceleration law. The radial slope remains smooth:

$$\frac{dU}{dr} \text{ remains finite and continuous across the retained regularized branch chart.}$$

So the transition between the $v = c_f$ regime and the self-hit regime is a **regularized branch transition**, not a kink in the potential. The distinction shows up in **how action and energy bookkeeping are routed** between binaries, not in a new macroscopic slope.

The discrete step is a causal-root ledger effect, not an assumption that energy itself is made of independent chunks. On a fixed branch chart, the active causal intersections have an integer multiplicity: a self-hit count N and an analogous partner-hit or channel count M. In the circular binary notation this same idea appears as the pair (N_s, M_p) in Super-Field-Speed Root Ledgers and Resonance Lock. Within one ledger cell the underlying trajectory and $U(r)$ remain continuous. A visible h-like transaction occurs when a separator crossing changes the admissible integer ledger, for example by adding one grouped channel or, in the raw simple-root table, by a fold-pair jump satisfying $\Delta N \in 2\mathbb{Z}$ with $\Delta D = 0$.

The mechanical event behind such a ledger change can be a caustic-grazing impulse. When a regularized branch crosses a $J = 0$ caustic, the pointwise branch expression may become large while the integrated velocity change remains finite, as in Caustic Transit and Finite Impulse:

$$\Delta \mathbf{V}_{a,n} = \int_{T_n^-}^{T_n^+} \mathbf{A}_a^{(\eta)}(T)\, dT$$

This finite impulse is a candidate substrate mechanism for changing the active causal-root ledger by a discrete amount without making primitive energy granular.

Thus the candidate quantum of action is geometric bookkeeping: it is the action scale assigned to a threshold crossing of the causal-root ledger. The energy shift appears in steps because the allowed causal intersections have changed discretely, even though the path-history geometry and the local potential slope remain continuous through the regularized fold layer. A closed branch chart must still expose the root-change energy, wake exchange, closure-channel adjustment, and any mismatch routed into unresolved modes.

Working bookkeeping hypothesis:

- Source-record binary 3 registers a single-step transaction (h-like unit), meaning one minimal admissible update of its active partner and self channel ledger.
- Source-record binary 2 adjusts to conserve total energy.
- Source-record binary 1 executes a two-step shift ($2h$-like unit), i.e., two discrete ledger updates rather than one. The "step" corresponds to the system crossing a separatrix between basins of attraction in the nonlinear delay dynamics. While the underlying trajectory is continuous, the energy redistribution stabilizes only at discrete resonances (winding numbers and causal-root multiplicities), making the effective energy transfer appear quantized.

This can read as an "amplified" response, but only because source-record binary 1 is **releasing or reconfiguring retained internal energy** when the self-hit echo is engaged. It is **not** net energy creation; it is a redistribution between internal stores under a smooth $U(r)$. The assigned transaction, closure, and self-hit roles in this working record are hypotheses; the persistent indices do not carry those meanings in the taxonomy.

Candidate Braid as Routing/Locking Circuit (Analogy)

It is useful (as a **bookkeeping analogy**) to think of this candidate braid record as a **routing/locking circuit** rather than a simple reservoir. An incoming single-step transaction (h-like) couples most strongly to source-record binary 3, binary 2 acts as a closure buffer that maintains overall consistency, and binary 1 can respond with a two-step reconfiguration when the self-hit echo is engaged. These provisional roles do not identify a taxonomy member. The effective response can resemble a geared or ratcheted redistribution, but the mechanism is still deterministic energy routing, not creation.

In this language, a discrete input can **lock in** a new candidate braid configuration: a threshold-triggered, history-dependent update that selects one stable branch over another. This is a **collapse-like** event in the phenomenological sense (a sudden, discrete state update), but in $\mathbb{AAA}$ it is treated as a **deterministic, microstate-sensitive bifurcation**, not an intrinsically stochastic collapse.

Closed-Cycle Action Bookkeeping Table for the Sub-Field Source Record

This table records one h of closed-cycle action for source-record binary 3 in the sub-field-speed regime $v_3 < c_f$.

For the h versus $\hbar$ convention used here, see Angular Momentum and Spin.

Assumptions for this bookkeeping pass:

- f labels a discrete binary-3 orbital state (frequency index). The three rows are **pre-hit** ($f-1$), **action/transition** (f_ψ), and **post-redistribution** (f). There is **one** step in frequency. The f_ψ label is a transient bookkeeping state, not a new frequency index or literal wave function.
- The transaction is a single closed-cycle action unit, $\Delta A_{\text{cycle}} = +h$, coupled first to source-record binary 3 while $v_3 < c_f$.
- The symbol h labels action per full causal phase cycle. The associated radian-normalized rotational-action increment is $\hbar = h/(2\pi)$; in this local bookkeeping pass ΔI denotes that angular-momentum/action variable.
- Energy bookkeeping uses action-angle language: for a small discrete step, $\Delta E \approx \omega\, \Delta I = f\, \Delta A_{\text{cycle}}$. This is a **notation choice**, not a claim about the exact micro-law.
- Source-record binary 1 responds with a two-step reconfiguration. Binary 2 adjusts to satisfy conservation of total energy and total angular momentum (including any causal-wake exchange).

Notation in the table:

- K_3, U_3 = binary-3 kinetic and potential energies.
- K_2, U_2 = binary-2 kinetic and potential energies.
- K_1, U_1 = binary-1 kinetic and potential energies.

- Superscripts $(f-1)$, (f_ψ), and (f) denote the state index (one-step update).

Per-step increments (explicit, no deltas):

- Binary-3 step energy: $\varepsilon_3 \equiv \omega_3\hbar$ with

$$k_3 \equiv \chi_3\,\varepsilon_3, \quad u_3 \equiv (1-\chi_3)\,\varepsilon_3,$$

so $k_3 + u_3 = \varepsilon_3$.

- Binary-1 step energy: $\varepsilon_1 \equiv \omega_1\hbar$ with

$$k_1 \equiv \chi_1\,\varepsilon_1, \quad u_1 \equiv (1-\chi_1)\,\varepsilon_1,$$

so $k_1 + u_1 = \varepsilon_1$. Because binary 1 takes **two steps** in this source record, it adds $2k_1$ and $2u_1$.

- Binary-2 adjustment energy: ε_2 is whatever is needed to close the ledger. Here ε_w denotes the **causal-wake exchange energy** during the step:

$$\varepsilon_2 \equiv \varepsilon_w - 2\varepsilon_1,$$

and we split it as

$$k_2 \equiv \chi_2\,\varepsilon_2, \quad u_2 \equiv (1-\chi_2)\,\varepsilon_2.$$

State	Binary 3	Binary 2	Binary 1	Notes
$f-1$	K_3^{f-1}, U_3^{f-1}	K_2^{f-1}, U_2^{f-1}	K_1^{f-1}, U_1^{f-1}	Baseline. No pending transaction.
f_ψ	$K_3^{f_\psi} = K_3^{f-1} + k_3$ $U_3^{f_\psi} = U_3^{f-1} + u_3$	$K_2^{f_\psi} = K_2^{f-1}$ $U_2^{f_\psi} = U_2^{f-1}$	$K_1^{f_\psi} = K_1^{f-1}$ $U_1^{f_\psi} = U_1^{f-1}$	Immediate post-hit. Binary 3 receives $\Delta I_3 = +\hbar$ in the initial bookkeeping gauge. Binary 3 records a (k_3, u_3) increment.
f	$K_3^{f} = K_3^{f-1} + k_3$ $U_3^{f} = U_3^{f-1} + u_3$	$K_2^{f} = K_2^{f-1} + k_2$ $U_2^{f} = U_2^{f-1} + u_2$	$K_1^{f} = K_1^{f-1} + 2k_1$ $U_1^{f} = U_1^{f-1} + 2u_1$	Post-redistribution. Binary-3 update is complete at f_ψ; only binaries 2 and 1 continue to settle.

Constraints to apply across the $f-1 \to f$ transition (bookkeeping level):

- **Angular momentum / rotational action**: the sign rule is gauge-invariant only after declaring the allowed wake share:

$$\Delta I_3 + \Delta I_2 + \Delta I_1 + \Delta I_{\text{wake}} = +\hbar, \qquad |\Delta I_{\text{wake}}| \le \epsilon_w\hbar$$

For a **net positive** transaction, the binary increments must satisfy $\Delta I_a \ge -\epsilon_w\hbar$ for $a \in \{1,2,3\}$. For a **net negative** transaction, the same bound applies with signs reversed. The nonnegative-increment claim is therefore an up-to-wake-tolerance statement, not a gauge-free statement that the wake channel carries exactly zero rotational action.

- **Energy**: $(k_3+u_3) + (k_2+u_2) + 2(k_1+u_1) = \varepsilon_3 + \varepsilon_w$. This is the explicit version of conservation using the per-step increments defined above.
- **Root-ledger closure**: the transition must move from one admissible integer causal-root ledger to another and then close consistently over the full cycle. In a raw self-root table, separator crossings obey the parity rule $\Delta N \in 2\mathbb{Z}$ and $\Delta D = 0$; in a grouped channel ledger, the same event may be recorded as one newly active channel.
- **Cross-ledger gauge matching**: any jump in $r_{\min}^{(b)}$ and $B_{\max}^{(b)}$ is part of the declared Δ_{ledger} budget above. A table row may not count the same gauge-origin shift once in $U^{(b)}$ and again as an extra wake or oscillator energy.
- **Smooth slope**: dU/dr remains continuous across the graft; the discrete behavior comes from **state updates**, not a kink in $U(r)$.

This table is intentionally explicit: every h closed-cycle action transaction is represented by a radian-normalized $\hbar$ rotational-action increment, split into a kinetic part (k) and a potential part (u). The remaining freedom is **how** each binary partitions its step (the χ fractions) and how binaries 2 and 1 plus the causal-wake channel redistribute the initial binary-3 coupling in this source record.

Comparison to Coulomb and Standard Conventions

In pure Coulomb,

$$V(r) = -\frac{kq^2}{r},$$

so there is no inner bound and no natural finite zero. Classical mechanics therefore chooses $V(\infty) = 0$.

In $\mathbb{AAA}$, a certified hard inner bound **supplies** a natural zero at $r_{\min}$, which is the lowest accessible state. The bookkeeping therefore switches from "energy relative to infinity" to "energy relative to the ground state."

Summary Table (Operational Meaning)

Region	K	U	Meaning
$r = r_{\min}$	max	0	Fully bound (ground)
$r > r_{\min}$	↓	↑	Climbing out / rebound
escape limit	0	$B_{\max}$	Free (unbound)

One-Line Rule

If the model has a hard inner bound, **set the potential zero at that bound** and measure all energies outward from it.

Adiabatic branch invariant target. On a certified branch chart for binary layer a, suppose the reduced cycle admits a canonical pair (Q_a, Π_a) and a slowly varying branch parameter $\lambda(T)$, such as a local Noether sea response variable, shielding parameter, or neighboring-layer phase parameter. Define the rotational action

$$I_a(\lambda) \equiv \frac{1}{2\pi} \oint_{\gamma_a(\lambda)} \Pi_a \, dQ_a$$

If the parameter changes slowly compared with the cycle period $T_a(\lambda)$,

$$\epsilon_{\mathrm{ad},a} \equiv \max_{T \in W} \left(T_a(\lambda(T)) \left\| \frac{d\lambda}{dT} \right\| \ell_\lambda^{-1} \right) \ll 1$$

and the path remains a positive distance from the causal-root ledger-cell boundary,

$$\mathrm{dist}(\gamma_a(\lambda), \partial \mathcal{G}_a) \geq \delta_{\mathrm{cell}} > 0$$

the interior adiabatic theorem target is

$$\frac{dI_a}{dT} = O(\epsilon_{\mathrm{ad},a}) + \mathcal{R}_{\mathrm{int},a}(T)$$

Here ℓ_λ is the declared scale over which the reduced Hamiltonian changes appreciably, and $\mathcal{R}_{\mathrm{int},a}$ records omitted wake-history exchange, non-characteristic boundary leakage, or small chart error while the branch stays inside one ledger cell. At a separator crossing or root-fold boundary, the interior estimate is void. The crossing rule is instead

$$\Delta I_a \big|_{\mathrm{fold}} = \frac{1}{2\pi} \left(\oint_{\gamma_a'} \Pi_a \, dQ_a - \oint_{\gamma_a} \Pi_a \, dQ_a \right) = \Delta I_{\mathrm{ledger},a}$$

where $\Delta I_{\mathrm{ledger},a}$ is the declared quantized ledger increment associated with the change in active causal-root multiplicity or branch chart. Thus the action variable is expected to drift only adiabatically inside a ledger cell, while a root-ledger transition may produce the discrete ΔI recorded above. This turns the h-like bookkeeping into a branch-boundary invariant target rather than an assumption that energy itself is quantized at the primitive level.

In this form, an h-like action transaction is the finite phase-space area jump across a root-fold wall, not a primitive grain of energy. The floor $\delta_{\text{cell}} > 0$ is the adiabatic validity condition: inside the cell the action is nearly invariant; at the wall the fold impulse, ledger update, and cross-ledger gauge matching must be booked together on the same retained branch record.

Action-Energy

Action Model

This note compares three modeling options for the emission-propagation-interaction pipeline and recommends a primary approach, with supporting roles for the others. We work in normalized wake-speed units with $c_f = 1$ unless stated otherwise; emission cadence and per-wavefront amplitude are constant at the transmitter; per-hit accelerations are directed along $\hat{\mathbf{r}}$ with inverse-square geometric decay and transmitter-side acceleration weight $W^{\text{acc}} = c_f/|D_t|$; $H(0) = 0$ excludes the coincident-time self-kick; no cross products or right-hand-rule terms appear.

Setup / assumptions

- The transmitter is at position $\mathbf{X}_t(T)$ in 3-D space and may move.
- The transmitter emits **thin causal wake surfaces**. Each wake surface is created at a single instant T_t and then expands outward **spherically** from the creation point.
- The wake surface radius after emission time T_t is

$$r(T, T_t) = c_f\,(T - T_t) \quad \text{for } T \geq T_t$$

where c_f is the constant **field speed**.

- Each emitted wake surface carries a **strength** Q, interpreted here as wake-surface amplitude. Its physical bookkeeping role depends on the comparison target: polarity, potential impulse, energy, or another declared quantity.
- Continuous source term (preferred): model the transmitter as a moving point injection with time-density $q(T)$ (amplitude per unit time) at its instantaneous position, i.e., $S(\mathbf{X}, T) = q(T)\,\delta\big(\mathbf{X} - \mathbf{X}_t(T)\big)$. Each instant T_t contributes a causal wake surface; we do not count "wake surfaces per second" (pulse trains are merely numerical surrogates).
- The diagnostic target is the effective scalar potential $\phi(\mathbf{X}, T)$ produced at any point $\mathbf{X}$ and time T.
- Global neutrality (working hypothesis): on large scales the total architrino polarity inventory sums to zero (equal counts of $\pm\epsilon$); use this as the default boundary condition in PDE/Green's-function comparisons.

We compare three frameworks: (1) a time-domain PDE source term, (2) an integral/Green's-function path-history solution, and (3) event-driven radial transport plus the per-hit EOM. For each, we define symbols, show how the expanding causal wake surfaces appear, discuss how slowing or stopping the transmitter is handled, and weigh trade-offs to inform a recommendation.

Time-based PDE (wave equation with a moving point source term)

Physical idea: keep the mathematical source term as an injection per unit time at the transmitter location, put that into a PDE surrogate for causal wake propagation at speed c_f, and let the PDE produce expanding spherical causal wake surfaces. This is a standard grid formulation; its cost and accuracy still have to be measured for the declared domain and resolution.

PDE model

Use the scalar wave equation as a continuum comparison surrogate for finite-speed causal-wake reconstruction. The source normalization below is chosen so its free-space Green function has the $1/(4\pi r)$ convention used later:

$$\boxed{\frac{\partial^2 \phi}{\partial T^2}(\mathbf{X}, T) - c_f^2\,\nabla^2 \phi(\mathbf{X}, T) \;=\; c_f^2 S(\mathbf{X}, T)}$$

Symbols

- $\phi(\mathbf{X}, T)$: scalar potential surrogate at position $\mathbf{X} \in \mathbb{R}^3$ and time T.
- c_f: field propagation speed (units length/time).
- ∇^2: Laplacian operator in space (sums second spatial derivatives).
- $S(\mathbf{X}, T)$: source term (right-hand side) — this is how the transmitter injects wake surfaces into the field.

Moving point source-term form

Use a continuous time-density of emission at the moving point:

$$S(\mathbf{X}, T) \;=\; q(T)\,\delta\big(\mathbf{X} - \mathbf{X}_t(T)\big)$$

Here $q(T)$ has units "amplitude per unit time." The finite-speed wave operator then generates outgoing spherical causal wake surfaces automatically; no discrete wake surface count is assumed.

How expanding causal wake surfaces appear

- The source term does not explicitly insert a radius into the right-hand side. Instead, the PDE and the finite speed c_f cause any instantaneous injection at the point $\mathbf{X}_t(T_t)$ to produce an outgoing spherical causal wake surface whose front moves outward at speed c_f. That is the built-in behavior of the wave-equation surrogate.
- The Green's function ensures that, at $(\mathbf{X}, T)$, only simple causal roots satisfying $T - T_t = r(T_t)/c_f$ contribute. A moving or super-field-speed transmitter can supply more than one such root. Thus Method 1 with $S(\mathbf{X}, T) = q(T)\delta(\mathbf{X} - \mathbf{X}_t(T))$ yields finite-speed outgoing support, while the root multiplicity remains part of the path-history geometry.

Why $\|\mathbf{V}\|$ (transmitter speed) does not cause blow-ups

- If the transmitter slows or stops, $S(\mathbf{X}, T)$ remains nonzero at the same spatial location; the wave equation spreads each injection outward at speed c_f. No $1/\|\mathbf{V}\|$ singularity appears because the formulation does not convert from per-time emission to per-distance emission.
- Numerically, represent the point delta by a small, smooth kernel when avoiding grid artifacts. For example, instead of $\delta(\mathbf{X} - \mathbf{X}_t)$ use a small Gaussian of width σ comparable to grid spacing.

Numerical recipe (simple)

- Choose spatial grid $\mathbf{X}_i$ and time step ΔT satisfying CFL stability (roughly $c_f \Delta T/\Delta X \leq \mathrm{const}$).
- Use a standard finite-difference time stepping for the wave equation (centered difference in time and space).
- At each time step T_n add the source contribution $S(\cdot, T_n)$ to the right-hand side at the grid cells nearest $\mathbf{X}_t(T_n)$. If the transmitter stops, it remains injecting at that grid location—the solver propagates outgoing wake surfaces.
- To avoid a numerical spike, spread the delta over a few cells with a mollifier, representing a thin wake surface of finite thickness.

Summary for Method 1

- Model is explicit, straightforward, numerically robust.
- Emission is naturally time-based; wake surfaces expand automatically at speed c_f.
- No division by transmitter speed appears; stopping the transmitter is handled simply by keeping the source term at the same location.

Integral (Green's function / path-history potential) approach

Physical idea: instead of evolving a PDE in time, write the solution as the sum of contributions from every past emission. For the wave equation the contribution from an impulse emitted at time T_t and place $\mathbf{X}_t(T_t)$ arrives at a field point $\mathbf{X}$ only at the **path-history time** when the causal wake surface reaches $\mathbf{X}$. The Green's function neatly encodes the expanding causal wake surface.

Fundamental formula (general)

If the wave equation is

$$\frac{\partial^2 \phi}{\partial T^2} - c_f^2 \nabla^2 \phi = c_f^2 S(\mathbf{X}, T)$$

then the solution may be written as the space–time convolution with the Green's function G:

$$\boxed{\phi(\mathbf{X}, T) \;=\; \iint G\big(\mathbf{X}, T; \mathbf{Y}, T_t\big)\; S(\mathbf{Y}, T_t)\; dT_t\, d^3Y}$$

- $G(\mathbf{X}, T; \mathbf{Y}, T_t)$ is the response at $(\mathbf{X}, T)$ to an instantaneous unit impulse at $(\mathbf{Y}, T_t)$.

The 3-D free-space wave Green's function

For three spatial dimensions (the usual case for causal wake surfaces), the causal Green's function is

$$G(\mathbf{X}, T; \mathbf{Y}, T_t) \;=\; \frac{\delta\big(T - T_t - \frac{\|\mathbf{X}-\mathbf{Y}\|}{c_f}\big)}{4\pi\,\|\mathbf{X}-\mathbf{Y}\|}, \qquad T > T_t$$

Interpretation: a unit impulse at location $\mathbf{Y}$ and time T_t influences $\mathbf{X}$ at time T only when the travel time $\|\mathbf{X}-\mathbf{Y}\|/c_f$ has elapsed; the $1/(4\pi r)$ factor is the usual geometric decay of an outgoing spherical wave in 3D.

Plugging in a moving point source term

If the transmitter supplies a moving point source term with time-dependent amplitude $q(T_t)$ at location $\mathbf{X}_t(T_t)$, then $S(\mathbf{Y}, T_t) = q(T_t)\,\delta(\mathbf{Y} - \mathbf{X}_t(T_t))$. Plugging this into the convolution gives an integral over T_t only:

$$\boxed{\phi(\mathbf{X}, T) \;=\; \int_{-\infty}^{T} \frac{q(T_t)\;\delta\big(T - T_t - \frac{\|\mathbf{X}-\mathbf{X}_t(T_t)\|}{c_f}\big)}{4\pi\,\|\mathbf{X}-\mathbf{X}_t(T_t)\|}\, dT_t}$$

- $q(T_t)$ is the continuous emission density per unit time at the emission instant T_t. For a steady transmitter, $q(T_t) = q_0$ (constant); more generally, q may vary smoothly with T_t.

Evaluating the integral — the path-history time

The δ-function in the integrand enforces the *path-history-time condition*:

$$T - T_t = \frac{r(T_t)}{c_f}, \qquad r(T_t) \equiv \|\mathbf{X} - \mathbf{X}_t(T_t)\|$$

So the contribution to $\phi(\mathbf{X}, T)$ comes only from times T_t such that the expanding causal wake surface emitted at T_t has just reached $\mathbf{X}$ at time T.

Mathematically, use the identity $\delta(g(T_t)) = \sum_i \delta(T_t - T_{t,i})/|g'(T_{t,i})|$ where $T_{t,i}$ are simple roots of g. With $g(T_t) = T - T_t - r(T_t)/c_f$ we find (after algebra) the standard path-history solution:

$$\boxed{\phi(\mathbf{X}, T) \;=\; \sum_{T_{t,i}} \frac{q(T_{t,i})}{4\pi\, r(T_{t,i})\,\big|1 + \frac{1}{c_f}\, r'(T_{t,i})\big|} \;=\; \sum_{T_{t,i}} \frac{q(T_{t,i})}{4\pi\, r(T_{t,i})\,\big|1 - \frac{\mathbf{n}(T_{t,i})\cdot\mathbf{V}_t(T_{t,i})}{c_f}\big|}}$$

where:

- the sum runs over **path-history times** $T_{t,i}$ solving $T - T_{t,i} = r(T_{t,i})/c_f$ (usually there is a single relevant root).
- $r(T_{t,i}) = \|\mathbf{X} - \mathbf{X}_t(T_{t,i})\|$.

- $r'(T_t) = \dfrac{d}{dT_t}\|\mathbf{X} - \mathbf{X}_t(T_t)\| = -\mathbf{n}(T_t) \cdot \mathbf{V}_t(T_t)$.
- $\mathbf{V}_t(T_t) = \dfrac{d\mathbf{X}_t}{dT_t}$ is the transmitter velocity at emission time T_t.
- $\mathbf{n}(T_t) = \dfrac{\mathbf{X} - \mathbf{X}_t(T_t)}{r(T_t)}$ is the unit vector pointing from the transmitter at emission to the field point.

In standard wave-equation solutions, a Jacobian factor $|1 - \mathbf{n}\cdot\mathbf{V}_t/c_f|$ arises from the change of variables used to evaluate the path-history-time delta. In this project's canonical per-hit law, emission cadence and per-wavefront amplitude are constant and do not depend on transmitter speed. The same transmitter-side factor controls root transversality, while the active acceleration weight is $W^{\mathrm{acc}} = c_f/|D_t|$. The receiver-side factor D_r is retained separately for signed root playback; it does not multiply the instantaneous acceleration.

Special simple case — stationary transmitter

If $\mathbf{X}_t(T_t) = \mathbf{X}_0$ (transmitter fixed) and $q(T_t) = Q\,\delta(T_t - T_{t,0})$ (single wake surface at $T_{t,0}$), then the formula reduces to the intuitive result:

- The field at $(\mathbf{X}, T)$ is nonzero only when $T - T_{t,0} = \|\mathbf{X} - \mathbf{X}_0\|/c_f$, i.e., when the causal wake surface of radius $r = c_f(T - T_{t,0})$ reaches $\mathbf{X}$.
- The amplitude is $\phi(\mathbf{X}, T) = \dfrac{Q}{4\pi\, r}$ (no extra Jacobian factor because $v_s = 0$).

How wake surfaces show up here

- Each emitted wake surface corresponds to one emission time T_t. The delta in the Green's function selects the observation times T at which the wake surface reaches $\mathbf{X}$.
- The shape of the contribution is the $1/(4\pi r)$ geometric factor for wave amplitude; the wake surface is thin in time if $q(T_t)$ is a delta in T_t, so the receiver gets a short impulse when the wavefront passes.

Handling a transmitter that stops / $\|\mathbf{V}_t\| \to 0$

- If the transmitter slows or stops, the Jacobian factor $1 - \mathbf{n} \cdot \mathbf{V}_t/c_f$ tends to 1 and nothing singular happens. The path-history equation still has a solution and each wake surface arrives at the predicted time.
- If the transmitter sits still and emits many wake surfaces (continuous $q(T_t)$), the field is the time integral or sum of all wake-surface contributions evaluated at their respective causal times. No $1/\|\mathbf{V}_t\|$ blowup occurs.

Event-driven Radial-Transport + Per-Hit EOM (Canonical Method)

Physical idea: represent emission as a conserved, razor-thin causal wake surface (a measure on the causal isochron), then drive particle motion by summing line-of-action per-hit accelerations with transmitter-side acceleration weight at causal intersection times. Numerical instantiations use $c_f = 1$; symbolic derivations retain c_f where its dependence matters.

Field representation (transport/continuity form)

- Source impulse at $(T_t, \mathbf{X}_0)$ creates a wake surface supported on $r = c_f(T - T_t)$ with surface density that conserves a constant per-wake surface amplitude q:

$$\rho(T, \mathbf{X}) \;=\; \frac{q}{4\pi r^2}\,\delta\big(r - c_f(T - T_t)\big)\,H(T - T_t), \quad r = \|\mathbf{X} - \mathbf{X}_0\|$$

- This solves the radial continuity (transport) equation

$$\partial_T \rho + \nabla_{\mathbf{X}}\cdot\big(c_f\,\hat{\mathbf{r}}\,\rho\big) \;=\; q\,\delta(T - T_t)\,\delta^{(3)}(\mathbf{X} - \mathbf{X}_0)$$

- A continuous emission density is obtained by integrating these impulse responses over T_t with $q(T_t) \equiv q_0$.

Per-hit equation of motion (EOM)

- For a receiver o' at reception time T_r and a transmitter j, causal emission times satisfy

$$\|\mathbf{X}_{o'}(T_r) - \mathbf{X}_j(T_t)\| = c_f\,(T_r - T_t), \qquad T_t < T_r$$

- Each root contributes a line-of-action acceleration

$$\mathbf{A}_{o'\leftarrow j}(T_r;T_t) \;=\; \kappa\,\sigma_{q_j q_{o'}}\,\frac{|q_j q_{o'}|}{r^2}\,W^{\mathrm{acc}}_{o'j}(T_r;T_t)\,\hat{\mathbf{r}}, \quad \hat{\mathbf{r}} = \frac{\mathbf{X}_{o'}(T_r) - \mathbf{X}_j(T_t)}{r},\; r > 0$$

with $W^{\mathrm{acc}}_{o'j} = c_f/|D_{t,o'j}|$, $D_{t,o'j} = c_f - \mathbf{V}_j(T_t)\cdot\hat{\mathbf{r}}$, and $D_{r,o'j} = c_f - \mathbf{V}_{o'}(T_r)\cdot\hat{\mathbf{r}}$. Total acceleration is the sum over transmitters and roots. Convention $H(0) = 0$ removes the instantaneous self-kick at zero delay. Optional mollification replaces $\delta(\cdot)$ by $\delta_\eta(\cdot)$ to produce smooth acceleration contributions.

Implementation checklist

- Root finding: solve $F(T_t;T_r) = \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_j(T_t)\| - c_f(T_r - T_t) = 0$ for all transmitters j (including $j = o'$ for self-hits when kinematics permit).
- Accumulation: compute $r, \hat{\mathbf{r}}$, D_t, D_r, and W^{acc}, apply W^{acc}/r^2, then superpose.
- Time stepping: impulsive mode (events) or mollified mode ($\eta > 0$) with a delayed-history integrator that retains and interpolates the required path segment.
- Self-interaction: a super-field-speed history interval nominates the channel, but an admitted self-hit still requires a nonzero-delay same-transmitter root and the declared branch floors; accepted self-hits are repulsive (like-on-like).

Relation to Methods 1 and 2

- This is a transport/continuity model, not the scalar wave equation. The $1/r^2$ factor is a surface-density normalization (Gauss-like on the spherically expanding causal wake surfaces); it is compatible with conserving total emission per wake surface. In Method 2 the $1/(4\pi r)$ factor appears for a wave amplitude; taking gradients connects these scalings when mapping to accelerations.
- The Doppler-type Jacobian $1 - \mathbf{n}\cdot\mathbf{V}_t/c_f$ from Method 2 is the transmitter-side branch-transversality factor. Geometric constants are absorbed into κ by convention, but the canonical per-hit strength uses the transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$; no additional transmitter-speed amplitude factor is introduced.
- Numerically, this method targets particle dynamics directly (per-hit ODEs) rather than evolving a full field (Method 1) or evaluating fields at sparse probes (Method 2).

Operator diagnostics (finite-window checks)

- Use vector-calculus identities only on declared, reconstructed diagnostic channels such as $\nabla\Phi_\eta$ or the mollified transport current $\mathbf{J}_\eta = c_f\,\hat{\mathbf{r}}\,\rho_\eta$. These channels are validation objects, not new substrate ontology.
- For any finite control volume $V \subset \Sigma_T$ with outward unit normal $\hat{\mathbf{n}}$, define the Gauss residual

$$R_G[V,T;\mathbf{Y}_\eta] \equiv \frac{\left|\int_{\partial V}\mathbf{Y}_\eta\cdot\hat{\mathbf{n}}\,dS - \int_V \nabla\cdot\mathbf{Y}_\eta\,dV\right|}{\int_{\partial V}|\mathbf{Y}_\eta\cdot\hat{\mathbf{n}}|\;dS + \int_V |\nabla\cdot\mathbf{Y}_\eta|\;dV + \varepsilon_G}$$

- For any oriented smooth surface $S \subset \Sigma_T$ with boundary ∂S, define the Stokes residual

$$R_S[S,T;\mathbf{Y}_\eta] \equiv \frac{\left|\oint_{\partial S}\mathbf{Y}_\eta\cdot d\mathbf{X} - \int_S(\nabla\times\mathbf{Y}_\eta)\cdot\hat{\mathbf{n}}\,dS\right|}{\oint_{\partial S}|\mathbf{Y}_\eta\cdot d\mathbf{X}| + \int_S |(\nabla\times\mathbf{Y}_\eta)\cdot\hat{\mathbf{n}}|\;dS + \varepsilon_S}$$

- A PDE surrogate and event-root reconstruction are comparable only after a common observable map, normalization, boundary condition, and regulator have been declared. Their agreement then tests the implementations of that declared map; it is not independent evidence for the canonical acceleration law. If $\Delta\mathbf{Y}_\eta = \mathbf{Y}^{\mathrm{PDE}}_\eta - R(\mathbf{Y}^{\mathrm{root}}_\eta)$, use

$$E_{\mathrm{op}}(V,S,T) \equiv \max\{R_G[V,T;\Delta\mathbf{Y}_\eta],\, R_S[S,T;\Delta\mathbf{Y}_\eta]\}$$

For the conservative potential channel $\mathbf{Y}_\eta = \nabla\Phi_\eta$, nonzero circulation is a numerical, boundary, or coordinate-operator error unless a non-gradient effective channel has been explicitly declared.

Plain language: treat the potential contribution as a conserved amount spread over a growing causal wake surface. When a wake surface reaches a receiver, the receiver gets a straight-line push that falls off like $1/r^2$; the calculation may treat it as a sharp kick or as a short, smooth nudge.

Cross-Method Guidance

Cross-Method Selection

- Method 1 (PDE): whole-field grid simulations, visualization, and complex media/boundaries. Deposit a smeared source term each step; robust when a transmitter slows or stops. Aggregate particle data to coarse-grained densities $n(\mathbf{X},T)$, $\rho(\mathbf{X},T)$, and $\mathcal{E}(\mathbf{X},T)$ as inputs/targets for PDE runs and validation.
- Method 2 (Green's function / path-history integral): closed forms and sparse probe evaluation. Enforce the path-history condition $T-T_t=\|\mathbf{X}-\mathbf{X}_t(T_t)\|/c_f$ and handle the geometric factor $1-\mathbf{n}\cdot\mathbf{V}_t/c_f$ during evaluation; root-solve one or more T_t values per observer-time pair.
- Method 3 (Event-driven canonical): production many-body dynamics. Find causal roots and sum per-hit W^{acc}/r^2 pushes; prefer η-mollified mode for smooth ODEs when needed.

Short worked example — stationary transmitter, continuous source term (consistent across methods)

- Setup: transmitter at origin $\mathbf{X}_t=0$ with $q(T)\equiv q_0$ (constant).
- Method 1: for a source active since T_0, solving the wave PDE with $S(\mathbf{X},T)=q_0\,\delta(\mathbf{X})H(T-T_0)$ gives $\phi(r,T)=q_0H(T-T_0-r/c_f)/(4\pi r)$ under the declared normalization.
- Method 2: the path-history formula gives the same switched-on profile, with the path-history time $T_t=T-r/c_f$ admitted only when $T_t\geq T_0$.
- Method 3: the path-history condition selects the single causal time $T_t=T-r/c_f$; the per-hit EOM yields one radial push along $\hat{\mathbf{r}}$ with $1/r^2$ scaling, consistent with taking spatial gradients of the $1/r$ potential to connect amplitude to acceleration.

Practical implementation notes (concise)

- PDE: smear $\delta(\mathbf{X}-\mathbf{X}_t)$ to grid scale; enforce CFL ($c_f\,\Delta T/\Delta X$ within the scheme's bound).
- Path-history: robust root-finding for T_t from $T-T_t=r(T_t)/c_f$; take care near grazing geometries where $1-\mathbf{n}\cdot\mathbf{V}_t/c_f$ is small.
- Event-driven: bracket causal roots for continuity, optionally use δ_η for smooth pushes, and limit step sizes so only a controlled number of mollified wake surfaces overlap.

Operational Summary

- Model the transmitter through the source term $S(\mathbf{X},T)=q(T)\,\delta\big(\mathbf{X}-\mathbf{X}_t(T)\big)$ (time-based emission density).
- Use Method 3 as the primary dynamics engine; use Method 2 for declared-normalization and implementation spot checks; use Method 1 for whole-field or comparison-media studies.
- After the normalization and observable map are fixed, all three coincide on the declared stationary comparison case. That shared construction checks implementation parity, not the truth of the common rule.

Differential analysis (criteria-by-criteria)

Axiomatic fidelity (delayed-only, line-of-action, constant transmitter emission)

- Method 1: Partially aligned. The PDE yields $1/(4\pi r)$ wave amplitudes; mapping to $1/r^2$ per-hit accelerations requires gradients and conventions. Radial-only action is not built-in.
- Method 2: Causality and superposition are exact; amplitudes are $1/(4\pi r)$ with a transmitter-side Jacobian $|1-\mathbf{n}\cdot\mathbf{V}_t/c_f|^{-1}$ when evaluating the path-history time delta. The canonical law keeps the corresponding transmitter-side factor as root-transversality data, while received acceleration magnitude uses $W^{\mathrm{acc}}=c_f/|D_t|$ and overall geometric normalizations are absorbed into κ when comparing accelerations.

- Method 3: Exact match. Delayed-only, line-of-action per-hit with constant transmitter emission is native, and the transmitter-side acceleration weight appears explicitly in the received acceleration magnitude. Geometric normalizations are conventionally absorbed into κ.

Causal root structure, self-interaction, multiplicity

- Method 1: Self-hits and multiple roots are implicit in the evolving field; they are not directly enumerated as discrete events.
- Method 2: Causal roots arise via solving $T - T_t = r(T_t)/c_f$; multiple roots and tangencies are explicit but require robust root-finding.
- Method 3: Roots are primitive; multi-hit and self-hit regimes are treated natively. Conventions H(0)=0 and exclusion of $r = 0$ beyond $T_t = 0$ are explicit.

Energetics and work

- Method 1: Continuum energy bookkeeping is natural (ϕ, $\partial_T\phi$, $\nabla_{\mathbf{X}}\phi$). Mapping to radial per-hit work needs careful averaging and alignment with the EOM.
- Method 2: Exact potentials in free space; gradients give acceleration contributions; care is needed near $|1 - \mathbf{n} \cdot \mathbf{V}_t/c_f| \to 0$ geometries.
- Method 3: Energetics are tested via η-mollified potentials Φ_η and work–energy residuals on resolved windows. An impulsive $\eta \to 0$ claim requires a separate weak-convergence result with stable root identity.

Numerical stability and well-posedness

- Method 1: CFL constraints; dispersion/reflection control needed; robust under regularized sources; well posed on grids.
- Method 2: Stable as an evaluation formula; computational issues concentrate in robust, multi-root solving and handling near-tangency Jacobians.
- Method 3: Event handling or η-regularization supplies a candidate numerical chart. Well-posedness still requires the declared history class, root floors, continuation bounds, and regulator-refinement checks.

Computational scaling

- Method 1: Work and storage scale with grid volume, spatial resolution, duration, and the CFL-limited step count.
- Method 2: Work scales with receivers × sample times × transmitters × causal roots, plus the cost of root solving.
- Method 3: Work scales with receivers × transmitters × active roots per step and with retained-history reconstruction. Actual wall time and memory must be profiled for the declared implementation.

Boundaries, media, and heterogeneity

- Method 1: Natural for comparison media and boundaries—modify effective coefficients such as $c_{\text{eff}}(\mathbf{X}, T)$, damping, and boundary data without changing the primitive wake speed c_f.
- Method 2: Natural only in homogeneous free space; complex media/boundaries require bespoke Green's functions.
- Method 3: Natural in free space. Media/boundaries need additional modeling (e.g., corridor-level effective rules); not PDE-native.

Observables and Inference

- Method 1: Full-field pictures aid intuition and corridor studies but obscure per-hit ambiguity without extra processing.
- Method 2: Clarifies causal timing and geometry at probes; good for inference templates and surrogate-location recasts.
- Method 3: Directly aligned with hit histories $\{A(T_k), L(T_k)\}$ and therefore the most direct substrate representation among these three options.

Summary (one line each)

- Method 1: Best for whole-field, media, and visualization; poorest fit to per-hit radial-only axioms without translation layers.
- Method 2: Best for exact, pointwise analysis of the scalar-wave surrogate in free space; useful for declared-normalization and sparsely sampled implementation checks.
- Method 3: Native choice for many-architrino and assembly dynamics under the canonical law.

Operational guidance — when to use which method

- Method 1 (PDE): use this for whole-field grid simulations, visualization, and complex media or boundaries; step the wave PDE forward with a smeared source term. Robust when a transmitter slows or stops.
- Method 2 (Path history integral): use this for closed forms, analytic insight, or sparse probe evaluation; enforce the path-history condition $T - T_t = \|\mathbf{X} - \mathbf{X}_t(T_t)\|/c_f$ and handle the geometric factor $1 - \mathbf{n} \cdot \mathbf{V}_t/c_f$ in evaluation; solve one root per observer-time pair in slow-motion, more if transmitters move fast.
- Method 3 (Event-driven canonical): use this for production many-body dynamics; find causal roots and sum per-hit W^{acc}/r^2 pushes; prefer η-mollified mode for smooth ODEs when needed.

Pros and cons (comparative)

Method 1 — Time-based PDE (wave equation)

- Pros
- Physically standard propagation at fixed speed c_f; expanding causal wake surfaces emerge automatically.
  - Robust on grids; handles inhomogeneous media, damping, and boundaries.
  - Good for full-field visualization and energy bookkeeping in continuum form.
- Cons
  - Computationally heavy for many-particle dynamics (3D grids, CFL constraints).
  - Requires careful numerics to avoid dispersion/reflection; mesh choices can bias results.
  - Mapping grid fields to the radial-only per-hit ODE can add another modeling layer.

Method 2 — Green's function (path-history integral)

- Pros
  - Exact for the declared scalar-wave comparison problem in homogeneous free space; no grid or time stepping for that surrogate field.
  - Makes causality explicit via path-history times; captures Doppler/Jacobian $1 - \mathbf{n} \cdot \mathbf{V}_t/c_f$ automatically.
  - Efficient for field evaluation at a few observation points; excellent for analysis and cross-checks.
- Cons
  - Requires root-finding for each receiver-time pair; multiple roots are possible when transmitters outrun wake surfaces.
  - Costly when many receivers and transmitters are present; bookkeeping grows quickly.
  - Needs careful handling near tangencies (small Jacobians) and in multi-hit/self-hit regimes.

Method 3 — Event-driven radial-transport + per-hit EOM (canonical)

- Pros
  - Directly implements the project's delayed, radial-only interaction law with constant emission cadence.
  - Natural support for self-hits and superposition; local $1/r^2$ weighting makes nearby coherent roots dominate once the far-field cutoff, screening, cancellation, or summation prescription is declared.
  - Numerically lightweight for particle dynamics; works cleanly with impulsive or mollified ODE integration.
- Cons

- Not derived from the scalar wave equation; global field-energy accounting is indirect (via mollified potentials).
- Must retain the transmitter-side factor and transmitter-side acceleration weight from the Master EOM; a reduced test harness that omits either one is a noncanonical approximation rather than a calibration of κ.
- Accuracy depends on robust causal-root finding and regularization choices in complex multi-hit scenarios.

Recommendation

- Use Method 3 as the primary engine for architrino and assembly dynamics. It directly implements radial-only action and constant emission cadence.
- Adopt Method 2 as an analytic comparison instrument for the scalar-wave surrogate. Fix normalization on the stationary-transmitter case, then verify that the moving-source Jacobian maps once, and only once, to W^{acc} under the declared observable map. Because both methods share that map, their agreement is implementation parity rather than an independent oracle.
- Baseline formula (stationary transmitter at origin): with $q(T) \equiv q_0$, $\phi(r,T) = \dfrac{q_0}{4\pi r}$ since the path-history condition selects $T_t = T - r/c_f$; if q varies, $\phi(r,T) = \dfrac{q(T - r/c_f)}{4\pi r}$.
- Reserve Method 1 for full-field studies (visualization, media, boundary effects) and for end-to-end tests of numerical stability; it is valuable but unnecessary for routine ODE-based assembly simulations.
- Keep the continuity-form wake definition and per-hit EOM as the canonical statement. Any density-to-potential comparison must declare the operator that maps the $1/r^2$ surface measure to the $1/r$ scalar surrogate, including normalization and boundary conditions.
- Numerical cautions:
  - Always smear $\delta(\mathbf{X} - \mathbf{X}_t)$ to a normalized kernel of width σ comparable to the grid spacing in PDE runs to avoid grid-scale artifacts.
  - Enforce CFL: choose ΔT so that $c_f\, \Delta T/\Delta X$ meets the stability bound for the chosen stencil to prevent instability.
  - Path history solving: solve $T - T_t = r(T_t)/c_f$ carefully; near $\|\mathbf{V}_t\| \approx c_f$, root finding and the factor $1 - \mathbf{n} \cdot \mathbf{V}_t/c_f$ require extra care.
  - Finite temporal thickness: if wake surfaces have duration, replace $\delta(T - T_t)$ with a smooth profile to model finite-width wavefronts.

Plain language: use the event-driven, radial-only method for dynamics, use the path-history integral to check the declared comparison map, and use the PDE when the calculation needs whole-field pictures or explicitly modeled comparison media.

Recap

- Model the transmitter through the source term $S(\mathbf{X},T) = q(T)\, \delta\big(\mathbf{X} - \mathbf{X}_t(T)\big)$ (time-based emission density).
- Method 1: easiest for grid-based whole-field runs; wake surfaces emerge at speed c_f.
- Method 2: exact path-history formula; contributions occur only when $T - T_t = \|\mathbf{X} - \mathbf{X}_t(T_t)\|/c_f$, with amplitude decaying as $1/(4\pi r)$ and a geometric $1 - \mathbf{n} \cdot \mathbf{V}_t/c_f$ factor in evaluation.

The comparison ends at propagation and acceleration-method selection. Particle-penetration, shielding, neutrino, photon, and dark-sector claims require their own assembly records and observer-level instruments; this method note does not assign those outcomes.

Sibling Derivation Notes

This note is the hub of the action-energy derivation set. The companion notes develop the individual pieces:

- Background and Simple Action and Analytic Baselines — starting point and closed-form checks.
- Causal Set and Delay Geometry and Delay Dynamics Energy — path-history geometry and its energy bookkeeping.
- Radial Attraction, Attraction, and Like-Polarity Symmetric Repulsion — signed two-body cases.

- Self-energy and Regularization Notes and Self-interaction Switch — self-hit handling.
- Superposition and Locality, Informational Ambiguity, and Receiver Velocity and Work — multi-source and receiver-side effects.
- Numerical Recipe and Stability, Units and Constants, and Well-posedness and Regularization — implementation and regulator discipline.

Analytic Baselines

Purpose:

- State the delay differential equations (DDEs) that govern canonical interactions under the delayed line-of-action law with transmitter-side acceleration weight.
- Record exact analytical solutions only where they exist; otherwise, state solvability status without approximations.

Models:

- Fixed center (one receiver, one stationary transmitter):
  - For unlike polarities, $\sigma_{qq'} = -1$. The causal root is explicit and $D_t = c_f$, so $W^{\mathrm{acc}} = 1$ independently of receiver velocity. The canonical radial equation is $\ddot{r} = -K/r^2$ with $K = \kappa|qq'| > 0$. This is an exact fixed-transmitter attraction baseline for the corrected delayed law.

- Two-body mutual interaction (opposite or equal charges):
  - Coupled DDEs with causal roots T_t defined by $|X_i(T) - X_j(T_t)| = T - T_t$ ($c_f = 1$); accelerations superpose as $\pm\kappa\epsilon^2 W^{\mathrm{acc}}/r^2$ along the line of action.
  - No exact closed-form solutions are presently known for the coupled DDEs in general.

Methodological priority:

- Treat the two-point-potential problem as the canonical first laboratory for the delayed theory.
- Any proposed energy, momentum, virial-like, or kinetic/potential closure claim should be checked here before being generalized to assemblies or Noether sea response arguments.
- In practice this means: solve the fixed-center and symmetric two-body cases first, then ask which familiar ODE identities survive, which acquire delay corrections, and which fail outright.
- For the nontrivial electrino:positrino binary, use the finite-η closure packet and canonical residual tuple owned by Binary Dynamics, together with the constructive residual definitions in Delay-Dynamics Energy. This document does not restate the tuple. Until every owned entry is computed on the same window, regulator, and branch chart, the binary remains an existence candidate rather than a validated closure result.
- The first constructive energy baseline for such a branch is the branch-local work reconstruction

$$U^{(\eta)}_{b,\mathrm{work}}(T) = U_b(T_*) - \int_{T_*}^{T} \sum_i \mu_{\mathrm{arch}}\, \mathbf{A}^{(\eta)}_{i,b}(T') \cdot \mathbf{V}_i(T')\, dT'$$

with the same replacement by $\mu_K(\|\mathbf{V}_i\|)$ when the primitive kinetic scalar is used. For a circular branch, the period-averaged integrand reduces to $\mu_{\mathrm{arch}} s_b \langle A^{\tan}_{\eta,b}\rangle_{P_b}$ in the quadratic proxy.

- The adiabatic consistency check is branch preservation under slow drift. Along a quasi-static path $\gamma : \lambda \mapsto (R(\lambda), s(\lambda), b)$ that does not cross a root-ledger threshold, the work-integral energy change should match the energy difference inferred from the neighboring solved branch family:

$$\Delta^{2\mathrm{B}}_{\mathrm{ad},E}(\gamma) = \frac{\left|\Delta_\gamma U^{(\eta)}_{b,\mathrm{work}} - \left(E^{(\eta)}_b(\lambda_1) - E^{(\eta)}_b(\lambda_0)\right)\right|}{\left|\Delta_\gamma U^{(\eta)}_{b,\mathrm{work}}\right| + \left|E^{(\eta)}_b(\lambda_1) - E^{(\eta)}_b(\lambda_0)\right| + \varepsilon}$$

Here $E_b^{(\eta)}(\lambda)$ denotes the candidate branch energy extracted at fixed λ by the same declared construction route. The test is valid only while the same signed causal-root ledger persists with positive Jacobian and inactive-root gap floors. A jump in the ledger is a bifurcation, not a failure of adiabatic energy consistency.

- Branch-virial theorem target: separate the kinematic virial identity from the stronger classical potential virial theorem. On a fixed finite-η branch chart b over an averaging window $W = [T_a, T_b]$, define the branch virial diagnostic

$$\mathcal{G}_b^{(\eta)}(T) = \sum_i \mu_{\text{arch}}\, \mathbf{X}_i(T) \cdot \mathbf{V}_i(T)$$

and the quadratic kinetic bookkeeping scalar

$$T_{\mu,b}^{(\eta)}(T) = \frac{1}{2} \sum_i \mu_{\text{arch}}\, \|\mathbf{V}_i(T)\|^2$$

Before the branch average is formed, retain the root-resolved virial rows

$$V_{i \leftarrow j, T_t}^{(\eta)}(T) = \mu_{\text{arch}}\, \mathbf{X}_i(T) \cdot \mathbf{A}_{i \leftarrow j}^{(\eta)}(T; T_t)$$

and the corresponding delivered-power rows

$$P_{i \leftarrow j, T_t}^{(\eta)}(T) = \mu_{\text{arch}}\, \mathbf{A}_{i \leftarrow j}^{(\eta)}(T; T_t) \cdot \mathbf{V}_i(T)$$

for every retained source/root hit $T_t \in \mathcal{C}_{ij,b}^{(\eta)}(T)$. The net virial term is then the ledger-preserving sum

$$\sum_i \mu_{\text{arch}}\, \mathbf{X}_i(T) \cdot \mathbf{A}_{i,b}^{(\eta)}(T) = \sum_i \sum_j \sum_{T_t \in \mathcal{C}_{ij,b}^{(\eta)}(T)} V_{i \leftarrow j, T_t}^{(\eta)}(T)$$

on the same active causal-root ledger used by the acceleration residual and energy crosswalk. Thus a small branch-virial residual is meaningful only after transmitter identity, polarity, emission time, Jacobian, transmitter-side acceleration weight, and receiver radial power have survived aggregation over the retained records.
When the branch is differentiable after mollification and the same signed causal-root ledger is retained, direct differentiation gives the finite-window identity

$$\left\langle 2T_{\mu,b}^{(\eta)} + \sum_i \mu_{\text{arch}}\, \mathbf{X}_i(T) \cdot \mathbf{A}_{i,b}^{(\eta)}(T) \right\rangle_W = \frac{\mathcal{G}_b^{(\eta)}(T_b) - \mathcal{G}_b^{(\eta)}(T_a)}{T_b - T_a}$$

The branch-virial closure target is the special bounded or periodic case in which the right-hand side is zero or below the declared tolerance:

$$\mathcal{R}_{\text{vir},b}^{(\eta)}(W) = \left| \left\langle 2T_{\mu,b}^{(\eta)} + \sum_i \mu_{\text{arch}}\, \mathbf{X}_i(T) \cdot \mathbf{A}_{i,b}^{(\eta)}(T) \right\rangle_W \right| \le \epsilon_{\text{vir}}$$

This is not yet the classical potential statement. The reduction to $\langle 2T - pU \rangle = 0$ additionally requires a branch-local potential $U_b^{(\eta)}$ whose scale variation is controlled by a homogeneity degree p,

$$U_b^{(\eta)}(\lambda \mathbf{X}) = \lambda^p U_b^{(\eta)}(\mathbf{X})$$

together with a proof that the same branch acceleration is generated by that potential over W. A scale/virial residual that contains zero is therefore diagnostic only until it supplies the same-domain scale generator, homogeneity degree, and branch coordinate needed for this stronger reduction.

- Velocity-regime scope for the branch-virial target:
  - Strict sub-field-speed branch windows are the closest to the classical comparison because nontrivial self-hit roots are excluded on the strictly sub-field-speed interval; delayed partner hits, transmitter-side factors, and transmitter-side acceleration weights still remain in the acceleration term.
  - Field-speed or near-field-speed windows are threshold-sensitive. They require an explicit Jacobian floor, inactive-root gap floor, and unchanged causal-root ledger before the virial residual is meaningful.
  - Super-field-speed history requires the retained self-hit and multi-root rows to be included in $\mathbf{A}_{i,b}^{(\eta)}(T)$. A speed label alone never certifies the branch; root existence, transversality, transmitter-side acceleration weight, and bounded endpoint virial drift do the work.
- Failure modes:
  - $\mathcal{G}_b^{(\eta)}$ has unbounded secular drift on W.
  - The causal-root ledger changes, an inactive-root gap closes, or the Jacobian floor fails.
  - Collision support or the $\eta \to 0$ limit is not controlled.
  - No branch-local potential, scale generator, or homogeneity degree is supplied, so the classical potential virial theorem has not been recovered.

Symmetric two-body on a line (exact DDE; challenges):

- Let $X_1(T) = +\frac{1}{2}r(T)$ and $X_2(T) = -\frac{1}{2}r(T)$ with $r(T) > 0$ and $c_f = 1$. The causal-time condition implies

$$\frac{r(T) + r(T_t)}{2} \;=\; T - T_t, \qquad T_t < T$$

or, writing $\Delta(T) = T - T_t > 0$ implicitly,

$$r(T) + r\big(T - \Delta(T)\big) \;=\; 2\,\Delta(T)$$

- For opposite polarities, the exact relative-coordinate equation is the state-dependent DDE

$$\frac{d^2 r}{dT^2} \;=\; -\,\frac{8\,\kappa\,\epsilon^2}{\big(r(T) + r(T - \Delta(T))\big)^2} W^{\mathrm{acc}}(T)$$

with $\Delta(T)$ determined by the implicit constraint above. For equal charges, the sign is reversed.

Integral (delta) form selecting the causal root:

- For particle 1 one may write

$$A_1(T) \;=\; -\,\kappa\,\epsilon^2 \int_0^\infty \frac{c_f\,\delta\big(|X_1(T) - X_2(T-\Delta)| - c_f\Delta\big)\,\mathrm{sgn}\big(X_1(T) - X_2(T-\Delta)\big)}{|X_1(T) - X_2(T-\Delta)|^2}\,d\Delta$$

whose evaluation selects the causal delay $\Delta(T)$. The delta change of variables contributes $c_f/|c_f - \hat{\mathbf{r}}\cdot\mathbf{V}_2(T-\Delta)| = W^{\mathrm{acc}}$ automatically. Multiplying by another W^{acc} after evaluating the integral would double-count the transmitter-side Jacobian.

Why closed-form solutions are unlikely (even with symmetry):

- The delay is state-dependent: the unknown $r(T)$ appears both in the right-hand side and in the implicit constraint defining $\Delta(T)$, making the problem a nonlinear functional equation rather than an ODE.
- Even linear constant-delay DDEs rarely admit elementary closed forms; state-dependent delays are generically non-integrable. The fixed-center problem is a special case that collapses to an ODE (see Radial Attraction).

Solution techniques (toolbox for delayed, radial DDEs):

- Method of steps (constant delays): for problems with fixed delay Δ and a given history $X(T) = \phi(T)$ on $T \in [-\Delta, 0]$, integrate an ODE on successive intervals, using the known past segment on each step.
- State-dependent delay root-tracking: treat $\Delta(T)$ as an algebraic unknown constrained by the causal-time equation (e.g., $r(T) + r(T - \Delta) = 2\Delta$). On each step, solve the coupled system with a Newton corrector for $\Delta(T)$; ensures consistency of the delay with the evolving state.
- Collocation / implicit Runge–Kutta with history interpolation: represent the recent history by Hermite/spline polynomials; at each step solve stage equations together with the causal constraint(s), updating a continuous extension of the history.
- Shooting and continuation for periodic motions: pose a boundary-value problem over one period with delay constraints; solve by Newton shooting or collocation and continue solutions via pseudo-arclength. Useful for detecting limit cycles and their stability.
- Spectral-in-time methods: on (quasi-)periodic windows, expand in Fourier/Chebyshev bases; constant delays enter as phase factors, while state-dependent delays are handled by iterating a frozen-delay linearization.
- Stability analysis (qualitative): Lyapunov–Krasovskii and Razumikhin functionals yield sufficient conditions for stability without solving trajectories; applicable to history classes with bounded delays.
- PDE embeddings (transport representation): introduce an auxiliary history field $Y(T, \theta)$ on $\theta \in [-\Delta_{\max}, 0]$ with $\partial_T Y + \partial_\theta Y = 0$ and boundary $Y(T, 0) = X(T)$; discretize in θ (method of lines). For state-dependent delays, use a moving boundary; aligns with the project's radial-transport perspective.
- Green's-function / hit-integral formulations: write per-hit actions as delta-weighted time integrals selecting causal roots; evaluate by robust root-finding and quadrature. This matches the event-driven law used here.
- Measure-driven/event-driven solvers with mollification: replace surface deltas by narrow Gaussians ($\eta > 0$) to obtain C^1 trajectories; take $\eta \to 0$ in the weak sense after validating work–energy over resolved windows.
- Linear constant-delay benchmarks: for linear DDEs (e.g., $dX/dT = aX + bX(T - \Delta)$) use Laplace transforms/characteristic equations and Lambert W; helpful for validation and step-size/error control, even though the canonical two-body problems here are nonlinear and state-dependent.
- A posteriori error control: use defect/residual of collocation, step halving with history re-interpolation, and event-time error estimates for adaptive step and tolerance selection.
- Fixed-point frameworks: establish local existence/uniqueness by contraction on history spaces $C([-\Delta T_{\max}, 0])$ (or their mollified variants); use Picard iterations as a solver preconditioner.

Deliverables:

- Precise DDE forms and causal-root conditions for use in analysis and computation.
- Cross-references to sections with receiver-side baseline equations and status notes.
- A minimal benchmark ladder for closure tests:
    - fixed-center ODE recovery,
    - symmetric two-body delayed dynamics,
    - finite-η two-body binary closure packet with branch floors and characteristic frequency extraction,
    - work-energy balance on resolved windows,
    - branch-virial residuals where periodic, quasi-periodic, or bounded-drift regimes exist.

Plain language: We give only the exact delayed equations; where an exact solution exists (fixed source), we present it, and where it does not (mutual interaction), we say so without approximations.

Attraction

Setup:

- Two architrinos with polarities $q_1 = -\epsilon$ and $q_2 = +\epsilon$.
- Initial velocities $V_1 \approx 0$, $V_2 \approx 0$; initial separation r_0 is large relative to the declared reference length and mollifier width.

- For all examples, we restrict motion to a single geometrical line.

Objectives:

- Delay-only formulation of the equations of motion (DDEs).
- Exact analytic solutions if available; otherwise, status of solvability.

Canonical delayed-law considerations:

- Delay enters through the implicit emission times T_t satisfying $|X_1(T) - X_2(T_t)| = T - T_t$ (and its counterpart).
- All per-hit actions are radial along the line of action and carry the transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$; $H(0) = 0$ excludes $T_t = T$.

Equations of motion (canonical delayed law; two-body, $c_f = 1$):

- Definitions:
  - Polarities: $q_1 = -\epsilon$ (particle 1), $q_2 = +\epsilon$ (particle 2); $\epsilon > 0$ is the polarity-unit magnitude.
  - Coupling: $\kappa > 0$ is the universal coupling constant; numerical instantiations use normalized wake-speed units with $c_f = 1$.
  - Separation: $r(T) = |X_1(T) - X_2(T)| > 0$.
- Causal (path-history) times:
  - $T_t^{(2\to1)} \in \mathcal{C}_2(T)$ solves $|X_1(T) - X_2(T_t)| = T - T_t$.
  - $T_t^{(1\to2)} \in \mathcal{C}_1(T)$ solves $|X_2(T) - X_1(T_t)| = T - T_t$.
- Per-particle accelerations (sum over all causal roots if multiple exist):

$$A_1(T) \;=\; \sum_{T_t \in \mathcal{C}_2(T)} -\kappa\,\epsilon^2\, W_{12}^{\mathrm{acc}}(T;T_t) \frac{\operatorname{sgn}\!\big(X_1(T) - X_2(T_t)\big)}{r_{12}^2}, \quad r_{12} = \big|X_1(T) - X_2(T_t)\big|$$

$$A_2(T) \;=\; \sum_{T_t \in \mathcal{C}_1(T)} -\kappa\,\epsilon^2\, W_{21}^{\mathrm{acc}}(T;T_t) \frac{\operatorname{sgn}\!\big(X_2(T) - X_1(T_t)\big)}{r_{21}^2}, \quad r_{21} = \big|X_2(T) - X_1(T_t)\big|$$

Here $\sigma_{q_2 q_1} = \sigma_{q_1 q_2} = -1$ (unlike polarities attract),
$W_{ab}^{\mathrm{acc}} = c_f/|D_{t,ab}|$ is the transmitter-side
acceleration weight on the corresponding root, $H(0) = 0$ excludes $T_t = T$, and
$\operatorname{sgn}(\cdot)$ denotes the sign function.

Relative-coordinate DDE:

- Define $r(T) = X_1(T) - X_2(T) > 0$. Then
  $s_{12}(T;T_t) = X_1(T) - X_2(T_t)$ and
  $s_{21}(T;T_t) = X_2(T) - X_1(T_t)$ are the signed delayed separations, with
  $r_{12} = |s_{12}|$ and $r_{21} = |s_{21}|$. Subtracting the two
  per-particle rows gives

$$\frac{d^2 r}{dT^2} \;=\; A_1(T) - A_2(T) \;=\; -\kappa\,\epsilon^2 \sum_{T_t \in \mathcal{C}_2(T)} W_{12}^{\mathrm{acc}}(T;T_t) \frac{\operatorname{sgn}\!\big(s_{12}(T;T_t)\big)}{r_{12}^2} + \kappa\,\epsilon^2 \sum_{T_t \in \mathcal{C}_1(T)} W_{21}^{\mathrm{acc}}(T;T_t) \frac{\operatorname{sgn}\!\big(s_{21}(T;T_t)\big)}{r_{21}^2}$$

with the two absolute distances fixed by their respective causal-root
conditions. For an ordered symmetric history with $X_1 > 0 > X_2$, the first
signed separation is positive and the second is negative, so both displayed
terms are negative and the instantaneous separation accelerates inward.
No exact closed-form solution is presently known for the coupled DDE system.

Nonlinear history-anchored form (vector notation for clarity):

$$\mathbf{A}_1(T) \;=\; -\,\kappa\,\epsilon^2\,W^{\rm acc}_{12}\,\frac{\mathbf{X}_1(T)-\mathbf{X}_2\big(T_t^{(2\to1)}\big)}{\big\|\mathbf{X}_1(T)-\mathbf{X}_2\big(T_t^{(2\to1)}\big)\big\|^3},\qquad \mathbf{A}_2(T) \;=\; -\,\kappa\,\epsilon^2\,W^{\rm acc}_{21}\,\frac{\mathbf{X}_2(T)-\mathbf{X}_1\big(T_t^{(1\to2)}\big)}{\big\|\mathbf{X}_2(T)-\mathbf{X}_1\big(T_t^{(1\to2)}\big)\big\|^3}$$

The attachment points are the partners' path-history locations at their respective causal emission times; linearizations and small-parameter expansions are intentionally omitted.

Central-origin kinematics (1D positions and velocities; symmetric two-body frame)

- Choose a fixed origin at the geometric midpoint. With equal-magnitude charges and symmetric initial data, this midpoint remains at rest by symmetry.
- Define the separation

$$r(T) \equiv X_1(T) - X_2(T) > 0$$

Positions relative to the central origin are then

$$X_1(T) = \tfrac{1}{2}\,r(T), \qquad X_2(T) = -\,\tfrac{1}{2}\,r(T)$$

- Velocities follow by differentiation:

$$V_1(T) = \frac{dX_1}{dT} = \tfrac{1}{2}\,\frac{dr}{dT}, \qquad V_2(T) = \frac{dX_2}{dT} = -\,\tfrac{1}{2}\,\frac{dr}{dT}$$

- Symmetric initial conditions (example):

$$X_1(0) = \tfrac{r_0}{2}, \quad X_2(0) = -\tfrac{r_0}{2}, \quad V_1(0) = V_2(0) = 0$$

Deliverables:

- Exact DDE statements and causal-root definitions suitable for analysis and computation.
- Solvability status: no known closed-form solution; numerical integration requires robust root-finding and event-aware stepping.

Plain language: Start very far apart and nearly at rest—motion remains on the initial line. Delay enters through the partner's past position via the causal-time condition; there is no sideways component in this example.

Background and Simple Action

The dynamics of an architrino are governed by a simple action: acceleration occurs when the receiver intersects a delayed causal wake surface emitted by a transmitter architrino.

The background is fixed absolute time times Euclidean space. Free paths are straight. Accelerations come only from delayed causal hits, with line-of-action direction and transmitter-side acceleration weight, never from background curvature.

Dynamical Geometry

- Background kinematics (Newton-Cartan/Galilean):
  - The arena is absolute time × Euclidean space, $\mathcal{M} = \mathbb{R} \times \mathbb{R}^3$, with simultaneity slices $\Sigma_T = \{T\} \times \mathbb{R}^3$ carrying the flat spatial metric $h_{ij} = \delta_{ij}$.
  - "Geodesics are straight" means: in the absence of any interaction, a worldline $\mathbf{X}(T)$ satisfies $\mathbf{A}(T) = d^2\mathbf{X}/dT^2 = \mathbf{0}$; motion is uniform and rectilinear in each slice Σ_T. The fixed background contributes no acceleration.
- Wake geometry as a continuous causal flux:

- Each architrino streams potential continuously. At any reception time T_r, the contribution emitted at past time T_t sits on the **causal wake surface** (spherical isochron) $r = c_f(T_r - T_t)$ centered on $\mathbf{X}(T_t)$, with surface density $\propto 1/r^2$ so the integrated flux remains q.
- The potential wake is the superposition of all such causal isochrons from past emissions. The flux never shuts off; the surfaces are bookkeeping devices isolating portions of the path history whose intersection with a receiver delivers acceleration.

- Intersection as the driver of acceleration:
  - The receiver's worldline is $\mathbf{X}_{o'}(T_r)$. An intersection at reception time T_r means some earlier emission time $T_t < T_r$ satisfies the causal-distance condition

$$\|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\| = c_f(T_r - T_t)$$

```
That event is a causal hit from transmitter $o$'s emission event to the receiver's reception event.
```

- At a hit, the acceleration impulse is directed along

$$\hat{\mathbf{r}} = \frac{\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)}{\|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\|}$$

```
No cross products or right-hand-rule terms appear; the action is collinear with $\hat{\mathbf{r}}$. Its magnitude is weighted by the transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$: $D_t$ captures transmitter-side wake spacing and root transversality, while $D_r$ captures how the receiver cuts through that wake sequence.
```

- "Simple action" in precise terms:
  - The law is event-driven: acceleration is a sum of per-hit line-of-action contributions, each scaled by W^{acc}/r^2. Between hits (as $\eta \to 0$) motion is inertial; with mollification ($\eta > 0$) the impulses become short, smooth pushes.
  - The background adds no acceleration; departures from straight motion arise only from these intersections with emitted causal wakes, including self-hits when the causal-root and branch conditions allow.

- Physical picture:
  - Picture many continuously expanding wake surfaces (causal isochrons). An acceleration contribution occurs whenever one of those surfaces intersects the receiver, directed straight along the radius back to its emission point, with inverse-square geometric decay multiplied by the transmitter-side acceleration weight. Receiver crossing rate belongs to root playback and does not multiply that arriving contribution.

Causal Set and Delay Geometry

The receiver o' at reception time T_r interacts with transmitter o through the possibly multi-valued set of causal emission times

$$\mathcal{C}_o(T_r) = \{\, T_t < T_r \mid \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\| = T_r - T_t \,\}$$

Local sub-field-speed transversality guarantees a unique smooth root branch near a given root. It does not by itself make the global set $\mathcal{C}_o(T_r)$ a singleton. Global uniqueness follows when $\|\mathbf{V}_o(T_t)\| < c_f$ throughout the entire searched history interval; histories that reach or exceed c_f may admit folds or multiple solutions, including self-hits when $o' = o$.

Clarification: "Multi-valued" means that, for a fixed reception time T_r, there can be more than one emission time T_t that satisfies the causal-distance condition. This multiplicity requires the transmitter history to reach or exceed field speed somewhere on the searched interval; tangency can occur at equality. If $\|\mathbf{V}_o\| < c_f$ everywhere on that interval, $F(T_t; T_r)$ is strictly increasing in T_t and the causal root is unique.

Terminology note: the `causal set` in this simulation note is the causal interaction set $\mathcal{C}_o(T_r)$: a set of delayed emission times that reach a receiver at reception time T_r. It is not Causal Set Theory, the external quantum-gravity program that treats discrete spacetime events and partial order as fundamental. That outside program remains useful as a comparison for causal ordering and continuum emergence, but the substrate object here is a path-history root set inside absolute timespace.

Geometry of Delay and Roots

- Root condition as an expanding causal isochron intersection:
  - Define $F(T_t; T_r) \equiv \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\| - c_f(T_r - T_t)$. Numerical runs use $c_f = 1$. Causal roots satisfy $F(T_t; T_r) = 0$ with $T_t < T_r$ and $H(T_r - T_t)$.
- Geometrically: the transmitter point $\mathbf{X}_o(T_t)$ must lie on the causal wake surface (isochron) of radius $\Delta = T_r - T_t$ centered at the receiver's reception position $\mathbf{X}_{o'}(T_r)$.
- Local uniqueness (sub-field-speed, transverse crossing):
  - If the transmitter speed is locally sub-field-speed and the derivative $\partial_{T_t} F(T_t; T_r) = c_f - \hat{\mathbf{r}} \cdot \mathbf{V}_o(T_t)$ is nonzero at the root, then the implicit function theorem guarantees a unique, smooth root branch near T_r.
  - Intuition: the expanding causal isochron intersects the moving transmitter path transversely.
- Multiple roots (require super-field-speed):
  - When $\|\mathbf{V}_o\| \geq c_f$ at some emission times, the transmitter history can develop tangencies or outpace recent wake surfaces, allowing several distinct historical points to satisfy the same distance-time constraint. If $\|\mathbf{V}_o\| < c_f$ everywhere on the searched interval, $F(T_t; T_r)$ is strictly increasing in T_t, so at most one causal root exists.
- Conventions at singular cases:
  - We adopt $H(0) = 0$ so the instantaneous emission at $T_t = T_r$ does not produce an immediate self-kick.
  - No $r = 0$ causal roots beyond $\Delta = 0$: because $r = c_f(T_r - T_t)$, $r = 0$ implies $\Delta = 0$; the $\Delta = 0$ case is excluded by $H(0) = 0$. Under mollification, any claimed symmetric $r \to 0$ limit must be verified for the declared kernel and geometry.

Plain language: a receiver is accelerated only by earlier transmitter events whose causal isochrons pass through it at reception time T_r. Usually there is one such event; if the transmitter is very fast or its path loops around, there can be several.

Non-technical visualization — outrunning your own wake (speedboat analogy):

- Picture a speedboat continuously laying down circular wake ridges that spread outward across the water at a fixed wave speed c_w (analogy variable: wake ridge expansion speed). If the boat stays slower than c_w, it remains inside its newest ridge and will never meet it again, no self-hits. Once the boat exceeds c_w, it moves ahead of its freshest ridge. Later, if it curves or slows, it can run into older ridges it created earlier. Each crossing delivers a brief shove normal to the ridge (straight outward from the ridge's center), mirroring the model's line-of-action push. The ridge "drop rate" never changes. Earlier transmitter motion bunches or dilates ridge spacing and therefore maps to the transmitter-side acceleration weight; receiver motion changes the order and rate at which the ridge history is replayed, not the strength of a ridge that has already arrived. This is an analogy: real Kelvin wakes are dispersive; we idealize to circular ridges expanding at one speed to match the model's fixed-speed causal isochrons.

Four self-hits in one maneuver (storyboard):

1. Sprint phase (exceed the field speed): The boat accelerates to a speed strictly greater than c_w and holds it for several ticks. During this super-speed run it lays down several concentric ridges that it immediately outruns.
2. Set up spacing: Maintain the super-speed for long enough to create at least four successive ridges with noticeable gaps (their radii grow at $c_w \cdot \Delta T$ while the boat advances faster than c_w).
3. Curving return: Bank into a broad, smooth turn (a teardrop/U-turn or a gentle outward spiral) that arcs back toward the track laid moments earlier.
4. Crossings: As the boat's curved path cuts across the expanding circles, it re-enters first the outermost of those recent ridges, then the next three in sequence. With a steady arc and timing, four distinct ridge crossings occur in quick succession—four self-hits. The shove at each crossing points straight away from the center of that ring (the boat's earlier position).
5. Tuning intuition: to make four hits likely, use a fast straight run ($|v| > c_w$) to lay multiple rings, then a wide-radius turn whose chord length is comparable to the ring spacing. Tighter loops and longer super-speed runs increase the chance of multiple crossings; without exceeding c_w, this multi-hit pattern cannot occur.

Delay Dynamics Energy

This chapter isolates the energy problem created by causal-delay dynamics. It is foundations-adjacent because it states what kind of energy object the substrate law is allowed to use before later chapters invoke conservation, no-runaway arguments, event ledgers, or Noether sea exchange.

The core warning is simple: time-translation invariance of a state-dependent delay equation does not by itself supply the familiar local Noether energy of finite-dimensional mechanics. In $\mathbb{AAA}$, any term written as E_{wake} must be constructed from the same causal-history law, regularization, branch chart, and boundary convention that generate the acceleration contribution. Otherwise it is a diagnostic label, not a conserved charge.

Energy Construction Problem

Fix a finite retained system over a time window $W = [T_a, T_b]$, a spatial window $\Omega \subset \Sigma_T$ when boundary flux is relevant, memory depth $H_{\mathrm{hist}} < \infty$, causal-surface width $\eta > 0$, optional core cutoff $\epsilon_c > 0$, and branch chart

$$\mathfrak{B}(\Gamma, \mathcal{S}; H_{\mathrm{hist}}, \eta, \epsilon_c)$$

for the same active causal-root rows used by the Master Equation. The retained history at time T is the segment

$$X_T = \{\mathbf{X}_a(T+\theta), \mathbf{V}_a(T+\theta), q_a : a \in A_\Omega,\ -H_{\mathrm{hist}} \le \theta \le 0\}$$

with any excluded rows, endpoint conventions, and boundary crossings recorded explicitly.
Here A_Ω is the retained architrino index set for the window, not a new kind of assembly.

A promoted delay-energy functional has the form

$$E^{(\eta)}_{\mathrm{delay}}[X_T; \mathfrak{B}, \Omega] = K^{(\eta)}_{\mu}(T) + E^{(\eta)}_{\mathrm{wake},\mathfrak{B}}(T) + E^{(\eta)}_{\mathrm{sea},\Omega}(T)$$

where $K^{(\eta)}_{\mu}$ is the declared mechanical kinetic bookkeeping proxy, $E^{(\eta)}_{\mathrm{wake},\mathfrak{B}}$ is the causal-history interaction contribution, and $E^{(\eta)}_{\mathrm{sea},\Omega}$ is included only when retained Noether sea degrees of freedom are part of the window. None of these terms is allowed to absorb an unreported boundary flux or unresolved reaction channel.

Observer-level gravitational potential energy is therefore a comparison construct, not a fourth primitive term. When a Newtonian or general-relativistic benchmark writes a gravitational-potential term, this chapter must not carry that term into an $\mathbb{AAA}$ action as a primitive. Over a declared window it has to be reconstructed on the same branch chart from the existing packet: $K^{(\eta)}_{\mu}$, $E^{(\eta)}_{\mathrm{wake},\mathfrak{B}}$, any retained $E^{(\eta)}_{\mathrm{sea},\Omega}$, and the boundary-flux row required by finite-window balance. Until that reconstruction is supplied, the gravitational potential remains an effective comparison label rather than an action-level energy.

Accepted Construction Routes

There are three admissible ways to define the wake-energy term. A calculation may use one route directly, but a theorem-level conservation claim must also state why the other routes are equivalent or irrelevant on the declared chart.

Action-Boundary Route

If a symmetry-preserving nonlocal action supplies the acceleration contribution, then the energy term is the time-boundary charge induced by absolute-time translation. With causal-delay interaction kernel $\mathcal{K}^{E}_{ij}(T_1, T_t)$ chosen by the same action as the acceleration residual,

$$E^{(\eta)}_{\mathrm{wake},\mathfrak{B}}(T) = \frac{1}{2}\sum_{i,j}\int_{-\infty}^{T} dT_t \int_{T}^{\infty} dT_1\, \partial_{T_1}\mathcal{K}^{E,\eta}_{ij,\mathfrak{B}}(T_1, T_t)$$

is the candidate in-flight causal-history charge. This is the route developed in Master Equation and Effective Lagrangian. It becomes theorem-level only when the same action also gives the accepted acceleration law and the endpoint leakage residual vanishes.

Work-Integral Route

For a realized trajectory, one may reconstruct a compatible interaction contribution by integrating the delivered power:

$$U_{\mathfrak{B}}(T) = U_* - \int_{T_*}^{T}\sum_i \mu_{\mathrm{arch}}\, \mathbf{A}^{(\eta)}_{i,\mathfrak{B}}(T')\cdot \mathbf{V}_i(T')\, dT'$$

This route is trajectory-local. It is useful for simulations and branch replay, but it is not an off-shell conserved charge unless the same action and boundary convention have already been declared.

Binary Branch Work Ledger

For a solved two-body branch chart b, the work-integral route has a concrete first test. Let $\mathbf{A}^{(\eta)}_{i,b}(T)$ be the acceleration contribution obtained from exactly the active causal roots retained by the binary branch chart. With the quadratic kinetic proxy, define the delivered branch power by

$$P^{(\eta)}_{b,\mathrm{work}}(T) = \sum_{i=1}^{2}\mu_{\mathrm{arch}}\, \mathbf{A}^{(\eta)}_{i,b}(T)\cdot \mathbf{V}_i(T)$$

The same row must also be available before superposition. For each retained source/root hit (i, j, T_t) on the branch chart, define the root-resolved delivered power

$$P^{(\eta)}_{i\leftarrow j,T_t}(T) = \mu_{\mathrm{arch}}\, \mathbf{A}^{(\eta)}_{i\leftarrow j}(T; T_t)\cdot \mathbf{V}_i(T)$$

so that

$$P^{(\eta)}_{b,\mathrm{work}}(T) = \sum_i\sum_j \sum_{T_t\in\mathcal{C}^{(\eta)}_{ij,b}(T)} P^{(\eta)}_{i\leftarrow j,T_t}(T)$$

on the same active causal-root ledger. This root-resolved form is the accounting guardrail: transmitter identity, polarity, emission time, Jacobian, and receiver radial power are retained before the net branch work is collapsed to one scalar. The work-integral route then reconstructs the compatible causal-history interaction contribution by

$$U^{(\eta)}_{b,\mathrm{work}}(T) = U_b(T_*) - \int_{T_*}^{T} P^{(\eta)}_{b,\mathrm{work}}(T')\, dT'$$

For a primitive kinetic scalar, replace μ_{arch} by $\mu_K(\|\mathbf{V}_i\|)$ inside the sum. This is the operational binary definition: the wake-history row is whatever balances the delivered branch work along the realized trajectory, after the window, regulator, and branch ledger have been declared.

On a circular benchmark with speed s_b, the radial component is orthogonal to the receiver velocity, so the branch power is the tangential row:

$$\left\langle P^{(\eta)}_{b,\mathrm{work}} \right\rangle_{P_b} = \mu_{\mathrm{arch}}\, s_b \left\langle A^{\tan}_{\eta,b} \right\rangle_{P_b}$$

for the quadratic proxy. A nonzero value is not by itself an energy-conservation failure; it is the quantity that the boundary flux, recoil row, or constructed wake-history term must balance. A stable binary claim must therefore compute this row on the same branch chart as the motion residuals before invoking a Noether-style conserved energy.

Boundary-Flux Route

For finite retained windows, missing energy must be routed to boundary exchange rather than hidden in E_{wake}. The finite-window balance target is

$$\frac{dE^{(\eta)}_{\Omega}}{dT} + \int_{\partial\Omega} \mathbf{J}^{(\eta)}_{E} \cdot \hat{\mathbf{n}}\, dA = P^{(\eta)}_{\mathrm{ext},\Omega} + \mathcal{R}^{(\eta)}_{E,\Omega}$$

where $\mathbf{J}^{(\eta)}_{E}$ records causal-wake escapement, assembly crossings, and declared medium exchange through the retained boundary. The flux term is not a new substrate field; it is the boundary part of the retained causal-history ledger.

Crosswalk Residual

The three routes must not define three different energies for the same branch. On any chart where more than one construction is available, use the crosswalk residual

$$\Delta^{(\eta)}_{\mathrm{E,cross}}(W;\mathfrak{B}) = \frac{\left|\Delta_W E^{(\eta)}_{\mathrm{wake,act}} - \Delta_W U_{\mathfrak{B}} - \Phi^{(\eta)}_{\partial\Omega,E}(W)\right|}{\left|\Delta_W E^{(\eta)}_{\mathrm{wake,act}}\right| + |\Delta_W U_{\mathfrak{B}}| + \left|\Phi^{(\eta)}_{\partial\Omega,E}(W)\right| + \varepsilon}$$

where $\Phi^{(\eta)}_{\partial\Omega,E}(W) = \int_W \int_{\partial\Omega} \mathbf{J}^{(\eta)}_{E} \cdot \hat{\mathbf{n}}\, dA\, dT$ is the declared boundary energy flux. The chart promotes only if $\Delta^{(\eta)}_{\mathrm{E,cross}} \to 0$ under the same refinement limit used for the acceleration residual.

Conservation Residual

Let $\mathbf{R}^{(\eta)}_{i}$ be the Euler or acceleration residual of the declared action-derived model, and let $\mathcal{B}^{(\eta)}_{E}$ collect endpoint leakage, period cuts, excluded self-coincidence boundaries, and omitted branch rows. The finite-window conservation residual is

$$\mathcal{R}^{(\eta)}_{E}(W;\mathfrak{B}) = \Delta_W \left(K^{(\eta)}_{\mu} + E^{(\eta)}_{\mathrm{wake},\mathfrak{B}} + E^{(\eta)}_{\mathrm{sea},\Omega}\right) - \int_W \sum_i \mathbf{V}_i \cdot \mathbf{R}^{(\eta)}_{i}\, dT - \int_W \mathcal{B}^{(\eta)}_{E}\, dT - W^{(\eta)}_{\partial\Omega}$$

The normalized diagnostic is

$$\epsilon^{(\eta)}_{E}(W;\mathfrak{B}) = \frac{\left|\mathcal{R}^{(\eta)}_{E}(W;\mathfrak{B})\right|}{\left|\Delta_W K^{(\eta)}_{\mu}\right| + \left|\Delta_W E^{(\eta)}_{\mathrm{wake},\mathfrak{B}}\right| + \left|\Delta_W E^{(\eta)}_{\mathrm{sea},\Omega}\right| + \left|W^{(\eta)}_{\partial\Omega}\right| + \varepsilon}$$

An exact isolated conservation claim requires $\epsilon^{(\eta)}_{E} \to 0$, $\Delta^{(\eta)}_{\mathrm{E,cross}} \to 0$ when applicable, and stable branch floors as η and the numerical/history-window resolution are refined.

No-Double-Counting Rule

The interaction contribution may be carried by E_{wake}, by an equivalent work-integral reconstruction, or by an explicitly retained near-field decomposition, but not by all of them at once. If a pairwise U_{int} term is used inside an assembly, the wake-energy term must omit the same near-field content. If a Noether sea update is retained inside $E_{\mathrm{sea},\Omega}$, it must not also appear as an outgoing event-ledger channel. The same rule is used by Emergence and Energy.

Promotion and Failure Conditions

A delay-energy construction is promotable only when the branch chart names:

1. the retained history window h and memory truncation residual;
2. the causal-surface regularization η and any core cutoff ϵ_c;
3. active causal roots, inactive-root gaps, the active transmitter-side Jacobian floor, and the retained transmitter-side acceleration-weight floor or certified interval ν_{rec} for W^{acc};
4. the exact route used for E_{wake};
5. boundary flux, endpoint leakage, period-cut terms, and excluded self-coincidence rows;
6. the crosswalk residual whenever more than one energy construction is invoked;
7. the lower-bound condition needed for no-runaway arguments.

The construction fails if conservation is recovered only by changing the energy definition per observable, if $E^{(\eta)}_{\text{wake}}$ has no lower bound on the admitted chart, if endpoint leakage is silently discarded, if the regulator is not the same regulator used by the acceleration law, or if the branch chart loses its causal-root floors. In those cases E_{wake} remains a diagnostic placeholder and cannot be used to close energy bookkeeping, stability, or no-runaway claims.

Downstream Use

This chapter is the shared energy standard for Master Equation, Effective Lagrangian, Energy, Binary Dynamics, and event-ledger uses in Emergence. The two-body binary closure packet must report $\epsilon^{(\eta)}_E(W;\mathfrak{B})$, $\Delta^{(\eta)}_{\text{E,cross}}(W;\mathfrak{B})$, and the lower-bound entry on the same branch chart as its motion, branch-floor, stability, and frequency residuals. Existence and stability are not enough unless the accepted branch also carries a constructive energy ledger.

Informational Ambiguity

From the perspective of the receiving architrino, the information carried by an intersecting causal wake surface is limited. The receiver-local dynamical record contains two direct facts:

1. The net strength of the potential at the point of intersection.
2. The signed acceleration vector $\mathbf{A}$ at the receiver event.

The vector fixes the direction of the net acceleration. What it does not fix is the transmitter ray and polarity assignment that produced that vector. An attractive source on one ray and a repulsive source on the opposite ray can produce the same $\mathbf{A}$. Only after quotienting those source hypotheses does one obtain an unoriented inference axis; that axis is not the raw received datum.

Degeneracies and Inference Limits

- Many-to-one mapping:
  - Different combinations of transmitter identity, polarity magnitudes, distances, and emission timing/geometry can yield the same receiver-local magnitude and line-of-action record.
- Sign ambiguity across a line:
  - An attractive pull toward an opposite-polarity source on one ray is indistinguishable, at one receiver event, from a repulsive push by a same-polarity source on the opposite ray. If the receiver polarity flips, the physical source-polarity labels flip too; the invariant ambiguity is the exchange of side with attraction/repulsion.
- Consequence for reconstruction:
  - Instantaneous local data at the receiver are insufficient to invert for sources; this remains true even for an $\mathbb{U}_{\text{now}}$ universe-state perspective who knows the universal clock T and the Euclidean rest frame. The $\mathbb{U}_{\text{now}}$ universe-state perspective can eliminate coordinate uncertainty (perfect synchronization and alignment) but not the physical ambiguities below.
  - Irreducible ambiguities at an instant:

- Sign/side ambiguity: an attractive lift on one ray and a repulsive lift on the opposite ray can produce the same receiver-local acceleration record. With receiver polarity held fixed, this can be written as a side/polarity flip of the source; with receiver polarity flipped, the source-polarity labels interchange as well.
- Superposition along an axis: multiple sources aligned on either ray of the inference axis can sum to the same receiver-local acceleration vector at one instant, while their transmitter count, side distribution, and polarities remain hidden.
- Self-hit confound: a self-interaction and an external source can yield identical instantaneous data if they lie on the same line with compensating magnitudes.
- Super-field-speed self-history ambiguity: when same-transmitter delayed roots exist, the receiver-local event still reports an acceleration contribution, not the full past trajectory that produced it. The self-hit label must come from the retained causal-root ledger, not from the instantaneous vector alone.
- Continuum of surrogate locations: for any instantaneous hit there exists a continuum of stationary surrogate source positions on the two rays of the inference axis, with polarity chosen consistently and with a correspondingly adjusted emission time T_t, that reproduces the same instantaneous vector; hence instantaneous inversion is severely underdetermined.

- Surrogate-location recast:
  For one resolved line-of-action component at receiver event $R = (T, \mathbf{X}_{o'}(T))$, the receiver-local datum can be written as

$$D_R = (A_R, [\hat{\mathbf{u}}]), \qquad [\hat{\mathbf{u}}] = \{\hat{\mathbf{u}}, -\hat{\mathbf{u}}\},$$

```
where $A_R \geq 0$ is the net magnitude assigned to that component and $[\hat{\mathbf{u}}]$ is the unoriented axis through the receiver. A single surrogate lift chooses a side coordinate $\lambda \neq 0$, a stationary surrogate position, and a source polarity:
```

$$\mathbf{X}_{\text{sur}} = \mathbf{X}_{o'}(T) - \lambda \hat{\mathbf{u}}, \qquad \sigma_{\text{sur}} = \text{sign}(q_{\text{sur}} q_{o'}), \qquad \hat{\mathbf{r}}_\lambda = \text{sgn}(\lambda) \hat{\mathbf{u}}.$$

```
The surrogate contribution is
```

$$\mathbf{A}_{\text{sur}} = A_R \sigma_{\text{sur}} \hat{\mathbf{r}}_\lambda.$$

```
It is unchanged under
```

$$(\lambda, \sigma_{\text{sur}}) \sim (-\lambda, -\sigma_{\text{sur}}),$$

```
or, with receiver polarity fixed, by moving the surrogate to the opposite ray and flipping the surrogate source polarity. This recast is an inference device, not a claim that the original source inventory contained a single architrino.
```

- What helps (over time or with more views):
  - Track the time series of the line of action $\hat{\mathbf{r}}(T)$ and separation proxy $r(T)$ inferred from timing and geometry; curvature and rotation of $\hat{\mathbf{r}}$ constrain source trajectories.
  - Use multiple receivers (an array) to triangulate the unoriented inference axes obtained after the side/polarity quotient; intersecting rays at the same T narrow candidate locations while preserving the two-sided ambiguity.
  - Actively vary the receiver path to sample different directions and ranges, turning the inverse problem into a controlled experiment.
  - Impose priors: polarity inventories, speed bounds, and assembly templates reduce degeneracy space.

- Use surrogate-location recasts: for instantaneous hits, place a stationary surrogate source on either ray of the inference axis, choose the corresponding polarity, and adjust the emission time; this simplifies hypothesis testing without altering per-wavefront amplitude.
- Use solver-side quotient diagnostics: collapse exact branch contributions into receiver-local line bins, compare the bin to a one-surrogate representative, and treat the result as lossy compression. The quotient may help inverse-problem tests, noisy-background compression, and residual diagnosis, but it cannot replace retained causal-root ledgers because it discards transmitter count, side, polarity, emission time, transmitter velocity, and Jacobian data.

- Absolute-observer note: Access to absolute time and a common Euclidean frame enables global correlation of events across receivers, but unique inversion at an instant would require hidden information (the full emission ledger $\{(T_t, \mathbf{X}_j(T_t), q_j, \mathbf{V}_j(T_t))\}_j$). Practical reconstruction is therefore necessarily temporal, statistical, and multi-view.

Plain language: a hit reports magnitude and line of action, not transmitter identity or distance. Many different source histories can fit the same momentary push. A null action at an instant conveys no information about sources; superposition can cancel perfectly even in a non-empty universe.

Numerical Recipe and Stability

Event-aware integration (practical algorithm):

1. Root finding:
   - For each transmitter o (including $o' = o$ for potential self-hits), solve $F(T_t; T_r) = \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\| - (T_r - T_t) = 0$ for $T_t < T_r$.
   - Discard non-physical roots by convention $H(0) = 0$ (exclude $\Delta T = 0$); note $r = 0$ occurs only at $\Delta T = 0$ and is thus excluded.

2. Per-hit accumulation:
   - For each accepted root, compute r, $\hat{\mathbf{r}}$,
     $D_t = 1 - \mathbf{V}_o(T_t) \cdot \hat{\mathbf{r}}$,
     $D_r = 1 - \mathbf{V}_{o'}(T_r) \cdot \hat{\mathbf{r}}$, and
     $W^{\text{acc}} = c_f / |D_t|$. Then use

$$\mathbf{A}_{o' \leftarrow o}(T_r; T_t) = \kappa\, \sigma_{q_o q_{o'}} \frac{|q_o q_{o'}|}{r^2} W^{\text{acc}}\, \hat{\mathbf{r}}$$

- Sum over all transmitters and all roots (superposition).

3. Time stepping:
   - Impulsive mode: advance velocities with jumps at hit times (measure-driven ODE with velocity of bounded variation).
   - Mollified mode: replace $\delta(\cdot)$ by $\delta_\eta(\cdot)$ and integrate with a delayed-history solver or an augmented-state method that retains the required path segment; choose η small relative to local geometric scales.

4. Stability tips:
   - Use event bracketing or root trackers for continuity of $T_t(T)$ across steps.
   - Limit step size so that at most one (or a controlled number of) mollified wake surfaces overlap significantly per step.
   - Monitor invariants over resolved windows (work–energy balance with Φ_η) to validate settings.

5. Units:

- Use $c_f = 1$ nondimensionalization throughout. Remember: emission cadence and per-wavefront amplitude are constant; receiver speed enters signed root playback through D_r/D_t and instantaneous power through v_r, not the acceleration weight.

6. Two-body closure run packet:
   - For a candidate electrino:positrino binary, emit the signed branch ledger b, regulator η, step or collocation scale ΔT_{step}, candidate period P_b, and the canonical residual tuple owned by Binary Dynamics. This recipe does not define a second tuple or field order.
   - Do not advance the candidate if the signed ledger changes during the reported period, an active transmitter-side Jacobian floor or inactive-root gap vanishes, the transmitter-side acceleration weight leaves its certified interval or its floor $\nu_{\text{rec}}^{2\text{B}}$ vanishes, the projected return-map spectrum is not computed, the energy residuals use a different window or branch chart than the motion residuals, or the extracted frequency is not stable under refinement.
   - Treat a visually periodic orbit without these entries as a search hit only. It is not a binary closure certificate.

Plain language: At each reception time, find which past emissions can reach the receiver, compute how the transmitter laid down the wake and how the receiver crosses it, sum the radial acceleration contributions with W^{acc}/r^2 strength, and step forward either with sharp kicks at exact hit times or with thin mollified wake surfaces for smooth integration.

Radial Attraction

Setup:

- A test architrino with polarity q' falls radially toward a fixed center with polarity q.
- Attraction requires unlike polarities, so $\sigma_{qq'} = -1$.
- The fixed transmitter has a unique causal emission time. Its transmitter-side factor is $D_t = c_f$, so receiver radial velocity does not multiply the arriving acceleration.

Objectives:

- Receiver-side baseline equations for $r(T)$ and $V_r(T)$.
- Energy balance and integral expressions suitable for comparison.

Delay equation and exact reduction:

- With field speed normalized to $c_f = 1$ and a fixed transmitter location X_c, the causal root satisfies $|X(T_r) - X_c| = T_r - T_t$ with $T_t < T_r$.
- The per-hit law yields a line-of-action acceleration whose magnitude depends on the current separation $r(T) = |X(T) - X_c|$ and the transmitter-side acceleration weight:

$$\frac{d^2X}{dT^2} = \kappa\,\sigma_{qq'}\,\frac{|qq'|}{r(T)^2}W^{\text{acc}}(T)\,\operatorname{sgn}\bigl(X(T) - X_c\bigr)$$

With $\sigma_{qq'} = -1$, writing $K = \kappa\,|qq'| > 0$ and $r = |X - X_c|$, the radial ODE is

$$\frac{d^2r}{dT^2} = -\frac{K}{r(T)^2}W^{\text{acc}}(T), \qquad W^{\text{acc}}(T) = 1$$

in field-speed units.

Solvability status:

- The fixed-transmitter case reduces exactly to the inverse-square radial equation. Its mathematical closed forms are therefore valid comparison cases for the trajectory once initial conditions are declared.
- This does not establish a conserved Master-Equation energy account; it establishes only the reduced acceleration equation for this fixed-transmitter geometry.

Notes:

- For a fixed transmitter, $D_t = 1$ and $W^{\text{acc}} = 1$ in field-speed units. The receiver-side factor $D_r = 1 - dr/dT$ controls signed root playback, and radial velocity controls instantaneous power.

Use:

- An analytic fixed-transmitter check that must remain invariant when receiver velocity is varied at fixed reception position and retained transmitter history.

Plain language: At the same position and against the same fixed transmitter history, two receivers with different velocities get the same arriving acceleration. Their later paths and the rate at which they replay emission history differ.

Receiver Velocity and Work

Because $\mathbf{A}_{o' \leftarrow o}(T_r; T_t) \parallel \hat{\mathbf{r}}$, a single hit changes only the velocity component along its instantaneous line of action:

$$\frac{d}{dT_r}\mathbf{V}_\perp\Big|_{\text{this hit}} = \mathbf{0}, \qquad \frac{d}{dT_r}V_r\Big|_{\text{this hit}} = \mathbf{A}_{o' \leftarrow o}(T_r; T_t) \cdot \hat{\mathbf{r}} = \frac{\kappa\, \sigma_{q_o q_{o'}}\, |q_o q_{o'}|}{r^2} W^{\text{acc}}_{o' \leftarrow o}(T_r; T_t)$$

Decomposition and Energetics

- Decomposition at a hit:
  - Write $\mathbf{V} = V_r\,\hat{\mathbf{r}} + \mathbf{V}_\perp$, where $V_r = \mathbf{V} \cdot \hat{\mathbf{r}}$ and $\mathbf{V}_\perp \cdot \hat{\mathbf{r}} = 0$.
  - A single hit changes V_r but not $\mathbf{V}_\perp$ instantaneously.

- Power and work:
  - The signed instantaneous acceleration-power proxy is
    $\mathbf{A} \cdot \mathbf{V} = (\mathbf{A} \cdot \hat{\mathbf{r}})V_r$.
    It reduces to $\|\mathbf{A}\|V_r$ only for a repulsive contribution directed along $+\hat{\mathbf{r}}$; an attractive contribution carries the opposite sign.
  - For the specific kinetic proxy $K_{\text{spec}} = \frac{1}{2}\|\mathbf{V}\|^2$, the per-hit rate is $dK_{\text{spec}}/dT = \mathbf{A} \cdot \mathbf{V}$. An energy-valued bookkeeping row must instead declare the universal conversion μ_{arch} and use $K_\mu = \frac{1}{2}\mu_{\text{arch}}\|\mathbf{V}\|^2$, so $dK_\mu/dT = \mu_{\text{arch}}\mathbf{A} \cdot \mathbf{V}$.
  - Orthogonal motion contributes no instantaneous acceleration power. A fixed-transmitter benchmark may identify the radial integral with a potential-energy change, but moving-transmitter, self-hit, and open-boundary histories require the constructive wake/history and boundary terms in Delay Dynamics Energy.

- Local trend via $1/r^2$:
  - If $V_r < 0$ (moving inward), near-future hits tend to be stronger because r shrinks between events; if $V_r > 0$, they tend to weaken.

Plain language: Each hit changes only the along-the-line speed at that event; sideways speed is untouched by that contribution. The signed specific-power row follows directly from acceleration and velocity, while an energy claim additionally needs the declared bookkeeping conversion and the applicable history-aware energy construction.

Repulsion

Setup:

- Two identical-polarity architrinos (for example, $q_1 = q_2 = +\epsilon$) placed at separation r_0 with $V_1 = V_2 = 0$ and symmetry about the midpoint.

Objectives:

- Delay-only formulation of the equations of motion (DDEs).

- Exact analytic solutions if available; otherwise, status of solvability.

Delay differential equations (two-body, $c_f = 1$):

- Causal times:
    - $T_t^{(2\to1)} \in \mathcal{C}_2(T)$ solves $|X_1(T) - X_2(T_t)| = T - T_t$.
    - $T_t^{(1\to2)} \in \mathcal{C}_1(T)$ solves $|X_2(T) - X_1(T_t)| = T - T_t$.
- Accelerations (sum over all causal roots if multiple exist):

$$A_1(T) \;=\; \sum_{T_t \in \mathcal{C}_2(T)} +\kappa\,\epsilon^2\,W_{12}^{\mathrm{acc}}(T;T_t)\frac{\operatorname{sgn}\big(X_1(T) - X_2(T_t)\big)}{r_{12}^2}, \quad r_{12} = \big|X_1(T) - X_2(T_t)\big|$$

$$A_2(T) \;=\; \sum_{T_t \in \mathcal{C}_1(T)} +\kappa\,\epsilon^2\,W_{21}^{\mathrm{acc}}(T;T_t)\frac{\operatorname{sgn}\big(X_2(T) - X_1(T_t)\big)}{r_{21}^2}, \quad r_{21} = \big|X_2(T) - X_1(T_t)\big|$$

- W_{12}^{acc} and W_{21}^{acc} are the corresponding transmitter-side acceleration weights. A root with a failed transmitter-side floor is a branch-transition or caustic case, not an ordinary stable row of this two-body DDE.
- Because the two line-of-action signs are opposite, symmetry implies $X_1(T) = -X_2(T)$ and $A_1(T) = -A_2(T)$ for all T given symmetric initial data.

Solvability status:

- No exact closed-form solution is presently known for the coupled DDE system under mutual repulsion with delay.

Deliverables:

- Exact DDE statements and causal-root definitions suitable for analysis and computation.
- Notes on symmetry and qualitative properties without invoking approximations.

Plain language: Two like polarities at rest push apart along the line under the delayed law; the governing equations are implicit in the causal times, and no closed-form solution is currently known.

Self-Energy

Purpose: explain why classical “point-charge self-energy” divergences do not arise in this framework, and summarize the role of measure-valued causal surfaces, the $H(0) = 0$ convention, and η-mollification.

Classical self-energy pathology (contrast)

In classical electrostatics, a static $1/r$ potential yields an electric field $\mathbf{E} \propto 1/r^2$ with energy density proportional to $\|\mathbf{E}\|^2 \propto 1/r^4$. Integrating $1/r^4$ over a ball produces a divergent $\int (1/r^2)\,dr$ near $r \to 0$, the textbook “infinite self-energy of a point charge.” This is an artifact of modeling the source as an enduring, everywhere-filled near field.

Why the zero-radius divergence is quarantined here

This project does not posit a static near field. Instead:

- Measure-valued expanding causal surfaces (no static $1/r$ near field):
    - Each emission is a razor-thin causal isochron with surface density $q/(4\pi r^2)$, represented by $\rho(T, T_t) = (q/(4\pi r^2))\delta(r - c_f\Delta)H(\Delta)$. The support at fixed T is a causal wake surface S_r, not a three-dimensional $1/r^2$ fill down to $r = 0$. See Background and Simple Action.
- $H(0) = 0$ (no coincident self-kick):
    - The instantaneous emission ($\Delta = 0$) contributes no acceleration to the transmitter; $r = 0$ roots beyond $\Delta = 0$ do not exist because $r = c_f(T_r - T_t)$. This removes the only event where a literal $r = 0$ could enter. See Causal Set and Delay Geometry.

- η-mollification (finite, well-defined work over resolved windows):
  - Replace $\delta(r - c_f\Delta)$ by a narrow Gaussian δ_η with width $\eta > 0$ when differentiability is required. Potentials Φ_η and the corresponding potential-gradient bookkeeping variables are then regular functions. On a fixed-transmitter benchmark, a promoted run must test, rather than assume, the resolved-window identity
    $\Delta E_k = -\Delta U$, with $U = q'\Phi_\eta$,
    together with boundedness and regulator refinement. A moving-transmitter or self-hit branch instead requires the history-aware energy construction in Delay Dynamics and Energy; a local potential difference alone does not close its wake and boundary exchange. An $\eta \to 0$ claim requires weak convergence of the promoted integrals and stable causal-root identity; mollification alone does not prove that limit. See Well-posedness and Regularization.
- Event-driven geometry (self-hits occur at $r > 0$):
  - A super-field-speed history interval is necessary for simple nontrivial self roots, but the accepted channel additionally requires a same-transmitter causal root, positive separation or declared core regularization, and retained branch floors. On such a chart, self-hits occur at $r > 0$ and yield finite W^{acc}/r^2 contributions. The chart does not establish a global absence of short-distance or regulator-limit divergences.

Net effect: within a declared admissible finite-η branch chart, the canonical ontology does not include the static near-field integral that generates the classical point-charge divergence. The narrower result is a quarantine, not a global finiteness theorem: a failed branch floor, core convention, window limit, or $\eta \to 0$ convergence test still blocks promotion.

Practical guidance (numerics and analysis)

- Choose η small relative to local geometry (path curvature radius, inter-transmitter spacing) for smooth delayed-history integration. Use $\Delta E_k = -\Delta U$ only for the declared fixed-transmitter benchmark; use the history-aware ledger for general branches.
- Fix comparison normalization on an independently known stationary-transmitter baseline. Agreement between the Green-function surrogate and event-root implementation is parity evidence and does not calibrate away the canonical transmitter-side acceleration weight.
- Treat self-hits as finite-r events only after their root and branch floors pass; ensure $H(0) = 0$ in implementation to exclude coincident-time artifacts.

Sign-resolved bookkeeping

An additional numerical caution is worth stating explicitly: a Noether sea region or assembly may carry a large internal action budget even when its coarse far-wake potential appears weak.

- Positive and negative sectors can superpose so that the net far-field potential is small.
- That cancellation does **not** imply the underlying kinetic work or stored interaction content is individually small in each sector.
- For this reason, diagnostics should track sign-resolved contributions whenever possible rather than relying only on net-potential summaries.

This matters especially for shielding claims. A strongly shielded assembly may look energetically modest from afar while still containing substantial internal positive/negative activity whose cancellation is only effective after superposition. Sign-resolved ledgers therefore help distinguish true low-energy states from high-content states hidden by cancellation.

Plain language: We do not keep a permanent $1/r$ field attached to an architrino. Thin expanding causal surfaces and the $H(0) = 0$ endpoint rule remove the classical static self-energy construction from the admitted chart, while finite-width and zero-width limits still have to pass their own boundedness and convergence tests.

Self-Interaction Switch

An architrino can intersect an expanding causal isochron that it emitted earlier in its own history. Self-hit occurs when the same-transmitter causal-root set is nonempty, $\mathcal{C}_{aa}(T_r) \neq \varnothing$. Super-field-speed history is a necessary warning condition for simple nontrivial roots, but it is not sufficient by itself; curvature, branch geometry, and the transversality floor determine whether the worldline actually intersects its own causal wake, and an admitted self-hit contribution additionally carries a retained transmitter-side acceleration weight W^{acc}. The like-polarity self-hit contribution is repulsive. On the uniform-circular chart its radial projection is always outward, so it can oppose collapse but cannot supply centripetal support; stability belongs to the complete signed branch ledger.

Conditions and Effects

- Root multiplicity and self-roots:
  - The simulation should open the self-hit channel only when it finds same-transmitter roots

$$\mathcal{C}_{aa}(T_r) = \{\, T_t < T_r : \|\mathbf{X}_a(T_r) - \mathbf{X}_a(T_t)\| = c_f(T_r - T_t) \,\}$$

```
A speed excursion above c_f flags a candidate interval; it is not an acceptance test without root
existence, a nonzero Jacobian/transversality margin, and a retained transmitter-side
acceleration weight.
```

- Coincident $r = 0$ contact is not an active same-transmitter hit. At $\Delta = 0$ the convention $H(0) = 0$ blocks instantaneous self-kicks, and for a coincident delayed candidate the unit line of action $\hat{\mathbf{r}}$ is undefined. The active channel begins with a nonzero-delay same-transmitter root that supplies direction, transversality, and the transmitter-side acceleration weight.

- Repulsive character:
  - For like-on-like (self) interaction, $\sigma_{q_a q_a} = +1$ ensures the self-contribution points outward along $+\hat{\mathbf{r}}$, opposing further collapse.

- Barrier and scale selection:
  - In binaries and multi-binary assemblies, delayed attraction competes with self-repulsion. On a closed branch chart, the outward self-hit barrier can participate in setting a minimal sustainable radius d_0, but the fastest natural frequency $2\pi/t_0$ additionally requires tangential and return-map closure.

Plain language: A fast interval can make self-hit possible, but the code must still solve the same-transmitter root equation and weight each accepted hit by its transmitter-side acceleration weight; only actual same-transmitter hits push outward and help set the smallest sizes and fastest rhythms of stable structures.

Superposition and Locality

Potential wake contributions from all sources superpose linearly. The net potential at any point is the sum of the individual contributions:

$$\Phi_{\mathrm{net}} = \sum_i \Phi_i$$

The total acceleration on an architrino at any instant is the vector sum of the contributions from every intersecting causal wake surface. Operationally, every architrino is continuously immersed in the superposed wakes of all others and, when the same-transmitter root condition permits, its own. Calculating the path-history integral requires isolating each causal emission event, evaluating the transmitter-side W^{acc}/r^2 acceleration kernel at that emission, and then summing under a declared finite active horizon, screening rule, cancellation argument, or summation prescription.

The simple rule is: add every causal wake contribution that actually reaches the receiver, but do not pretend that distance alone solves the infinite-background problem. A local simulation must say how far-field wakes are cut off, screened, canceled, summarized, or subtracted.

Why Nearby Wakes Dominate

Linear addition happens at the causal-surface level. Each source contributes a distribution supported on its causal wake surfaces, the total wake measure is a sum of those measures, and the acceleration law is linear in the summed contributions.

Locality comes from $1/r^2$ only after convergence control is declared. The surface density on each causal wake surface scales as $1/r^2$, so nearby coherent hits contribute disproportionately compared to distant ones. In an infinite three-dimensional source population this does not by itself guarantee convergence, because the number of sources in a radial layer grows like $r^2\,dr$. Random phases, angular cancellation, screening, finite active horizons, or explicit mean-field/principal-value subtraction must be part of the branch prescription.

The practical consequence is narrow: simulations can prioritize nearby sources and recent roots only after declaring the far-field treatment. The declaration may be cutoff error, multipole cancellation, screened background, sampled mean field, principal-value subtraction, or another explicit summation prescription.

Plain language: Add the pushes from all causal wake surfaces, but do not assume one over distance squared makes an infinite universe automatically finite; the simulation must say how distant wakes cancel, screen, or get summarized.

Units and Constants

This note fixes the unit and symbol conventions used by the action-energy simulation notes. We work in normalized wake-speed units with $c_f = 1$ unless stated otherwise, use $\kappa > 0$ for the universal coupling, and use $\eta > 0$ as the default regularization thickness for causal isochrons.

Core symbols:

- $c_f = 1$: wake speed in normalized units.
- $\kappa > 0$: universal coupling constant.
- $\eta > 0$: causal-isochron thickness.
- $\epsilon > 0$: polarity-unit magnitude; Electrino $q = -\epsilon$, Positrino $q = +\epsilon$.
- $\sigma_{qq'} = \mathrm{sign}(q\,q') \in \{+1, -1\}$.
- $r = \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\|$, with $\hat{\mathbf{r}} = (\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t))/r$.

Dynamical Geometry

- Wake-speed units ($c_f = 1$):
    - Choosing L_0, T_0 with $c_f = L_0/T_0 = 1$ fixes a conversion between spatial and temporal scales so that all speeds are dimensionless ratios to the wake speed. Kinematics still lives on absolute time × Euclidean space; no spacetime substrate is introduced.
    - Consequence: every velocity appears as a pure number $\|\mathbf{V}\|$; the threshold $\|\mathbf{V}\| = c_f$ becomes $\|\mathbf{V}\| = 1$. Rescaling L_0 and T_0 together leaves all dimensionless predictions invariant.
- Coupling constant ($\kappa > 0$):
    - κ sets the overall scale of per-hit acceleration. In the canonical law,
      $
      \mathbf A_{o'\leftarrow o} = \kappa,\sigma_{q_o q_{o'}},\dfrac{|q_o q_{o'}|}{r^2}W_{o'\leftarrow o}^{\mathrm{acc}},\hat{\mathbf{r}},
      $
      larger κ uniformly strengthens every interaction.
    - Scaling insight: if you scale $\kappa \mapsto \alpha\kappa$ while keeping (ϵ, η) fixed, accelerations scale by α. Characteristic assembly scales such as the minimal binary radius d_0 and period t_0 shift accordingly through the dynamical

balance that defines them.

- Regularization width ($\eta > 0$):
  - η is the width applied to each causal isochron (wake surface) to mollify the surface delta $\delta(r - \Delta)$. It converts impulsive hits into brief, smooth pushes so pointwise quantities such as gradients are defined. The evolution remains a delayed-history problem; an ordinary instantaneous-state ODE solver is insufficient unless the retained history and root reconstruction are supplied explicitly.
  - Geometric guidance: choose η small relative to local geometric scales (e.g., the receiver's instantaneous curvature radius along its path and the local receiver-transmitter separation) so the regularized dynamics approximate the ideal path-history picture while remaining numerically stable.
- Polarity-unit magnitude ($\epsilon > 0$):
  - ϵ is the fundamental polarity scale of an architrino (Electrino $q = -\epsilon$, Positrino $q = +\epsilon$). The observer-level calibration target $|e| = 6\epsilon$ makes quark electric-charge labels integer multiples of ϵ; it is not an input to the substrate dynamics. The owning conversion convention is in Parameter Ledger.
  - Per-wavefront amplitude and emission cadence are constant at the transmitter. The received acceleration magnitude is modulated by the transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$, where D_t records transmitter-side root transversality and D_r records receiver-side playback geometry.
- Sign of interaction ($\sigma_{qq'}$):
  - $\sigma_{qq'} = \mathrm{sign}(q\,q')$ selects attraction vs repulsion while keeping the acceleration strictly collinear with $\hat{\mathbf{r}}$. Like-on-like (σ=+1) points along +$\hat{\mathbf{r}}$ (repulsion); unlike (σ=-1) points along -$\hat{\mathbf{r}}$ (attraction).
- Line of action (r, $\hat{\mathbf{r}}$, D_t, D_r, W^{acc}):
  - $r = \|\mathbf{X}_{o'}(T_r) - \mathbf{X}_o(T_t)\|$ is the separation between the receiver at reception time T_r and the transmitter at emission time T_t. $\hat{\mathbf{r}}$ is the corresponding unit vector. The transmitter-side factor is $D_t = c_f - \mathbf{V}_o(T_t) \cdot \hat{\mathbf{r}}$, the receiver-side factor is $D_r = c_f - \mathbf{V}_{o'}(T_r) \cdot \hat{\mathbf{r}}$, and the active branch strength is $W^{\mathrm{acc}} = c_f/|D_t|$. All per-hit acceleration contributions are directed along this line; no transverse or right-hand-rule terms appear.
- Combined role in assembly scales:
  - The trio (κ, ϵ, η), together with the $1/r^2$ law, determines emergent scales such as the smallest sustainable orbit d_0 and fastest natural frequency $2\pi/t_0$. Intuitively, stronger coupling (larger $\kappa\epsilon^2$) and sharper wake surfaces (smaller η) favor tighter, faster structures until self-interaction and delay balance inward trends.
- Dimensionless branch-scan controls:
  - Simulation sweeps should report dimensionless controls rather than only raw choices of $(\kappa, \epsilon, \eta, L_0, T_0)$. Choose a reference length $L_\star$ and the corresponding reference time $T_\star = L_\star/c_f$; in field-speed units, $c_f = 1$ and $T_\star = L_\star$.
  - **Speed ratio:** use

$$\beta_i(T) = \frac{\|\mathbf{V}_i(T)\|}{c_f}$$

```
and, for circular binary scans, the existing speed factor
```

$$s = \frac{R\omega}{c_f}$$

```
A branch scan must state whether the sampled histories remain below, cross, or remain above the
```

```
self-hit onset $\beta_f = 1$.
```

- **Delay/window ratio:** use

$$\Theta_{\Delta T} = \frac{\Delta T_{\max}}{T_{\mathrm{win}}}$$

```
where $\Delta T_{\max}$ is the longest active causal lookback time and $T_{\mathrm{win}}$ is the averaging, diagnostic, or return-map window. The stored history horizon $h$ must satisfy $h \geq \Delta T_{\max}$ on the scanned branch chart.
```

- **Regularization thickness:** use

$$\hat{\eta} = \frac{\eta}{L_\star}$$

```
with local checks such as $\eta/r_{\min}$ against the smallest resolved separation. A scan is numerically meaningful only when branch counts and averaged observables stabilize as $\hat{\eta}$ is reduced while the causal wakes remain resolved.
```

- **Coupling scale:** compare the per-hit acceleration scale with the reference acceleration $L_\star/T_\star^2$:

$$g_\kappa = \frac{\kappa \epsilon^2 T_\star^2}{L_\star^3} = \frac{\kappa \epsilon^2}{c_f^2 L_\star}$$

```
In field-speed units this reduces to $g_\kappa = \kappa\epsilon^2/L_\star$.
```

- **Branch/root tolerances:** for the causal-root residual

$$g_{ij}(\Delta T, \phi) = \|\phi_i(0) - \phi_j(-\Delta T)\| - c_f \Delta T$$

```
accept a root only when $|g_{ij}|/L_\star \leq \varepsilon_{\mathrm{root}}$, keep distinct roots separated by $|\Delta T_a - \Delta T_b|/T_\star > \varepsilon_{\mathrm{sep}}$, and treat $|J| \leq \varepsilon_J$ as a branch-birth or caustic zone rather than an ordinary stable branch.
```

- A branch-scan report should therefore include at least

$$(\beta_{\max} \text{ or } s,\ \Theta_{\Delta T},\ \hat{\eta},\ g_\kappa,\ \varepsilon_{\mathrm{root}},\ \varepsilon_{\mathrm{sep}},\ \varepsilon_J)$$

```
together with the active causal-root ledger. This prevents a change in units, regularization, or root finder tolerance from masquerading as a new physical branch.
```

Plain language: We measure speeds in units where the field speed is one, use κ to set how hard every hit pushes, use η to slightly thicken the razor-thin isochrons so calculus works, and use ϵ as the basic unit of polarity. The push is always straight along the line back to where the isochron was emitted, but its received strength is shaped by the transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$; like polarities push out, unlike polarities pull in.

Well-Posedness and Regularization

The regularized simulation replaces each sharp causal-surface delta by a narrow mollifier while preserving total emission q:

$$\delta(r - \Delta) \longrightarrow \frac{1}{\sqrt{2\pi}\,\eta} \exp\left(-\frac{(r-\Delta)^2}{2\eta^2}\right)$$

Impulses Versus Smooth Pushes

- Measure-driven dynamics:
  - With exact surface deltas, dynamics are impulsive: velocities are functions of bounded variation with jump discontinuities at hit times.
- Mollified isochron surfaces:
  - Replacing $\delta(\cdot)$ by a narrow Gaussian of width $\eta > 0$ spreads each causal surface's intersection into a short, smooth push. This can yield classical C^1 trajectories on an admitted history chart, but the solver must still retain and reconstruct the delayed path segment.
- Choosing η:
  - Select η small relative to local geometric scales (path curvature radius, inter-source spacing) to approximate the event-driven picture while maintaining numerical stability.
- Distributional wake-surface normalization:
  - Treat $\delta(r - c_f\Delta)$ and $\delta_\eta(r - c_f\Delta)$ as distributions, so the invariant statement is an integrated statement against a test function, not the sampled height of the spike. For $\Delta = T - T_t$ and $r = \|\mathbf{X} - \mathbf{X}_0\|$,

$$\rho_\eta(T, \mathbf{X}) = \frac{q}{4\pi r^2}\, \delta_\eta(r - c_f\Delta)\, H(\Delta)$$

```
must satisfy
```

$$\lim_{\eta\to 0} \int_{\Sigma_T} f(\mathbf{X})\, \rho_\eta(T, \mathbf{X})\, dV = \frac{qH(\Delta)}{4\pi} \int_{S^2} f(\mathbf{X}_0 + c_f\Delta\, \hat{\boldsymbol{\omega}})\, d\Omega$$

- In particular, $f \equiv 1$ gives the total-emission check

$$\int_{\Sigma_T} \rho_\eta(T, \mathbf{X})\, dV \longrightarrow qH(\Delta)$$

```
On a finite annulus $R_- \le r \le R_+$, the expected retained amount is
```

$$Q_\eta^{\mathrm{ann}}(R_-, R_+; T) = qH(\Delta) \int_{R_-}^{R_+} \delta_\eta(r - c_f\Delta)\, dr$$

```
The annular residual is therefore
```

$$R_N(R_-, R_+; T) \equiv \frac{\left| \int_{R_- \le r \le R_+} \rho_\eta(T, \mathbf{X})\, dV - Q_\eta^{\mathrm{ann}}(R_-, R_+; T) \right|}{|q| + \varepsilon_q}$$

```
This catches missing $4\pi r^2$ factors, lost radial Jacobians, and mollifiers that do not preserve
total emission.
```

- Curvilinear-coordinate hygiene:
  - Operator checks in spherical or cylindrical charts must use the Euclidean metric scale factors, not Cartesian component formulas applied to curvilinear components. For spherical coordinates (r, θ, φ) centered on the emission point,

$$dV = r^2 \sin\theta\, dr\, d\theta\, d\varphi, \qquad dS_R = R^2 \sin\theta\, d\theta\, d\varphi$$

```
and a radial diagnostic channel $F_r(r)\hat{\mathbf{r}}$ obeys
```

$$\nabla\cdot\big(F_r(r)\hat{\mathbf{r}}\big)=\frac{1}{r^2}\frac{\partial}{\partial r}\big(r^2F_r(r)\big)$$

```
For a radial scalar $f(r)$,
```

$$\Delta f=\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial f}{\partial r}\right)$$

```
The invalid shortcut $\nabla\cdot(F_r\hat{\mathbf{r}})=\partial_rF_r$ breaks the conservation normalization of causal wake surfaces.
```

- Finite-limit discipline:
  - Treat finite architrino count, finite memory depth, finite step size, finite domain/window, and finite $\eta>0$ as the first proof or simulation regime.
  - Promote large-system, continuum, or $\eta\to 0$ statements only after the retained observables converge under the declared refinement path.
  - Do not replace arbitrarily large finite systems with an actual infinite medium unless the limit preserves the causal-root count, transmitter-side Jacobian floors, transmitter-side acceleration weights, work-energy residuals, and thermodynamic summaries being claimed.
- State-dependent branch-transition discipline:
  - State-dependent delay systems can lose classical branch continuation at transition points where a delayed argument crosses a branch boundary, a causal-root count changes, or a derivative-sensitive row enters a fold-layer. A finite-η run must therefore record how the regularized trajectory crosses each such window rather than treating the crossing as ordinary time-step noise.
  - For every declared transition window $I_*=[t_*-\Delta_*,t_*+\Delta_*]$, emit

$$\mathcal{T}_{\eta,*}=\big(I_*,\mathcal{L}_{\mathrm{root}}|_{I_*},\mathsf{status}_{\eta,*},\mathsf{regularization}_{\eta,*},\mathsf{window\_scale}_{\eta,*},\mathcal{Y}_{\eta,*},\mathcal{E}_{\mathrm{trans},*}\big)$$

```
where $\mathsf{status}_{\eta,*}$ is the candidate branch status, chosen from the existing simple-root, fold-layer,
inactive-gap, or rejected statuses, $\mathsf{regularization}_{\eta,*}$ names the finite-$\eta$ route used through the
window, $\mathsf{window\_scale}_{\eta,*}$ records the declared transition scaling, and $\mathcal{Y}_{\eta,*}$ is the set of observables
promoted through that window.
```

- For each promoted observable $Y\in\mathcal{Y}_{\eta,*}$, define

$$E_{\mathrm{trans}}(Y;\eta,\eta/2;I_*)=\frac{\|R(Y_{\eta/2}|_{I_*})-Y_\eta|_{I_*}\|_{L^2(I_*,\{x_k\})}}{\|R(Y_{\eta/2}|_{I_*})\|_{L^2(I_*,\{x_k\})}+\varepsilon_0}$$

- The transition passes only if

$$\mathsf{status}_{\eta,*}=\mathsf{status}_{\eta/2,*},\qquad E_{\mathrm{trans}}(Y;\eta,\eta/2;I_*)\le\tau_{\mathrm{trans},Y}\quad\text{for every }Y\in\mathcal{Y}_{\eta,*}$$

```
and every root-ledger row in $I_*$ keeps transmitter identity, branch class, and status metadata
under the same matching rule used by $\Delta_{\eta,\mathrm{root}}$.
```

- If the branch status flips under η refinement, route the run to branch_root_instability. If the status is stable but the promoted transition observables fail the tolerance, route it to regulator_dependence. If the transition record is missing, route it to artifact_incomplete.

- For nonsmooth windows, the transition record must include jump-location rows

$$\mathcal{D}_{\text{jump}} = \{(\xi_a, k_a, \ell_a, \xi_{\pi(a)}, R_{\text{jump},a})\}, \qquad R_{\text{jump},a} = \frac{|t_{0,\ell_a}(\xi_a) - \xi_{\pi(a)}|}{\max(\Delta T, \Delta h, \eta/c_f, \varepsilon_0)}$$

```
Unstable jump identity routes to branch_root_instability; unresolved jump or interpolation convergence
routes to mesh_nonconvergence.
```

- Fold-layer status is only a transition classification. A stable fold-layer row may preserve branch identity through η refinement, but it does not prove branch-equation balance. When the run claims a corrected one-period carrier, the acceleration-balance residual for that period must also pass before the result can proceed to monodromy, $\Delta_{\mathbf{k}}$, or η-ladder persistence.
- Energetic consistency:
  - A fixed-transmitter benchmark may verify $\Delta E_k = -\Delta U$ with $U = q'\Phi_\eta$ on resolved intervals. A moving-transmitter, self-hit, or open-boundary branch must instead close the history-aware energy, wake, and boundary terms defined in Delay Dynamics and Energy. Convergence of interval integrals as $\eta \to 0$ is a separate claim governed by the continuation package below; it is not implied by choosing a Gaussian mollifier.

Formal $\eta > 0$ Continuation Package

The regularization package for a promoted run family is

$$\mathsf{Reg}_\eta = (\delta_\eta, \mathcal{A}_\eta, \mathsf{WP}_\eta, \mathsf{NR}_\eta, \mathsf{Cont}_\eta, \partial\mathcal{A}_\eta)$$

where δ_η is the mollified causal-wake kernel, $\mathcal{A}_\eta$ is the admissible history set, WP_η is the existence-uniqueness statement, NR_η is the no-runaway bound, Cont_η is the continuation criterion, and $\partial\mathcal{A}_\eta$ is the failure boundary.

On a finite interval $[0, T]$, the admissible history set is

$$\mathcal{A}_\eta(T; V, d, \nu, B) = \left\{ S_{\eta,U} : \sup_{U \le T} \|\mathbf{V}(U)\| \le V, \quad \inf r_{ij,\ell}(U) \ge d, \quad \inf |\partial_\Delta g_{ij,\ell}(U)| \ge \nu, \quad \sup B_{ij}^{\text{active}}(U) \le B \right\}$$

Existence and uniqueness mean that every declared initial history $S_{\eta,0} \in \mathcal{A}_\eta(T; V, d, \nu, B)$ generates a unique $S_\eta(U)$ on $[0, T]$ in the declared history class, and that the emitted root ledger is generated by that solution rather than by a post-hoc branch choice.

The no-runaway condition requires a validated energy construction, not time-translation symmetry alone. On the same branch chart and isolated window, the packet must identify one accepted construction route from Delay Dynamics Energy, retain the corresponding boundary convention, establish the lower bound

$$E_{\text{tot}}^{(\eta)}(T) = K_\mu(T) + E_{\text{wake}}^{(\eta)}(T), \qquad E_{\text{wake}}^{(\eta)}(T) \ge U_{\min}^{(\eta)} > -\infty$$

and report

$$\epsilon_E^{(\eta)}([0, T]; \mathfrak{B}) \le \tau_E$$

for a predeclared tolerance τ_E that remains satisfied under temporal, history-window, and regulator refinement. Only those jointly validated rows license the finite-window kinetic bound

$$K_\mu(T) \le E_{\text{tot}}^{(\eta)}(0) - U_{\min}^{(\eta)} + \left|\mathcal{R}_E^{(\eta)}([0, T]; \mathfrak{B})\right|$$

on the isolated run window. Preserved time-translation symmetry is a required input to an action-boundary construction, but it is not by itself a conservation or no-runaway certificate.

The continuation criterion is

$$S_\eta([0,T]) \subset \mathcal{A}_\eta(T;V,d,\nu,B) \quad \Longrightarrow \quad \text{the run may be extended past } T$$

using the same local well-posedness constants after refreshing the history segment at T. The failure boundary is

$$\partial\mathcal{A}_\eta = \{\|\mathbf{V}\| = V\} \cup \{r_{ij,\ell} = d\} \cup \{|\partial_\Delta g_{ij,\ell}| = \nu\} \cup \{B_{ij}^{\text{active}} = B\} \cup \{E_{\text{wake}}^{(\eta)} \downarrow -\infty\}$$

Crossing any component of $\partial\mathcal{A}_\eta$ changes the promotion status to `eta_continuation_failure` unless a stricter replacement bound is proved in the same artifact packet.

For the finite-η pathology theorem target in Master Equation, a promoted run family must report the same boundary components as observables, not only as solver diagnostics. Divergent self-energy is routed through the d or ϵ_c row, runaway behavior through the $E_{\text{wake}}^{(\eta)}$ lower-bound row, pre-acceleration through the retained-history and endpoint-convention row, and caustic blow-up through the ν and transition-status rows. The minimum residual packet is:

- root residual and root-transport residual for every retained row,
- active transmitter-side Jacobian floor, transmitter-side acceleration-weight floor or certified interval, and inactive-root gap,
- finite-memory coverage and endpoint or period-cut leakage,
- energy, momentum, and angular-momentum residuals computed with the same η, window, and endpoint convention,
- transition-observable refinement residuals $E_{\text{trans}}(Y;\eta,\eta/2;I_*)$ for every fold-layer or caustic transit promoted through the window,
- $\Delta_{\eta,\text{root}}$ for every active branch ledger in the η ladder.

If any row is missing, the artifact status is `artifact_incomplete`. If a row is present but fails under refinement, the status is the corresponding continuation, regulator-dependence, or branch-root instability failure already defined above.

The $\eta \to 0^+$ claim boundary is

$$\limsup_{\eta\to 0^+} E_\eta(Y;\eta,\eta/2) = 0, \qquad \limsup_{\eta\to 0^+} \Delta_{\eta,\text{root}} = 0$$

for every promoted observable and active branch ledger. Otherwise the result remains finite-η evidence only.

Plain language: The ideal model gives instantaneous kicks; a tiny thickening turns them into brief, smooth nudges that a delayed-history solver can integrate. Large-system or zero-width claims have to be earned by convergence, not assumed from the finite calculation.

Entropy

Entropy asks what a finite record has forgotten. In $\mathbb{AAA}$ it is not a primitive substance, not a field in the Euclidean void, not the generator of absolute time, and not an independent gravitational mechanism. It is a functional of the histories a declared observer, apparatus, simulation packet, or effective description retains after the complete deterministic state has been projected into a finite record.

This chapter collects the entropy rule used across time, energy, measurement, computation, horizon, and cosmology discussions. The central discipline is the same-record rule: a packet may not fit entropy, temperature, flux, probability weights, apparatus cost, or horizon labels from separate hidden ensembles. If a thermal, quantum, horizon, or computational comparison is claimed, the entropy appearing in that comparison must be a projection of the same record that supplies the other quantities.

Plain-Language Reading

A simple way to read entropy is: entropy measures how many hidden detailed stories could produce the same thing a record can see. A room does not contain an entropy substance. Rather, many exact arrangements of dust, air, books, and clothing can still project to the same coarse record of “messy room.” Entropy counts or measures those compatible detailed arrangements after the level of detail has been fixed.

This is also why visible disorder is only a shortcut, not the definition. A jagged, broken, or visually mixed object can still have lower entropy than a smoother thermal state if fewer complete histories are compatible with its retained record. In this chapter, disorder language is acceptable only when it tracks the declared measure, macrostate partition, and unresolved history count.

In $\mathbb{AAA}$ terms, inherited entropy language usually measures unresolved path history without naming it that way. Heat spreading, phase scrambling, apparatus irreversibility, and horizon bookkeeping all express the same pressure: a finite record no longer retains enough exact architrino, assembly, causal-wake, boundary, and Noether sea history to reconstruct one unique detailed past.

Entropy remains useful because it audits coarse descriptions. It asks whether a measurement record is really stable, whether heat and work bookkeeping close, whether computation or memory reset has a physical cost, whether a horizon label count comes from real boundary records, and whether a packet is using one hidden record for entropy while using another for temperature, flux, or probability. In that sense, entropy is not fundamental ontology, but it is a powerful test of whether an effective description is physically honest.

For a fixed coarse-graining and access window, entropy is determined by universe path history. The complete path history determines the retained record, the compatible alternatives, and the boundary exchanges. The entropy value is not just a bare property of the universe by itself; it is the value obtained after declaring which histories are being distinguished and which histories are being grouped together.

The retained record may also include incoming causal-wake and potential data. A wake-inclusive entropy measures how many complete source and path-history configurations could produce the same incoming potential record, boundary-wake record, or apparatus response in the declared window. This is the form needed when measurement, radiation, horizon, or Noether sea thermodynamic bookkeeping depends on incoming causal structure rather than only on material state variables inside the window.

A common thermodynamic lesson can therefore be restated without changing the ontology: the same amount of energy can be more or less usable depending on how concentrated, phase-organized, spectrally sharp, or gradient-bearing the retained record is. Energy conservation belongs to the full same-record ledger. Entropy asks how much of that ledger has been dispersed into unresolved alternatives.

The quantum version says the same thing in a sharper language. A complete comparison state may remain pure or measure-preserving, while a subsystem looks mixed after the rest of the entangled record has been placed outside the access window. In $\mathbb{AAA}$, that is not proof that information is a primitive substance. It is another record-coarse-graining: the retained channel cannot carry the full compatible path-history and correlation record.

Core Definition

Let μ_T be a measure on complete deterministic histories compatible with a declared preparation. In a deterministic substrate this measure is not fundamental randomness. It is the pushforward of preparation-limited ignorance over the unresolved initial history and incoming-wake data. If the preparation fixes the present record at T_{prep} only up to a retained history depth h, let ν_{prep} be the measure on the unfixed segment $[T_{\text{prep}} - h, T_{\text{prep}}]$ and let $\mathcal{F}_{T_{\text{prep}}\to T}$ be the deterministic delayed-flow map. Then

$$\mu_T = \left(\mathcal{F}_{T_{\text{prep}}\to T}\right)_* \nu_{\text{prep}}$$

This is the official reading of μ_T in this chapter: probabilities describe unresolved retained history under a declared preparation, not stochastic substrate law. Deterministic multistability becomes important because ν_{prep} can spread over multiple basins before the flow sharpens it into a record-limited outcome distribution.

Let $W(T)$ be the access window and let $\mathcal{Q}$ be the coarse-graining used by a Physical Observer, apparatus, or simulation packet. The record projection

$$\Pi_{\mathcal{Q},W} : \Gamma_T \longrightarrow \mathcal{Z}_{\mathcal{Q},W}$$

maps complete histories into retained record variables. Here Γ_T is the preparation-conditioned complete-history space at absolute time T, and $\mathcal{Z}_{\mathcal{Q},W}$ is the retained record-state space selected by the coarse-graining and access window. The pushed-forward record measure is

$$\nu_{\mathcal{Q},W,T} = (\Pi_{\mathcal{Q},W})_* \mu_T = (\Pi_{\mathcal{Q},W})_* \left(\mathcal{F}_{T_{\mathrm{prep}} \to T}\right)_* \nu_{\mathrm{prep}}$$

and the corresponding observer-window entropy is

$$S_{\Pi,W}(T) = k_B \, \mathcal{H}(\nu_{\mathcal{Q},W,T})$$

where $\mathcal{H}$ is the entropy functional appropriate to the retained record measure.

On a continuous record space, the entropy functional also requires a declared reference measure $\lambda_{\mathcal{Q},W}$. When $\nu_{\mathcal{Q},W,T}$ is absolutely continuous with respect to that reference, write

$$\mathcal{H}_{\lambda_{\mathcal{Q},W}}(\nu_{\mathcal{Q},W,T}) = -\int_{\mathcal{Z}_{\mathcal{Q},W}} \log\left(\frac{d\nu_{\mathcal{Q},W,T}}{d\lambda_{\mathcal{Q},W}}\right) d\nu_{\mathcal{Q},W,T}$$

Bare differential entropy is chart-dependent, so neither the coordinate chart nor its volume element may remain implicit in a quantitative entropy claim.

Thus the entropy is evaluated on the composite forgetting map from unresolved preparation history, through deterministic delayed evolution, into the retained record quotient. A quantity is entropy-relevant only when it is not constant on the fibers of this composite map. If two complete histories differ but project to the same retained record, that unresolved fiber contributes to the entropy; if an invariant remains constant across every compatible fiber, it does not create entropy in that coarse-graining.

The exact data-processing statement concerns distinguishability between candidate history measures. For two preparation-conditioned measures μ_T and μ'_T satisfying the required absolute-continuity conditions,

$$D_{\mathrm{KL}}((\Pi_{\mathcal{Q},W})_* \mu_T \parallel (\Pi_{\mathcal{Q},W})_* \mu'_T) \le D_{\mathrm{KL}}(\mu_T \parallel \mu'_T)$$

Projection cannot increase the retained record's ability to distinguish the two candidate history ensembles. This loss of distinguishability is not automatically an increase of Shannon or thermodynamic entropy; an entropy-growth claim still requires the fixed reference measure, coarse-graining, access window, and boundary ledger declared above.

For a discrete coarse partition with probabilities p_α, this reduces to the familiar Gibbs/Shannon form

$$S_{\mathcal{Q}} = -k_B \sum_\alpha p_\alpha \log p_\alpha$$

For a microcanonical retained window, the same idea is written as

$$S_{\mathcal{Q},W}(T) = k_B \log \mu\big(\Gamma_{\mathcal{Q},W(T)}\big)$$

where $\Gamma_{\mathcal{Q},W(T)}$ is the set of complete microhistories compatible with the retained macroscopic records in that window.

Plain language: entropy is not counted over reality in the abstract. It is counted over the alternatives left unresolved after the record map, measure, coarse-graining, and access window have been specified.

The exact-record limit is useful as a guardrail. If the retained partition distinguishes one complete deterministic history from every other complete deterministic history, then the active cell has probability one and the corresponding entropy is zero. That does not mean thermodynamics has disappeared from the world. It means the record has been refined until it no longer asks a thermodynamic question. A thermodynamic macrostate is a physically declared grouping of histories: a pressure, temperature, density, spectral, boundary, apparatus, or control-relevant record that a real system can retain and use.

Equivalently, entropy is a functional on the quotient $\Gamma_T/\sim_{\mathcal{Q},W}$. Refining the quotient shrinks fibers and cannot increase the active-cell log-fiber measure when the underlying preparation measure is held fixed; coarsening the quotient merges fibers and can increase it. The number therefore has physical content only after the quotient map, measure, access window, and comparison job are declared.

Measure-Domain and Flow Guardrail

The measure notation above is conditional on a declared delayed-history domain. For a finite retained memory depth h and regularization $\eta > 0$, one admissible setting is a path-history space

$$\mathfrak{X}_{h,\eta} = C([-h, 0]; \mathcal{Z}_\eta)$$

where $\mathcal{Z}_\eta$ is the declared regularized state space for Z $= (\mathbf{X}, \mathbf{V})$; a finite-dimensional Galerkin or return-section chart is another admissible setting when its projection error is included in the record. The preparation measure must be defined on that domain, and the delayed flow must at least be measurable on the retained window.

Conservation of fine-grained entropy requires more. The branch must supply an invariant or suitably quasi-invariant history measure for the declared flow, with its regularization, endpoints, and memory-boundary convention fixed. Determinism alone does not provide a Liouville theorem for a state-dependent or neutral delayed system. Extending a finite-memory or regularized claim to $h \to \infty$ or $\eta \to 0$ is therefore a closure target, not a consequence of the entropy definition.

Receiver Inference Fibers and Provenance Graphs

The wake-inclusive form has a canonical substrate construction. For a receiver i at event $(\mathbf{X}_i(T), T)$, let the retained hit record be

$$\mathcal{H}_i^{\text{hit}}(T) = \{(\ell_\rho, \|\mathbf{A}_\rho\|)\}_{\rho \in R_i(T)}$$

where $\rho \in R_i(T)$ indexes an active received root, ℓ_ρ is the retained unoriented line of action, and $\|\mathbf{A}_\rho\|$ is the retained hit strength. If an apparatus retains oriented directions or source tags, those data are added to $\mathcal{H}_i^{\text{hit}}$ explicitly. The receiver inference fiber is

$$\Gamma_i^{\text{hit}}(T) = \left\{\gamma \in \Gamma_T : \text{the delayed branch sum of } \gamma \text{ reproduces } \mathcal{H}_i^{\text{hit}}(T)\right\}$$

and the receiver-hit entropy is

$$S_i^{\text{hit}}(T) = k_B \, \mathcal{H}\left(\mu_T\big|_{\Gamma_i^{\text{hit}}(T)}\right)$$

This is the entropy of the receiver's inference fiber. The electrino/positrino antipode ambiguity and the surrogate-location recast described in Master Equation are then measure-preserving involutions on $\Gamma_i^{\text{hit}}(T)$ whenever the retained hit record is unchanged by the recast. Measurement uncertainty at this level is therefore a computable fiber multiplicity, not a slogan added after the dynamics.

When $\mathcal{H}$ is evaluated as a probability entropy, the restricted measure is normalized on $\Gamma_i^{\text{hit}}(T)$. If the fiber has zero or undefined measure under the declared preparation, the receiver-hit entropy is not licensed for that packet.

For windows with many retained roots, define the causal-wake provenance graph $G_{\text{prov}}(W)$: vertices are retained causal roots in W, and two vertices are joined when their roots trace to a common transmitter worldline segment in the compatible complete histories. This graph is the common native carrier for three entropy uses below: its connectedness supplies history-backed concordance, its edge cuts supply access-cut entropy, and its boundary-crossing edges supply the wake-escapement contribution to the arrow-of-time ledger.

More precisely, $G_{\mathrm{prov}}(W)$ is the 1-skeleton of the receiver-transmitter provenance complex retained by the packet. Its connected components give the local concordance structure, its cut space gives access-cut entropy, and its boundary operator records which provenance edges leave the retained window. The graph is therefore not an analogy for information. It is the combinatorial record of which transmitter labels and path-history distinctions remain recoverable after the hit record has been projected.

Minimum Specification

Every entropy statement in $\mathbb{AAA}$ should declare five ingredients before the number is treated as physical. First, it should name the preparation and measure μ_T on compatible deterministic histories. Second, it should name the access window $W(T)$ and retained record carrier: apparatus state, boundary wake data, Noether sea state, Physical Observer record, or simulation packet. Third, it should name the coarse-graining $\mathcal{Q}$ and the projection $\Pi_{\mathcal{Q},W}$. Fourth, it should state the comparison job: work availability, heat flow, coding, measurement locking, horizon label counting, cosmology, or another defined use. Fifth, for open windows, it should include boundary flux and record-change residuals rather than silently treating the window as isolated.

This checklist is not extra ontology. It is the minimum context needed for an entropy claim to say something definite. Without these ingredients, a phrase such as “the entropy increased,” “the system is maximally entropic,” or “information was lost” has not yet specified which alternatives were unresolved, which record retained them, or which comparison class made the claim meaningful.

Temperature as a Same-Record Ensemble Variable

Temperature inherits the same discipline. It is not a primitive substrate property of an architrino, a single Noether braid, or the Euclidean void. It is an effective ensemble variable admitted only when a declared coarse-graining retains enough accessible energy exchange, state counting, and local stability for a thermodynamic or kinetic readout to be meaningful.

A minimal temperature-availability record should declare the ensemble, retained window, measure, energy ledger, fixed inventory, fixed volume or access variable, retained Noether sea state, equilibrium or thermalization residual, and observer handoff. Schematically,

$$\mathcal{A}_T(W) = (\mathcal{Q}, W, \mu, E_{\mathcal{Q},W}, \mathcal{N}, \mathcal{V}, \theta_{\mathrm{sea}}, \mathcal{R}_{\mathrm{eq}}, \mathcal{O}_{\mathrm{obs}})$$

where $\mathcal{R}_{\mathrm{eq}}$ records whether local thermodynamic equilibrium, detailed balance, or another thermalization condition has been derived, and $\mathcal{O}_{\mathrm{obs}}$ records how the temperature is measured, redshifted, or reconstructed. If $S_{\mathcal{Q},W}$ is physical entropy and the derivative is stable inside the declared record, the temperature channel is

$$\frac{1}{T_{\mathcal{Q},W}} = \left(\frac{\partial S_{\mathcal{Q},W}}{\partial E_{\mathcal{Q},W}}\right)_{\mathcal{N},\mathcal{V}}$$

A kinetic temperature is a special limit of the same rule, not a separate ontology. It is available only when the accessible velocity or mode distribution has thermalized under the local interaction rules. For example, a Maxwell-Boltzmann comparison may be used only after the retained packet shows

$$f_{\mathcal{Q}}(\mathbf{v}; \theta_{\mathrm{sea}}) \approx f_{\mathrm{MB}}(\mathbf{v}; T_{\mathrm{kin}})$$

inside a declared tolerance. Without that ensemble measure or entropy-energy derivative, a high cadence, high internal energy, strong medium response, or local excitation is not yet a temperature.

At human scales, the temperature of matter is therefore a bulk property of Standard Model assemblies and their accessible modes. Atoms, molecules, solids, and plasmas redistribute energy through translational motion, molecular rotation and vibration, electron-envelope excitation, lattice or phonon occupation, photon exchange, recoil, and local Noether sea response. The scalar temperature summarizes the accessible distribution after coarse-graining; it does not measure all shielded internal assembly energy, and it is not a hidden sink for event-ledger imbalance. If a channel becomes heat, the event record must still route the energy into named electron-envelope, bonding or lattice, Noether sea, recoil, remnant, boundary, or radiation rows.

For Noether sea cadence transport, the same-record condition means temperature may bias the rates of accepted branch-ledger transitions but may not be treated as a direct single-braid heat property. The theorem target is stated in Noether Sea.

Work Availability and Energy Spread

Traditional thermodynamics often introduces entropy as a measure of energy spread. In this chapter that is the work-availability face of record coarse-graining. A hot reservoir, chemical store, coherent photon-channel stream, or gravitational potential gradient is low entropy only relative to a work channel and comparison record that can use the concentration. After the same energy is distributed among many thermal, boundary, or wake-history microrecords, the total energy ledger may still close, but the retained record supports less extractable work.

For a fixed reference bath or readout channel with temperature T_R declared by the same record, define the availability diagnostic

$$A^{(T_R)}_{\mathcal{Q},W}(T) = E_{\mathcal{Q},W}(T) - T_R S_{\mathcal{Q},W}(T)$$

This is a diagnostic, not a new substrate property. In a closed isothermal comparison, the useful work extractable from the retained packet is bounded by the decrease of this same-record availability,

$$W_{\text{useful}} \le A^{(T_R)}_{\mathcal{Q},W}(T_i) - A^{(T_R)}_{\mathcal{Q},W}(T_f)$$

up to declared control and boundary residuals. A packet that conserves $E_{\mathcal{Q},W}$ while increasing $S_{\mathcal{Q},W}$ has not lost energy. It has lost retained work availability in that comparison channel.

For resource-theory uses, the maximum work must also be indexed by the allowed apparatus control and readout class. Let $\mathcal{C}^{\text{ctrl}}_W$ denote the declared controls, measurements, feedback operations, and reset operations available in the window, and let R_f denote the required final record. Then the same physical packet supports the diagnostic

$$W_{\max}\big(\theta_W; \mathcal{C}^{\text{ctrl}}_W, R_f\big) = \sup_{\alpha \in \mathcal{C}^{\text{ctrl}}_W} \Delta E_{\text{weight}}[\alpha : \theta_W \to R_f]$$

The value can change when the apparatus record contains which pressure side, molecule class, isotope channel, or other controllable distinction is present. That is not a psychological addition to physics. It is a different physical record and a different control/readout channel. In $\mathbb{AAA}$, an entropy that claims to measure available work must therefore declare θ_W, $\mathcal{C}^{\text{ctrl}}_W$, and R_f together.

This also disciplines heat-death language. A claim that a universe window has no usable work left is not a bare statement about the complete microstate; it is a statement about a declared class of controls, readouts, reservoirs, and final records. For a control family $\mathcal{C}^{\text{ctrl}}$ over admissible windows, the remaining work-availability envelope can be written schematically as

$$\mathcal{A}_{\text{use}}(T; \mathcal{C}^{\text{ctrl}}) = \sup_{W, R_f} W_{\max}\big(\theta_W(T); \mathcal{C}^{\text{ctrl}}_W, R_f\big)$$

For $\mathbb{AAA}$ this envelope must distinguish exposed gradients from shielded internal assembly energy. If the declared control class includes operations that can change shielding, write schematically

$$\mathcal{A}_{\text{use}} = \mathcal{A}_{\text{exposed}} + \mathcal{A}_{\text{deshield}}, \qquad \mathcal{A}_{\text{deshield}} = \sup_{\alpha \in \mathcal{C}^{\text{ctrl}}_{\text{shield}}} \sum_A \big(\zeta_{\text{probe},\alpha}(A) - \zeta_{\text{probe},0}(A)\big)_+ E_{\text{internal}}(A)$$

Here $\mathcal{C}^{\text{ctrl}}_{\text{shield}}$ is the possibly empty class of operations that can raise an assembly's probe-channel leakage in the declared window, $\zeta_{\text{probe},0}$ is the initial probe-channel leakage, and $[x]_+ = \max(x, 0)$. If topological assembly protection forbids such leakage-raising operations, $\mathcal{A}_{\text{deshield}}$ is not available to the control family. If shielding is reversible or partially controllable, heat-death language is stronger than exposed-gradient exhaustion and must include the accessible de-shielding term.

This reservoir term is not unlimited. The reservoir branch must begin inside the same scalar-mass shielding window used by the mass map. In the probe channel, deep shielding is constrained by the positivity condition in Energy:

$$\zeta_{\text{probe}}(A)(1+\delta\mathcal{M}_0) > \frac{1}{3}\left|\mathcal{Z}_{\text{tf},ab}(A)\delta\mathcal{M}_{\text{tf}}^{ab}\right|$$

If the initial branch lies below that window, it has not supplied a positive scalar-mass reservoir for this work-availability comparison. Raising ζ_{probe} can expose internal energy, but the extraction path is still constrained by branch survival: an assembly de-shielded so far that it exits the mass map or dissociates has stopped being the same matter reservoir whose work availability was being counted.

A heat-death statement for that control family means $\mathcal{A}_{\text{use}}$ tends to zero or below the declared operational threshold. It does not prove that every possible future record system, assembly class, or Noether sea access channel has no usable distinction. It proves only the exhaustion of usable gradients and accessible shielded reservoirs for the stated comparison class.

For open windows, the same point must be stated with boundary records. A planetary, biological, or engineered window may receive and emit nearly equal total energy while still being driven by low-entropy input. The relevant record distinguishes incoming concentrated photon-channel packets, chemical gradients, or potential-gradient data from outgoing lower-frequency radiation, heat, and boundary-wake history:

$$\mathcal{B}_{\partial W}^{\text{therm}} = \left(\dot{E}_{\text{in}}, \rho_{\text{in}}(\nu,\Omega), \dot{E}_{\text{out}}, \rho_{\text{out}}(\nu,\Omega), \mathcal{B}_{\text{wake}}\right)$$

where ρ_{in} and ρ_{out} are retained spectral/angular records, not new ontological fluids. The entropy claim is physical only when this boundary record is the same one used for energy flux, internal work, heat, and observer readout.

Complexity and Driven Intermediate Windows

Entropy and complexity answer different questions. Entropy compares how many compatible histories remain unresolved after a coarse-graining. Complexity asks whether the path between low-entropy and high-entropy records passes through organized intermediate structures. Low entropy can be simple, high entropy can be simple, and the interesting dynamics often occur in a driven window between them.

For a locally organized window W, the same-record statement is not that organization defeats the second law. It is that internal record maintenance is paid for by boundary exchange:

$$\Delta S_{\mathcal{Q},W}^{\text{inside}} + \Delta S_{\mathcal{Q},\partial W+\text{env}}^{\text{export}} \geq 0, \qquad \Delta S_{\mathcal{Q},W}^{\text{inside}} \leq 0$$

where both terms are computed from the same access window, coarse-graining, and boundary record. The first term may describe the maintained organization of a cell, reaction network, engineered refrigerator, or other open subsystem. The second term records the exported heat, lower-grade radiation, reaction byproducts, wake-boundary history, and environmental disorder that make the local organization possible.

Origin-of-life and metabolism-first arguments are useful comparison pressure at this level. They do not show that entropy creates life, and they do not add biological ontology to $\mathbb{AAA}$. They say that a plausible prebiotic reaction window must name usable gradients, compartment-like retention, reaction throughput, and entropy export. In native terms, that becomes a finite-window reaction-ledger problem: the source record must show how low-entropy chemical, photon-channel, geothermal, or potential-gradient input is converted into persistent organized records while the boundary ledger exports a larger entropy burden.

For assembly formation, the driven intermediate window can be made into an order parameter rather than only a qualitative contrast. Split the retained wake record in W into a coherent phase-locked part and an incoherent exported or background part under the same coarse-graining $\mathcal{Q}$. Define

$$\mathcal{C}_W = \frac{S^{\rm incoh}_{\mathcal{Q},W}}{S^{\max}_{\mathcal{Q},W}} \left(1 - \frac{S^{\rm coh}_{\mathcal{Q},W}}{S^{\max}_{\mathcal{Q},W}}\right)$$

The quantity peaks when a sharply organized coherent core coexists with substantial exported or surrounding incoherent entropy. Stable assemblies are therefore candidate local maxima or ridges of $\mathcal{C}_W$ under the second-law export constraint above. The Noether braid program can test this directly by asking whether phase-locked trajectory bundles sit on such ridges while the surrounding Noether sea and wake-boundary ledger pay the entropy cost.

Mapping in from Standard Entropies

Legacy entropy formulas survive as effective projections with different prerequisites.

Clausius entropy, $dS = \delta Q_{\rm rev}/T_{\rm temp}$, is licensed only in a regime where the reversible comparison class, heat channel, and temperature channel are defined by the same physical record. Without that record, the formula is a comparison mnemonic rather than a substrate claim.

The Clausius definition also has a direction of dependence that must not be reversed. A cycle statement can be made without entropy:

$$\oint \frac{\delta Q}{T} \le 0, \qquad \oint_{\rm rev} \frac{\delta Q_{\rm rev}}{T} = 0$$

for the declared heat reservoirs, temperature scale, and reversible comparison class. Only after that integrability condition is available does the entropy difference

$$\Delta S_{\rm Cl} = \int_A^B \frac{\delta Q_{\rm rev}}{T}$$

become path-independent. In this chapter, a claim that "entropy broke the second law" must therefore specify which entropy is being used. If the Clausius integrability condition fails, the thermodynamic entropy used in that comparison was not well-defined in the first place.

The framework also conditionally expects, on a certified sea branch, where this integrability fails. Let the Noether sea retuning lag on a thermodynamic cycle be

$$\Lambda_{\rm sea}(W) = \frac{T_{\rm retune}(\theta_{\rm sea})}{T_{\rm cycle}}$$

where $T_{\rm retune}$ is the relaxation time for the Noether sea response variables retained by the packet and $T_{\rm cycle}$ is the duration of the reversible-comparison cycle. Clausius entropy is expected to be path-independent only in the regime $\Lambda_{\rm sea} \ll 1$. When $\Lambda_{\rm sea} \gtrsim 1$, the sea carries cycle-scale hysteresis, the heat channel is history-dependent, and $\oint \delta Q_{\rm rev}/T_{\rm temp}$ is not a well-defined state function for that record.

In differential-form language, $\delta Q/T_{\rm temp}$ is an exact 1-form only in the fast-retuning regime where the Noether sea response closes before the comparison cycle completes. When $\Lambda_{\rm sea} \gtrsim 1$, the same form acquires a nonzero period around the cycle: the hysteresis-loop area is the observable obstruction to treating thermodynamic entropy as a state function on that packet. The predicted simulation signature is a loop area that grows with the sea-retuning lag rather than with an independently assigned entropy defect.

Boltzmann entropy, $S = k_B \log \Omega$, maps to the count or measure of complete architrino and assembly histories compatible with the retained macrostate. The textbook counting form is the uniform-weight special case of Gibbs/Shannon entropy:

$$p_\alpha = \frac{1}{\Omega} \quad \Longrightarrow \quad -k_B \sum_{\alpha=1}^{\Omega} p_\alpha \log p_\alpha = k_B \log \Omega$$

Thus the count is not licensed by cardinality alone. It also assumes the measure that gives the compatible microstates equal weight, usually through an isolated equilibrium comparison or another declared physical preparation. The macrostate partition is part of the claim. Changing the partition or the measure changes the entropy statement. A singleton partition over exact complete histories would assign zero Boltzmann entropy to every cell, but it would also erase the thermodynamic question. Useful Boltzmann entropy requires retained macrostates tied to measurable, controllable, or dynamically stable distinctions.

Elementary thermal examples often count energy-quanta arrangements: one macrostate may specify only how much energy lies in each body, while many bond-level or molecule-level allocations remain unresolved. The $\mathbb{AAA}$ replacement is the same mathematical role with a deeper state space: count complete deterministic histories compatible with the retained energy, wake, boundary, apparatus, and Noether sea records.

Gibbs and Shannon entropies map to pushed-forward measures over unresolved alternatives. They are useful for apparatus states, basin weights, branch records, and coding descriptions, but they become thermodynamic only when the apparatus, environment, boundary exchange, and work or heat ledger are physical parts of the same packet. Gibbs entropy is the natural comparison when the retained measure encodes uncertainty over alternatives that change available work under a declared control class; Boltzmann entropy is tied to the retained macrostate partition itself. Both are valid only with their intended job stated.

At deterministic-multistability points, the same measure gives the effective branch weights a record-limited observer must assign. If the unresolved preparation fiber is Γ_{prep} and the deterministic basins $\{B_k\}$ partition the post-event branch outcomes, define

$$w_k = \frac{\mu_T\left(\mathcal{F}^{-1}_{T\to T_+}(B_k) \cap \Gamma_{\text{prep}}\right)}{\mu_T(\Gamma_{\text{prep}})}$$

and the effective outcome entropy is $-k_B \sum_k w_k \log w_k$. Entropy does not select which branch the actual complete microstate takes. The measure μ_T predicts the branch weights that any record-limited observer must assign before the missing path-history distinctions are recovered. This is the direct entropy handoff to Born-rule closure.

Von Neumann and entanglement entropies map to a declared quantum comparison record, factorization, and access cut. For a retained sector A and unresolved complement $\bar{A}$, the standard reduced record is

$$\rho_A(\theta) = \mathrm{Tr}_{\bar{A}} \rho_{A\bar{A}}(\theta)$$

with entropy

$$S_A(\theta) = -k_B \, \mathrm{Tr}(\rho_A(\theta) \log \rho_A(\theta))$$

Even when the full comparison state is pure, reversible, or measure-preserving, S_A can be nonzero because correlations with $\bar{A}$ have been excluded from the retained record. In $\mathbb{AAA}$ this is an access-cut entropy: the same mathematical role must be recovered as coarse-graining over unresolved path-history, apparatus, boundary-wake, and Noether sea correlations that cross the declared cut.

The native carrier is the provenance graph across the access cut. For a cut Σ separating retained sector A from complement $\bar{A}$, build

$$G_{\text{prov}}(\Sigma) = (V_A \sqcup V_{\bar{A}}, E_\Sigma)$$

where vertices are retained roots on the two sides and an edge records that two roots share a compatible transmitter worldline segment. The record entropy across the cut is governed by the number of transmitter-history assignments compatible with the same boundary hit record,

$$S^{\text{rec}}_\Sigma \sim k_B \log |\mathrm{Assign}\left(G_{\text{prov}}(\Sigma), \mathcal{B}_\Sigma\right)|$$

The global record can remain pure or closed because G_{prov} is connected in the complete history, while the retained subregion is mixed because the edge cut has hidden the complementary provenance.

This gives a native area-law route. The access-cut entropy is bounded by the crossing-edge capacity $|E_\Sigma|$: it cannot exceed the log of the compatible assignments carried by provenance edges that thread the cut. For a horizon interface, the terminal-alignment target becomes the special case in which the crossing-edge density is set by aligned Noether braid patches and their admissible labels $(\chi_u, N_{s,u}, M_{p,u})$. The $1/4$ coefficient is then a statement about cut capacity per retained patch area, not a coefficient fitted after a separate horizon entropy has been assumed.

For a coding record with source distribution $P = \{p_i\}$, the Shannon entropy in bits is

$$H_2(P) = -\sum_i p_i \log_2 p_i$$

This has a precise compression interpretation: for any prefix-free code $\mathcal{C}$ that encodes symbols drawn from P, the average code length obeys

$$\bar{L}_{\mathcal{C}}(P) \geq H_2(P)$$

with block codes able to approach the bound under the usual coding assumptions. In $\mathbb{AAA}$, this is not free-floating information. It is an entropy of a declared symbol record, model class, and decoding channel.

Cross-entropy makes the model dependence explicit. If an encoding or prediction model uses $Q = \{q_i\}$ while the retained source record is distributed as P, the expected code length is

$$H_2(P, Q) = -\sum_i p_i \log_2 q_i$$

The excess over $H_2(P)$ measures model mismatch, not a new substrate ingredient. This is why next-symbol prediction and compression can be equivalent for a predictive coding apparatus while remaining an observer-level modeling statement. The entropy becomes physical only after the symbol carrier, probability source, encoder, decoder, training or update channel, and device/boundary cost are part of the same record.

Record entropy maps to durable alternatives in an apparatus or observer channel. A record is not merely a symbolic label. It is an assembly/environment state that persists long enough to be read, copied, or reset within a declared window.

Horizon entropy maps to observer-accessible boundary or horizon-interface label capacity. It is not a literal statement that the Euclidean void is made of area bits. The label count must be derived from strong-field Noether sea and Family-A records.

Computation entropy maps to implemented device cost. Bit logic alone does not create a thermodynamic cost. A cost claim is physical only after the device state space, success criterion, reset operation, heat/work ledger, and boundary exchange have been declared.

Mapping out to Effective Physics

The outward map from $\mathbb{AAA}$ to effective entropy has five steps.

First, choose the physical window W and the record carrier: apparatus, boundary wake data, Noether sea state, simulation domain, or Physical Observer record. When work extraction is in view, also choose the allowed control/readout class. Second, choose the coarse-graining $\mathcal{Q}$ that defines which complete histories count as the same retained state. Third, push the complete-history measure forward through $\Pi_{\mathcal{Q},W}$. Fourth, compute the entropy functional on the retained measure. Fifth, compare that result to the relevant effective law only with the same record still in force.

For open or cosmological windows, entropy bookkeeping must expose production, boundary flux, and record-change residuals:

$$\frac{dS_{\mathcal{Q},W}}{dT} = \sigma_W(T) - \int_{\partial W(T)} (\mathbf{J}_S - s_{\mathcal{Q}} \mathbf{u}_{\partial W}) \cdot \hat{\mathbf{n}}\, dA + \mathcal{R}_{\mathcal{Q}}(T)$$

Here σ_W is local production inside the retained window, $\mathbf{J}_S$ is entropy flux through the boundary, $s_{\mathcal{Q}}$ is the retained entropy density, $\mathbf{u}_{\partial W}$ is the velocity of a moving window boundary, and $\mathcal{R}_{\mathcal{Q}}$ records changes in the coarse-graining or retained record set. For a fixed window, $\mathbf{u}_{\partial W} = \mathbf{0}$ and the expression reduces to the ordinary boundary-flux form.

On a regular observer chart, the projection rank, retained variables, reference measure, and coarse-graining are fixed. When a branch fold, record separator, projection-rank change, or coarse-graining handoff changes that chart, $\mathcal{R}_{\mathcal{Q}}$ is the bookkeeping correction produced by comparing the old and new record maps. It is not a local production term and must not be absorbed into σ_W or the boundary flux. A quantitative chart-change row must name both maps and compare them through a declared common refinement; otherwise an apparent entropy jump cannot be assigned uniquely to physical irreversibility rather than changed bookkeeping.

A monotone entropy statement is therefore conditional:

$$\frac{dS_{\mathcal{Q},W}}{dT} \geq 0 \quad \Longleftrightarrow \quad \sigma_W(T) + \mathcal{R}_{\mathcal{Q}}(T) \geq \int_{\partial W(T)} (\mathbf{J}_S - s_{\mathcal{Q}} \mathbf{u}_{\partial W}) \cdot \hat{\mathbf{n}}\, dA$$

for the declared record. The phrase “entropy of the universe” is not a complete claim unless it supplies the measure, window, boundary, and residual terms.

The entropy-arrow theorem target ties this boundary term to wake escapement. Let $\mathcal{E}_{\rm esc}(W)$ be the wake-escapement set defined in Energy, and let $\Sigma_{\rm esc}(\mathcal{E}_{\rm esc}(W), T)$ be the rate at which retained path-history distinctions leave W on causal wakes that no longer hit a retained receiver. The structural target is

$$\frac{d}{dT} S_{\Pi,W}(T) = k_B\, \sigma_W^{\rm int}(T) + k_B\, \Sigma_{\rm esc}\left(\mathcal{E}_{\rm esc}(W), T\right) + \mathcal{R}_{\Pi,W}(T)$$

on a fixed coarse-graining and boundary convention. In words: observer-window entropy production equals the retained-history distinctions lost to escaping wakes plus the declared interior production and projection-residual terms. The thermodynamic arrow is therefore a theorem target about the same causal-wake boundary ledger used by finite-window energy bookkeeping, not a second primitive arrow.

The same memory-boundary flux has several readings in the dynamics stack. As an energy 0-form it is wake escapement; as a corrected symplectic 2-form it is the $\omega_{\rm mem}$ leak in Effective Lagrangian; as a momentum 1-form it is the response-center drift obstruction in Energy; and as a record count it is entropy production. A retained branch is energy-flat, Hamiltonian-promotable, response-center stable, and entropy-flat only when this memory-boundary flux is recurrent over the return window. A secular boundary flux is the common source of apparent dissipation, non-Hamiltonian projection, center drift, and observer-window entropy growth.

Second Law and Same-Record Monotonicity

The traditional second law has several equivalent-looking forms only after the comparison class has been fixed. Clausius uses a cycle or reversible-comparison statement, Kelvin-Planck forbids a cyclic device from converting heat from one reservoir wholly into work, Boltzmann says overwhelmingly many compatible microstates lie in larger macrostates, and Maxwell-demon analyses require memory and reset costs to be included. These are not four independent substances called entropy. They are four projections of the same discipline: the complete thermodynamic packet must not shrink the retained compatible-history record for free.

The traditional slogan that entropy increases is therefore a shorthand. The safer statement is that, for an admissible isolated comparison with fixed record class and no hidden boundary or apparatus reset, the retained entropy must not decrease beyond the allowed finite-window fluctuation. It can remain constant in an ideal reversible comparison, and it can be exactly zero for a singleton exact-history partition that has stopped asking a thermodynamic question. Irreversibility enters when the retained macrostate loses access to distinctions that the complete deterministic history still contains.

The conservation instinct behind stronger universal-entropy claims should therefore be placed at the complete-ledger level, not written as a universal entropy equality. Energy, architrino inventory, causal-root provenance, and complete path history may close on the full same-record ledger while $S_{\mathcal{Q},W}$ still increases for a finite observer window because $\Pi_{\mathcal{Q},W}$ has projected away distinctions the complete state still carries. The $\Delta S_U = 0$ shorthand is not the rule; the rule is same-record closure plus projection-dependent entropy accounting.

In $\mathbb{AAA}$, the second law is therefore not the source of absolute time and not a primitive command that a substance called entropy must always rise. It is a finite-window typicality and bookkeeping claim over a declared record. For a fixed window, coarse-graining, boundary record, and apparatus/control class, the same-record second-law diagnostic is

$$\Delta S_{\mathcal{Q},\mathrm{tot}}(\theta_W; T_i, T_f) = \Delta S_{\mathcal{Q},W} + \Delta S_{\mathcal{Q},\partial W+\mathrm{env}} + \int_{T_i}^{T_f} \mathcal{R}_{\mathcal{Q}}(T)\, dT \geq -\epsilon_{\mathrm{fluc}}(W, \mathcal{Q}, T_f - T_i)$$

Here $\Delta S_{\mathcal{Q},W}$ is the retained entropy change inside the window, $\Delta S_{\mathcal{Q},\partial W+\mathrm{env}}$ is the boundary and environmental entropy change assigned by the same record, $\mathcal{R}_{\mathcal{Q}}$ records changes in the retained coarse-graining or record set, and ϵ_{fluc} allows finite-window statistical fluctuations. In the macroscopic thermodynamic regime, ϵ_{fluc} is negligible for ordinary comparisons. In microscopic or short-time windows it is not.

This formula explains how the familiar readings fit together. For an isolated macroscopic packet with fixed coarse-graining and no boundary term, it reduces to the usual effective statement $\Delta S \gtrsim 0$. For a refrigerator, cell, planet, or reaction network, $\Delta S_{\mathcal{Q},W}$ may be negative while the boundary and environment term is larger and positive. For an ideal reversible comparison, the inequality is saturated. For an irreversible comparison, the residual is positive. For a Maxwell-demon packet, the memory, actuator, partition, target, and reset channel must all be included in the same θ_W, or the apparent violation is a split-record error.

Record-circularity pressure lands exactly here. The second law does not by itself prove that a present record descends from a low-entropy past; it uses a low-defect boundary condition and ordinary history-backed records to make the second-law inference trustworthy. In this chapter that burden is not hidden. The path-history measure, boundary-condition prior, and observer record all belong in θ_W, and the Boltzmann-brain residual $\mathcal{R}_{\mathrm{BB}}(\theta)$ below is the extreme test of whether isolated observer-fluctuation records have been suppressed relative to shared history-backed records.

What survives from the traditional interpretation is strong: thermodynamics is not being rejected. Heat engines, irreversible mixing, work availability, macrostate dominance, memory reset, decoherence, and horizon bookkeeping remain real effective constraints. What changes is the level assignment. The second law is a theorem target about projected deterministic histories and declared records, not an ontological rival to the substrate dynamics.

Same-Record Closure Rule

A thermodynamic packet has one declared record. In a local horizon, measurement, computation, or near-equilibrium simulation, write that record schematically as

$$\theta_W = \left(\mathcal{H}^W, \mathcal{B}^{(O)}(W), \mathcal{N}_{\mathrm{sea}}|_W, O_W, \Pi_{\mathrm{eff}}, \mu_\theta\right)$$

where $\mathcal{H}^W$ is retained path-history data, $\mathcal{B}^{(O)}(W)$ is observer-accessible boundary or apparatus record data, $\mathcal{N}_{\mathrm{sea}}|_W$ is the resolved Noether sea state on the window, O_W is the observer clock/ruler/readout state when an observer is part of the comparison, Π_{eff} is the effective projection, and μ_θ is the conditional measure over unresolved deterministic histories.

The admissible comparison has the form

$$(S,\, T,\, dQ,\, \Delta E,\, \{p_i\},\, \mathcal{B}_{\mathrm{rec}}) = \mathcal{P}_{\mathcal{Q},W}(\theta_W)$$

where all listed quantities are projections of the same θ_W. If entropy is computed from one θ_W, temperature from another, Born-style basin weights from a third, and flux from a fourth, the packet has not derived a closure. It has fitted separate descriptions.

This rule is why entropy appears as a discipline across many chapters. It protects the Born-rule program from using one ensemble for outcome weights and another for apparatus thermodynamics. It protects horizon thermodynamics from assigning independent entropy, temperature, and stress records. It protects computation-cost claims from treating logical form as a free physical process.

In the language of the core definition, the same-record rule says that entropy, temperature, heat flux, basin weights, and record costs must all factor through one projection of the same fiber. Fitting them from separate ensembles is a split-fiber error: the quantities may be individually meaningful, but the packet has not shown that they are compatible projections of one physical record.

Entropy and Absolute Time

Absolute time is the ordering parameter of the substrate law. Entropy does not create it. The causal arrow enters the dynamics through delayed causal wakes: only emissions from $T_t < T_r$ can contribute to a receiver at reception time T_r. Thermodynamic, biological, measurement, and cosmological arrows are finite-window consequences of dynamics, boundary conditions, and retained records.

Even if the complete deterministic dynamics preserve the underlying measure, the observer-window entropy $S_{\Pi,W}$ can increase when $\Pi_{Q,W}$ discards path-history, boundary-wake, or apparatus-record information. That increase is a projection effect inside the declared record. It is not evidence that time itself is generated by entropy.

The arrow-of-time closure problem is therefore sharper than a generic second-law slogan. A mature account must explain why the admissible early record is low-defect or low-entropy in the relevant coarse-graining, and why later macroscopic reversal would require reconstruction of path-history and wake-phase detail no finite observer or apparatus can retain.

The past-hypothesis comparison also depends on the partition. A nearly uniform early matter record can look high entropy under a non-gravitating gas coarse-graining and low entropy under a gravitational coarse-graining, because gravitational clumping, potential-energy release, and horizon labels open far larger compatible records later. In $\mathbb{AAA}$ the lesson is not that gravity is entropy. It is that a cosmological entropy statement must name whether its macrostate includes Noether sea state, potential gradients, causal-wake boundary data, and horizon-interface records.

The standard cosmology comparison gives a useful scale check for this distinction. Standard-literature estimates often summarize a radiation-only CMB count as $S_{\gamma,\mathrm{CMB}} \sim 10^{89} k_B$, the present observable universe as black-hole dominated with $S_{\mathrm{BH,pop}} \sim 10^{104} k_B$, and a rough maximum black-hole-like entropy for the same mass-energy budget near $S_{\max} \sim 10^{123} k_B$. In this chapter those numbers are not treated as substrate entropy of the Euclidean void. They are comparison-scale records: the closure target is to recover the ordering $S_{\gamma,\mathrm{CMB}} \ll S_{\mathrm{BH,pop}} \ll S_{\max}$ only after the radiation, matter, Noether sea, and horizon-interface coarse-grainings are all declared. The corresponding Penrose-style initial-state fraction is a benchmark for the size of the compatible-history fiber,

$$f_{\mathrm{early}} \sim \exp\left[-\frac{S_{\max} - S_{\mathrm{early}}}{k_B}\right] \approx \exp(-10^{123})$$

not proof that an external random draw selected the universe.

Heat Death and Its Escapes

Claim level: the first escape is conditional on a measure-preservation certificate for the retained delayed-history flow; the negative-heat-capacity and horizon comparisons are standard physics observations stated at effective grade. A cyclic or recycling cosmology that would use them remains an open target.

A pure relaxation to maximum entropy — classical heat death — is not forced in this framework, and three openings keep the arrow from having to terminate. First, on a retained regularized branch for which the delayed flow is invertible and preserves the declared history measure, the fine-grained entropy is constant while coarse-grained observer-window entropy can rise. That is a conditional measure-preservation result, not a consequence of determinism alone; without the certificate, fine-grained entropy conservation remains a closure target and cannot yet support a globally reversible cosmological history. Second, self-gravitating systems have negative heat capacity and no equilibrium maximum-entropy state — the horizon-labelled records keep growing, as the ordering $S_{\gamma,\mathrm{CMB}} \ll S_{\mathrm{BH,pop}} \ll S_{\max}$ above already shows — so the premise that every gradient equilibrates and all shedding stops may simply be false. Third, a cosmological de Sitter-like horizon carries an entropy that grows with its area, so the accessible ceiling $S_{\max}(T)$ can recede at least as fast as $S(T)$ climbs; the record chases a moving bound rather than reaching a fixed one.

These are openings, not a mechanism. Any concrete cyclic or recycling cosmology that would exploit them must still close a global entropy ledger — every local decrease over-paid by disorder exported elsewhere — and that accounting, together with a named substrate driver, remains open work rather than a result asserted here.

Boltzmann-brain pressure exposes the same rule in extreme form. A retained observer record cannot certify the low-entropy history that is then used to certify the retained observer record. The packet must separate the internal consistency of a memory record from the boundary-condition claim that the record descends from a shared low-defect universe path history. Let Γ_{hist} denote compatible complete histories in which observer records, cosmological traces, and low-defect boundary data descend from one shared path-history record. Let Γ_{BB} denote compatible complete histories in which an observer record is an isolated high-entropy fluctuation with no shared supporting cosmological record. The corresponding fluctuation residual is

$$\mathcal{R}_{\mathrm{BB}}(\theta)=\frac{\mu_\theta(\Gamma_{\mathrm{BB}})}{\mu_\theta(\Gamma_{\mathrm{hist}})}$$

for the same declared measure, coarse-graining, and access window. A mature same-record entropy cosmology requires $\mathcal{R}_{\mathrm{BB}}(\theta)\ll 1$ or an explicit reason why the comparison class is not admissible. Otherwise the theory has only renamed the circularity: records infer a low-entropy past, while the assumed low-entropy past is what made the records trustworthy.

The delayed dynamics supply a sharper discriminator than the bare measure ratio. For a candidate observer record O_W, define the wake-concordance order parameter

$$\mathcal{K}(O_W)=\frac{\#\{\text{roots at } O_W \text{ sharing a transmitter worldline with roots at neighboring receivers}\}}{\#\{\text{incoming roots at } O_W\}}$$

with the denominator restricted to the retained incoming roots in the declared window. Equivalently, $\mathcal{K}$ is the local edge-connectivity fraction of G_{prov}: it measures how many retained incoming roots share transmitter-worldline edges with neighboring receivers' roots. History-backed records are expected to have $\mathcal{K}\to 1$ because the same matter and Noether sea transmitters illuminate a neighborhood with correlated causal timing. Isolated fluctuation records have $\mathcal{K}\to 0$ unless they also fabricate shared-transmitter concordance across neighboring receivers. Thus low-$\mathcal{K}$ configurations are measure-suppressed rather than forbidden by provenance mismatch, and high-$\mathcal{K}$ fluctuation records are costly because they require coherent transmitter-history coincidences, not only a memory snapshot. At this claim level, high-$\mathcal{K}$ fluctuations are treated as measure-suppressed rather than forbidden; forbiddance would require a separate theorem that no compatible transmitter-history assignment exists.

Measurement and Computation

Measurement records require entropy locking. For a declared apparatus/environment channel,

$$\Delta S^{\mathrm{app+env}}_{\mathcal{Q},W}=S^{\mathrm{app+env}}_{\mathcal{Q},W}(T_{\mathrm{rec},0}+T_{\mathrm{rec}})-S^{\mathrm{app+env}}_{\mathcal{Q},W}(T_{\mathrm{rec},0})$$

is the entropy change associated with the candidate record, with $T_{\mathrm{rec},0}$ the start of the record-formation window. A strong record candidate satisfies

$$\Delta S^{\mathrm{app+env}}_{\mathcal{Q},W}\geq S_{\mathrm{lock}}>0$$

with S_{lock} fixed by the apparatus class and readout channel. This is not a collapse law. It is the requirement that the branch has exported enough unresolved apparatus/environment history that coherent reversal is no longer part of the retained measurement window.

Resetting a memory-bearing apparatus with N distinguishable retained record classes also requires a physical entropy ledger:

$$\Delta S^{\mathrm{app+env}}_{\mathcal{Q},W}\geq k_B\log N-k_B\varepsilon_\mu,\qquad N\geq 2$$

with ε_μ the declared measure/readout tolerance.

For a non-uniform retained distribution, $k_B \log N$ is replaced by $-k_B \sum_i p_i \log p_i$.

A Maxwell-demon packet therefore has two admissible readings. If the demon does not reset, it spends a low-entropy blank-memory record as a resource and converts that resource into a pressure, temperature, or sorting record. If the demon is required to act cyclically, the memory, actuator, partition, target system, and boundary environment must return to the same physical record. A cyclic packet that claims to sort a broad complete-history region into a narrower one while preserving the same boundary and memory record is not a thermodynamic miracle. It is a failed same-record closure.

The same logic applies to computation. For an implemented step s with completion probability p_s, a lower-bound claim must attach to the device and boundary records:

$$\Delta S_{\mathrm{env},s} + \Delta S_{\mathrm{target},s} + \Delta S_{\mathrm{boundary},s} \geq k_B \log(1/p_s) - \epsilon_s$$

The inequality is not a new law of symbols. It states the burden that the same physical record defining success must also supply the entropy, heat, work, and boundary terms used to claim a cost.

Horizons and Emergent Gravity

Horizon entropy is the most stringent test of this mapping because it connects record counting, effective geometry, energy flux, and unitarity pressure. The useful comparison target is not that gravity is "really entropy." The target is that one strong-field Noether sea record supplies the observer-level entropy, temperature, flux, and metric response together.

For an observer-accessible local horizon patch $\partial\Omega$, the boundary-label entropy target is

$$S^{(O)}_{\partial\Omega}(\theta; W) = k_B \log \left| \mathcal{B}^{(O)}_{\partial\Omega}(\theta; W) \right|$$

with $\mathcal{B}^{(O)}_{\partial\Omega}$ defined by retained boundary-wake labels readable by the same Physical Observer record. The local Clausius comparison becomes a residual or variation target:

$$\delta_\ell Q^{(O)}_{\partial\Omega} = T^{(O)}_U \delta_\ell S^{(O)}_{\partial\Omega} + \mathcal{O}(k_B T^{(O)}_U \epsilon_{\mathrm{local}})$$

This is a recovery target, not a postulate. The proof fails if $S^{(O)}_{\partial\Omega}$, $T^{(O)}_U$, $dQ^{(O)}_{\partial\Omega}$, and the effective metric are assigned independent records.

For black holes, the area-law coefficient must come from terminal Family-A alignment and horizon-interface label compatibility. For a connected block U of alignment-area patches,

$$s_{\mathrm{align}}(\theta) = \lim_{|U|\to\infty} \frac{1}{|U|} \log |\mathcal{L}_U(\theta)|$$

when the limit exists after boundary corrections. The required coefficient is area-normalized:

$$\frac{s_{\mathrm{align}}(\theta)}{a_\theta} \longrightarrow \frac{1}{4}$$

This target avoids a false one-patch interpretation. The coefficient is a block entropy density and patch-area normalization, not a literal independent count on one microscopic patch.

The label set is not arbitrary. At terminal alignment a Family-A braid collapses its binary-axis directions onto one interface axis, so the surviving discrete labels are the handedness assignment and the causal-root ledger index still carried by the aligned branch. In a block U,

$$|\mathcal{L}_U(\theta)| = \prod_{u\in U} \# \{(\chi_u, N_{s,u}, M_{p,u}) : \text{admissible at patch } u\}$$

where χ_u is the retained terminal-alignment handedness label and $(N_{s,u}, M_{p,u})$ is the local self-hit and partner-hit root-ledger index. The $1/4$ coefficient is therefore a falsifiable statement about the per-patch admissible ledger multiplicity and the patch area a_θ in the accepted alignment units, not a coefficient to fit after the fact.

Page-curve, island, replica-wormhole, Ryu-Takayanagi, and AdS/CFT calculations remain high-value comparison mathematics. They sharpen the required entropy and unitarity bookkeeping. They do not provide the $\mathbb{AAA}$ mechanism unless their constraints are recovered from horizon-interface labels, path-history bookkeeping, Noether sea storage, and release-channel selection.

Entanglement-entropy calculations sharpen the access-cut side of that same problem. A horizon partition can make an outside retained record mixed while the full comparison record remains closed. The native target is therefore not to import an abstract inaccessible complement as ontology, but to derive which horizon-interface labels, Noether sea storage modes, and release-channel selections play the role of the traced-out complement.

Failure Modes

The most common failure mode is an unqualified entropy statement. An entropy claim is incomplete when it omits the measure, coarse-graining, access window, retained record, or boundary terms.

Another failure mode is disembodied information. Shannon uncertainty over symbols is not automatically heat, work, Clausius entropy, or physical record cost. A compression or prediction score is a statement about a declared symbol model and record channel. It becomes thermodynamic only when implemented through an apparatus and boundary ledger.

A third failure mode is entropic gravity as a substitute for the mass mechanism. Thermodynamic or entropic derivations of force are comparison benchmarks, but inertial mass remains open until the assembly ledger supplies closed internal causal history, shielding extraction, Noether sea response, and acceleration response.

A fourth failure mode is fitted horizon bookkeeping. If a black-hole or local-horizon packet uses one record for entropy, another for temperature, another for stress, and another for release channels, the apparent agreement is not a native closure.

The fifth failure mode is promoting entropy into time. Entropy can diagnose an emergent arrow inside a stated physical and inferential window. It does not supply the absolute ordering parameter T.

A sixth failure mode is confusing entropy with complexity. Low entropy can be simple, maximum entropy can be simple, and complex organized structures normally belong to driven intermediate windows that export more entropy than they locally suppress. For $\mathbb{AAA}$, biological or self-organizing examples are open-window bookkeeping, not exceptions to deterministic dynamics.

A seventh failure mode is record circularity. If a packet uses retained records to infer a low-entropy past while also using that inferred low-entropy past to justify the reliability of the retained records, it has not closed the arrow-of-time problem. It must expose the same-record path-history measure and boundary-condition prior that suppress isolated observer-fluctuation records relative to history-backed observer records.

An eighth failure mode is treating “entropy never decreases” as a primitive second law. Clausius entropy depends on a reversible-cycle integrability condition, statistical entropy can fluctuate in small or finite windows, and resource entropy depends on the declared control/readout class. A packet must state which second-law form it is invoking before monotonicity has content.

A ninth failure mode is quoting entanglement entropy without declaring the factorization and access cut. A subsystem entropy is not automatically entropy of the whole universe. It is a statement about what remains after a complement has been excluded from the retained record.

A tenth failure mode is promoting present human or laboratory macrostates into the final state-space partition of the universe. Heat-death claims, order claims, and “maximum entropy” claims must declare the manipulation class and record system for which usable gradients are exhausted. Otherwise they have converted a useful thermodynamic extrapolation into an unsupported ontology of all future access.

Interfaces

The energy-side residuals are stated in Energy. The time-side arrow distinction is stated in Absolute Time. Measurement locking is stated in Measurement Ontology. Computation cost is treated in Information / Computation. Local-horizon recovery is stated in Emergent Metric, with the simulation-facing scaffold in Thermodynamic Residual. The strong-field horizon target is stated in Black Holes.

The consolidated rule is simple: entropy is accepted only as a declared projection of retained deterministic histories, and every effective entropy claim must name the record that makes the projection physical.

Binary Dynamics

This chapter starts with the simplest possible assembly question: what happens when one Electrino and one Positrino try to stay together under delayed causal wakes? The answer is not ordinary central-force orbit mechanics. Each architrino responds to where the partner was when the relevant wake was emitted, not to where the partner sits at the same absolute time.

That delay makes the binary the first serious test of the Master Equation. Partner hits, self-hits, branch birth, caustic onset, circular anti-damping, non-circular spiral hypotheses, and maximum-curvature binary analysis all appear here before they are used in larger Noether braid structures. Two status boundaries govern the chapter: self-hit makes the dynamics non-Markovian (path-history dependent), and stability or attractor claims are conjectural unless explicitly established.

Read the chapter as a branch atlas, not as a single orbit story. The partner-only contribution shows why ordinary circular central-force intuition fails. The self-hit records show where the system becomes path-history dependent. The maximum-curvature and spiral sections are candidate ways to control that delayed feedback, and each must close its own root, action, wake, and stability ledger before it can become an assembly building block.

Claim-status convention. A **derived** statement follows from the declared circular or history-space equations on its stated chart. A **conditional** statement follows only under the assumptions named with it. A **target** states a proof or certificate obligation that is not yet closed. A **diagnostic** is a computable comparison or branch record whose agreement does not by itself promote the underlying claim. These labels apply chapter-wide; an unlabeled explanation does not upgrade a conditional, target, or diagnostic statement.

This chapter is the foundational precursor to A1 Dynamics, A3.3 Doubling-Frequency Resonance Lock, Master Equation, and the assembly-level Noether Braid. The primitive-entity ontology in Architrino points here once the discussion becomes a behavioral regime or assembly-stability mechanism.

The Spiral Orbiting Binary and the Contraction Phase

An orbiting binary is the simplest emergent assembly, consisting of two architrinos of opposite polarity: an Electrino and a Positrino. With polarities $-\epsilon$ and $+\epsilon$, the assembly is electrically neutral overall. This system is the first teaching case for delayed causal wakes, partner-hit contraction, and the self-hit onset boundary.

Consider the ideal case of a symmetric orbit in a universe with no other architrinos. In general, each architrino is subject to a superposition of external causal wake contributions from all other transmitters; the analysis below isolates the binary by setting those external contributions to zero.

Let the Electrino be architrino 1 and the Positrino be architrino 2.

- **Positions:** $\mathbf{X}_1(T)$ and $\mathbf{X}_2(T)$
- **Polarities:** $q_1 = -\epsilon$ and $q_2 = +\epsilon$

The motion of each architrino is determined by the wake emitted by the other at a delayed time. The acceleration of the Electrino (architrino 1) at absolute time T is caused by the Positrino's (architrino 2) wake emitted at an emission time T_t. This is governed by the interaction condition:

$$\|\mathbf{X}_1(T) - \mathbf{X}_2(T_t)\| = c_f(T - T_t)$$

The acceleration vector for the Electrino is attractive, pointing towards the Positrino's delayed position:

$$\mathbf{A}_1(T) \propto -\hat{\mathbf{r}}_{21} = -\frac{\mathbf{X}_1(T) - \mathbf{X}_2(T_t)}{\|\mathbf{X}_1(T) - \mathbf{X}_2(T_t)\|}$$

The Electrino's emissions govern the Positrino's symmetric response through the corresponding partner equation.

In the strictly sub-field-speed regime (no self-interaction, $\|\mathbf{V}\| \le c_f$), a stable, circular orbit is impossible. Because the attractive acceleration on each architrino points to the *past* position of its partner, it is not a true central acceleration. The principal circular branch proves a sharper direction diagnostic: the partner line of action has a forward tangential projection, so the partner-only near-circular ledger is anti-damped rather than a contraction proof. This diagnostic is not a receiver-side acceleration-balance certificate. A logarithmic inward spiral can still be used as a separate non-circular ansatz or capture target, but its radial tightening must be certified by solving that branch chart with same-record transmitter-side acceleration weight; it is not implied by the principal circular sign.

The receiver-side reduction makes the direction test exact. The signed pitch $p = -\dot{r}/(r\omega)$ is positive while the binary spirals inward and negative while it spirals outward. The closed spiral-direction flow computes how that sign changes from the radial and azimuthal wake contributions.

The practical conclusion is narrower than "binaries spiral in" or "binaries spiral out." A binary cannot follow an exact logarithmic spiral while simultaneously keeping a fixed spiral tightness, a fixed angular rate, and only one principal delayed partner root. Those assumptions are mutually incompatible under the transmitter-side Master Equation. An actual spiral must change its tightness or angular rate, acquire another causal root, enter the self-hit regime, or receive additional multi-body contributions. The formulas decide the direction once that evolving branch history is supplied.

Standard central-force mechanics conserves angular momentum because the force at absolute time T is collinear with the equal-time separation vector. The partner-hit branch does not have that geometry. Define the equal-time separation and delayed line of action by

$$\mathbf{r}_{12}^{\text{eq}}(T) \equiv \mathbf{X}_1(T) - \mathbf{X}_2(T), \qquad \hat{\mathbf{r}}_{12}(T; T_t) = \frac{\mathbf{X}_1(T) - \mathbf{X}_2(T_t)}{\|\mathbf{X}_1(T) - \mathbf{X}_2(T_t)\|}$$

The delayed partner branch carries the angular-momentum-change direction

$$\mathbf{r}_{12}^{\text{eq}}(T) \times \hat{\mathbf{r}}_{12}(T; T_t)$$

which is generically nonzero because $\mathbf{X}_2(T_t)$ is not the partner's equal-time position. Therefore the usual angular-momentum barrier and the instantaneous effective potential

$$V_{\text{eff}}(r) = V(r) + \frac{ml^2}{2r^2}$$

cannot be imported as the binary's governing reduction. A conserved angular-momentum-like quantity, if present, must include the causal-wake history term that balances the delayed torque.

Circular root-playback simplification for the sub-field partner contribution. In units with $c_f = 1$, the circular speed is $s = R\omega$. On the non-translating symmetric circular chart, the transmitter and receiver velocity projections on every retained chord are equal. If two points on the circle have angles a and b, then

$$\mathbf{e}_\theta(a) \cdot (\mathbf{e}_r(a) - \mathbf{e}_r(b)) = \sin(a - b) = \mathbf{e}_\theta(b) \cdot (\mathbf{e}_r(a) - \mathbf{e}_r(b)).$$

Thus $D_r = D_t$ and the signed root-playback derivative is one for every retained root on this chart. The acceleration weight is instead $W^{\text{acc}} = c_f/|D_t| = 1/|J^t|$. The circular partner contribution gives

$$T_p \propto \frac{\sin(\delta_p/2)}{\cos^2(\delta_p/2)} \quad (0 < \delta_p < \pi)$$

where δ_p is the partner delay angle. This is a canonical acceleration contribution only for the non-translating symmetric circular benchmark; deformed, translating, or non-circular histories must recompute the same-record D_t, D_r, and W^{acc} before any acceleration-balance conclusion is promoted.

- The circular geometry gives a positive tangential acceleration contribution for the partner-only ledger.
- The radial component points inward, but inward radial pull plus positive tangential work does not by itself prove a tightening spiral.

With perfectly symmetric initial conditions, the paths of the electrino and positrino are distinct but mirror-related. If the branch begins as a radial fall or enters a non-circular capture basin, it may still contract, but that is a separate branch-history statement. Emission cadence and intrinsic per-wavefront amplitude remain constant, while the **received** acceleration is velocity-dependent because the causal-delay Jacobian compresses or dilates the causal flux along each active branch. For action or wake-history rates accumulated along a moving receiver path, the same root also carries the receiver-side factor $dT_{t,\ell}/dT = (c_f - \hat{\mathbf{r}}\cdot\mathbf{V}_i(T))/(c_f - \hat{\mathbf{r}}\cdot\mathbf{V}_j(T_{t,\ell}))$. The evolution is therefore driven by delay geometry, branch bunching, receiver-path sampling, and, once active, self-interaction.

Initially, and as long as the speeds of both architrinos are less than or equal to the wake propagation speed c_f, they are only influenced by their partner's attractive wake. The total acceleration is simply the attractive acceleration contribution:

$$\mathbf{A}_{1,\mathrm{total}}(T) = \mathbf{A}_{1,2}(T) \quad \text{and} \quad \mathbf{A}_{2,\mathrm{total}}(T) = \mathbf{A}_{2,1}(T)$$

During this partner-only phase, the retained circular contribution has an inward radial component and a forward tangential work term. That combination is anti-damping: it accelerates the orbiting motion and prevents a partner-only constant-speed circle. Any sub-field-speed contraction claim must come from a certified non-circular branch, a capture basin, or an explicit finite-window wake-history account.

Ideal Symmetric Spiral Ansatz

The ideal binary spiral used in this opening analysis is not the same geometry as the later maximum-curvature circular benchmark. It is a **symmetric logarithmic-spiral ansatz**: the electrino and positrino follow two distinct planar curves related by the binary symmetry. At equal absolute time they remain opposite about the midpoint in the ideal center frame, but each architrino's path is the mirror-conjugate of the other's path rather than the same curve traced by both architrinos.

This matters because the ideal spiral is a **transient, scale-similar contraction ansatz**, not a consequence of the principal circular calculation. Within a fixed velocity regime and fixed active-root ledger, the model assumes that the local acceleration geometry repeats after a scale change and phase advance: radii shrink by a common factor, speeds rise according to the same delayed-geometry rule, and the partner/self branch structure is symmetric between the two architrinos. When the trajectory crosses a threshold such as $\|\mathbf{V}\| = c_f$ or a higher root-birth boundary, that scale-similar description must be re-matched on a new branch chart.

By contrast, the maximum-curvature binary section studies a **uniform circular benchmark**: fixed R, fixed s, and a single circular path geometry used to compute closed-form delay angles, branch Jacobians, and per-hit acceleration components. That circular model is useful as a limiting or diagnostic case, and it gives the anti-damping obstruction that any non-circular contraction story must beat. The detailed non-circular benchmark for the symmetric logarithmic spiral belongs in Master Equation; this chapter uses it only as the conceptual two-body entry point.

Translating Binary Trace

The same binary has a co-moving orbit and an absolute-history trace. If a circular binary translates with center velocity $\mathbf{V}$ while its orbital plane is spanned by orthonormal axes $\mathbf{e}_1, \mathbf{e}_2$, a first kinematic diagnostic is

$$\mathbf{X}_{\pm}(T) = \mathbf{X}_0 + \mathbf{V}T \pm R\left(\cos\omega T\,\mathbf{e}_1 + \sin\omega T\,\mathbf{e}_2\right), \qquad \mathbf{n} = \mathbf{e}_1 \times \mathbf{e}_2.$$

When $\mathbf{V}$ is parallel to $\mathbf{n}$, each architrino draws a constant-pitch helical trace with pitch $2\pi\|\mathbf{V}\|/\omega$ per binary cycle. At a tilted orientation, the absolute-history trace combines longitudinal pitch $2\pi|\mathbf{V}\cdot\mathbf{n}|/\omega$ with transverse drift from $\mathbf{V} - (\mathbf{V}\cdot\mathbf{n})\mathbf{n}$. This trace is a visualization and solver diagnostic, not a stability proof: the dynamical question is still whether the translated path-history ledger retains the same active causal roots, Jacobian floors, energy/action records, and branch identity.

Spiral Momentum Budget Across the Hinge (Speculative)

This subsection records a modeling hypothesis rather than a derived law. The desired closure would link the spiral path, the per-hit acceleration law, and the angular-momentum budget across the full velocity range. Below the wake speed, the binary feels only partner hits, and the principal circular branch has positive tangential work. A contraction ansatz must therefore explain how radial tightening survives that anti-damping record through non-circular geometry, wake-flux export, or a later multi-root ledger. We introduce a per-cycle gain parameter ΔL_c only as a provisional bookkeeping variable for that unresolved branch-history calculation.

Branch-birth jump target: a smooth doubling rule is too strong unless the active causal-root ledger stays unchanged. On a fixed signed branch chart $b(s)$, the per-cycle escaped angular-momentum entry should instead be written

$$\Delta L_{\text{cycle}}(s) = \sum_{\rho\in b(s)} \ell_\rho^{\text{esc}}(s),$$

where ρ ranges over the active partner and self records that actually send wake angular momentum through the window boundary. At a branch birth the ledger changes, so the cycle budget has a jump law rather than an automatic smooth continuation. At the principal self-hit hinge,

$$\Delta L_{\text{cycle}}(1^+) - \Delta L_{\text{cycle}}(1^-) = \ell_{\text{self},0}^{\text{esc}}(1^+),$$

with the right-hand side evaluated in the same finite-η chart that regularizes the caustic. The older heuristic $\Delta L_c \mapsto 2\Delta L_c$ is recovered only in the special case where the newly born principal self record exports exactly the same cycle increment as the pre-hinge partner ledger.
More precisely, $\ell_{\text{self},0}^{\text{esc}}(1^+)$ is not the value of a divergent pointwise tangential coefficient at the hinge. It is the finite angular impulse

$$\ell_{\text{self},0}^{\text{esc}}(1^+) = \lim_{\eta\to 0^+} \int_{T^-}^{T^+} R(T)\, A_{\text{self},0,\eta}^{\tan}(T)\, dT$$

when that limit exists under the same finite-caustic transit convention used for the velocity impulse. If the impulse limit is regulator-dependent, the branch-birth jump remains a diagnostic record rather than a promoted angular-momentum ledger entry.

This section treats an exponential-in-angle spiral (logarithmic spiral) as a **modeling assumption** rather than a derived law. It sets the bookkeeping target: a path-history acceleration sum whose signed branch-birth increments and boundary wake fluxes yield the spiral contraction. Near $s = 1^+$ the principal self branch inherits the transmitter-side fold onset displayed below, and the canonical acceleration weight is $W^{\text{acc}} = 1/|J_s|$. Its coincident endpoint birth is therefore more singular than the former stripped model, and its verification remains incomplete.

Spiral Binary Field-Speed Symmetry-Breaking Point

The binary system's evolution is organized around the **field-speed symmetry point** $\|\mathbf{V}\| = c_f$. This is a **hinge** where the causal structure changes: below c_f only partner-delay acceleration contributions exist, while above c_f self-hit roots appear. The hinge is not a hard barrier; it is the birth of the principal self branch. In the symmetric circular geometry the self-delay equation is

$$\delta_s = 2s\sin(\delta_s/2), \qquad s = \frac{\|\mathbf{V}\|}{c_f}$$

Writing $s = 1 + \mu$ with $\mu > 0$ small, the principal root satisfies

$$\delta_s \sim \sqrt{24\mu}, \qquad \sin(\delta_s/2) \sim \sqrt{6\mu}$$

The associated branch Jacobian is

$$J_s = 1 - s\cos(\delta_s/2) = 1 - \frac{\delta_s}{2}\cot(\delta_s/2) \sim 2\mu$$

The transmitter-side root-density diagnostics therefore scale as

$$\frac{1}{\sin(\delta_s/2)\,|J_s|} \sim \mu^{-3/2}, \qquad \frac{1}{\sin^2(\delta_s/2)\,|J_s|} \sim \mu^{-2}$$

This is the first major consequence of the transmitter-side Jacobian: the hinge is not merely a change in root count but a genuine **caustic onset** for transmitter-emission density and action counting. On the non-translating symmetric circular chart the equal-projection lemma gives $D_r = D_t$, but $W^{\mathrm{acc}} = 1/|J_s|$. The canonical self-hit acceleration components therefore scale as

$$\frac{1}{\sin(\delta_s/2)|J_s|} \sim \mu^{-3/2}, \qquad \frac{1}{\sin^2(\delta_s/2)|J_s|} \sim \mu^{-2}.$$

The principal self branch therefore has a non-integrable coincident-birth warning in the current analytic control. Any candidate maximum-curvature balance must route that transition through a finite accepted singular-event treatment before appealing to higher-winding smoothing.

Self-Hit: Definition and Diagnostics

Self-hit is the key non-Markovian feature of architrino dynamics. It occurs when an architrino interacts with potential it emitted earlier along its own worldline.

Geometric condition (absolute coordinates): For a given architrino with trajectory $\mathbf{X}(T)$, a self-hit event is a pair of times (T_t, T_{hit}) with $T_{\text{hit}} > T_t$ such that

$$\|\mathbf{X}(T_{\text{hit}}) - \mathbf{X}(T_t)\| = c_f(T_{\text{hit}} - T_t)$$

and the architrino is the transmitter of the causal wake surface emitted at T_t.

Terminology split: Hit type is determined by **transmitter identity**. A **self-hit** has the same transmitter and receiver; a **partner hit** has a different transmitter and receiver. Root count is a separate question: either transmitter can contribute one active causal root or multiple active roots at the same reception time. Thus “self-hit” does not mean “multi-hit,” and “partner hit” does not mean “single-hit.”

Dynamical role:

- On any interval with strict sub-field-speed motion, self-hit is absent by the triangle-inequality root test, unless older path-history emissions from a prior super-field-speed interval remain active.
- As velocities exceed c_f on curved histories, emission isochrons can catch up with the transmitter’s future positions, generating candidate nonlocal feedback and effective restoring or destabilizing accelerations depending on configuration.
- In generic trajectories, once an architrino has exceeded c_f and emitted wakes in that regime, it can later slow below c_f and still experience self-hits from those earlier emissions because the active record is non-Markovian.
- For binary and Noether braid assemblies, repeated self-hit events are a proposed outward barrier against collapse. Stable radii, frequencies, limit cycles, and attractors require separate tangential, radial, wake-boundary, and return-map closure.

For the circular-geometry details (principal angles, winding numbers, discrete self-hit branches), see **Setup and Notation (Symmetric Frame)** in **Maximum-Curvature Binary — Circular**.

Post-Threshold Self-Hit Phase

Once the circular branch admits same-transmitter roots, the architrinos interact with their own earlier, repulsive wakes. The total acceleration on each architrino then becomes a superposition of attraction from its partner and self-repulsion. For the electrino:

$$\mathbf{A}_{1,\text{total}}(T) = \mathbf{A}_{1,2}(T) + \mathbf{A}_{1,1}(T)$$

In the circular benchmark, the principal self-hit branch ($m = 0$) becomes available only on the super-field-speed side; at higher speeds, additional self-hit and partner-hit roots can turn on (see **Root Multiplicity vs. Speed**). The new self-repulsive term, $\mathbf{A}_{1,1}(T)$, grows rapidly as the path curvature increases and changes the tangential ledger. On the same-sheet principal chart that tangential contribution is forward; in the full signed ledger, older sheets can contribute with the opposite tangential sign. This post-threshold phase is therefore a branch-certificate target, not a generic tightening law: any radial arrest or continued contraction must be decided by the signed multi-root ledger, wake-history accounting, and stability certificate described below.

Maximum-Curvature Binary — Circular

Receiver-side validity notice. The circular MCB branch topology, root labels, transmitter-side Jacobian formulas, and canonical acceleration components use $W^{\text{acc}} = c_f/|D_t|$. The algebraic root-ledger result below is therefore a Master EOM measurement on the unregularized circular simple-root chart. Stability, finite-event continuation, action records, and retained-history claims remain outside that measurement.

Once self-hit turns on, the natural question is whether the dynamics converge to a limiting curvature. We call the candidate limit the **maximum-curvature binary (MCB)**. This section collects the full two-body, self-hit analysis for that candidate, including delay geometry, acceleration components, and stability criteria. It is the canonical reference for MCB attractor status.

MCB stability claims rely on the well-posedness of the regularized SD-NDDE. In this chapter we treat $\eta > 0$ as fixed; any $\eta \to 0$ statement is outside the claims established here unless a weak-limit argument is explicitly supplied. The formal state-space framework appears in **State Space and Well-Posedness of the Two-Body Delay System**.

Goal: Characterize the circular, constant-speed, constant-radius configuration of two opposite-polarity architrinos and investigate where curvature $1/R$ is maximized. We work in units with field speed $c_f = 1$ and use the canonical delayed per-hit law with radial line of action and transmitter-side acceleration weight.

Plain language: We seek the tightest (smallest-R) steady circle an opposite-polarity pair can trace when the only acceleration contributions come from delayed line-of-action interactions with the partner and from each architrino's own past emissions. In the canonical transmitter-side law, each retained hit carries $c_f/|D_t|$ as its acceleration weight and D_r/D_t separately for root playback.

Foundational Context (Ontological Clarification)

The Maximum-Curvature Binary (MCB) as Fundamental Unit

The architecture hypothesizes that the **maximum-curvature binary (MCB)** would be reachable first by one declared persistent binary index of a candidate Noether braid. On the super-field-speed circular chart, certified same-transmitter roots can supply only the outward barrier against collapse; centripetal and tangential closure must come from the complete signed ledger. This mechanism does not by itself assign a braid-taxonomy member. If the branch is certified as a stable and reproducible attractor, it would supply candidate **fundamental physical units** (length and time); see **Emergent Properties and Measurement Standards** below for the explicit definitions.

Universal cap target (explicit): If a stable MCB branch is certified, it would define a single limit state with one radius/speed pair. Binaries may sit below that limit, but the claim that no binary can exceed the MCB curvature or pass beyond its defining radius/speed remains conditional on the full signed-root ledger and stability certificate.

If realized, the MCB radius $r_{\min}$ is expected to be determined by the balance of:

1. opposite-polarity causal-wake attraction, with the stripped inverse-square surrogate scaling as ϵ^2/r^2,
2. self-hit repulsion (non-Markovian feedback when same-transmitter roots exist; super-field-speed circular history is the relevant branch),
3. Centripetal requirement for stable circular orbit.

Dynamical priority (attractor status): The architecture hypothesizes the MCB is a **robust attractor**, not a finely tuned periodic orbit. Only if the multipliers lie strictly inside the unit circle and the basin is non-trivial do we have the attractor the architecture relies on. If neutrality or instability is found, the candidate Family-A ladder and broader Noether braid claims must be downgraded or the interaction law revised (e.g., additional damping/medium effects).

Setup and Notation (Symmetric Frame)

- **Two architrinos** with polarity bookkeeping labels $q_1 = -\epsilon$ and $q_2 = +\epsilon$ (where $\epsilon = |e|/6$).
- **Equal-time positions** (in absolute time T) are diametrically opposite on a circle of radius R about the midpoint.
- **Uniform circular motion**: Angular speed ω, constant tangential speed $s = R\omega$.
- **Non-translating binary**: Circle center (midpoint) is fixed in Euclidean 3D space; no net translation.

Translating Binary Handoff to Lorentz Closure

The circular maximum-curvature benchmark is also the rest-frame boundary condition for the first material clock/ruler test. The translating ansatz keeps absolute time and the primitive wake speed explicit:

$$\mathbf{X}_\sigma(T) = uT\,\hat{\mathbf{e}} + \sigma\,\boldsymbol{\rho}_u(\theta(T)), \qquad \sigma \in \{+1, -1\}$$

where $\boldsymbol{\rho}_0$ is the circular branch studied here and $\boldsymbol{\rho}_u$ is the deformed periodic orbit, if it exists, on the retained moving branch chart.

This is a direct delayed-root calculation, not a coordinate boost imposed on the answer. The root equations must be solved again with the transmitter positions, transmitter velocities, partner-hit records, self-hit records, and Jacobian factors evaluated on the translating history. The decisive outputs are the moving period T_u and the projected size ratio $L_\parallel(u)/L_\perp(u)$. In primitive units the Lorentz target is

$$\frac{T_u}{T_0} = \gamma_f(u), \qquad \frac{L_\parallel(u)}{L_\perp(u)} = \frac{1}{\gamma_f(u)}, \qquad \gamma_f(u) = \left(1 - \frac{u^2}{c_f^2}\right)^{-1/2}$$

The exact residual definitions and Theorem G role are recorded in Lorentz Kinematics. A Lorentzian result would make the two-body branch the first derived substrate clock. A non-Lorentzian residual would be equally informative because it would identify the first place where the primitive two-body kernel pressures the larger Lorentz-closure program.

The moving-branch test also has a root-starvation obligation. If a forward transmitter root has minimum forward separation $d_{\min}$ in the direction of motion, then the causal delay needed to receive that root obeys the elementary bound

$$\Delta_{\text{forward}}(u) \geq \frac{d_{\min}}{c_f - u}.$$

This divergence is stronger than the Lorentz factor divergence,

$$\gamma_f(u) \sim (c_f - u)^{-1/2},$$

as $u \to c_f^-$. Therefore a bare translating binary cannot be promoted to the Lorentz handoff merely by showing that one clock period stretches. It must also show that the locked branch retains enough memory depth to supply the forward roots it claims. One diagnostic target is

$$\mathcal{R}_{\text{Lor-root}}(u)=\frac{\Delta_{\text{forward}}(u)/T_u}{M_b^{\text{mem}}(u)+\epsilon_h},\qquad M_b^{\text{mem}}(u)=\frac{h_b^{\text{lock}}(u)}{T_u},$$

where h_b^{lock} is the declared retained-history depth of the moving branch and $\epsilon_h>0$ is a fixed normalization floor. If this residual diverges on the finite-η moving chart, the two-body branch has run out of retained causal roots before it has derived Lorentz closure; the handoff must then move to a Noether-sea or larger assembly response rather than being booked as a bare-binary result.

The branch-qualified symbol matters: h_b^{lock} is the measured retained-history depth of this locked moving branch, whereas bare h later denotes a generic history-space horizon. A translating-branch certificate must report h_b^{lock} rather than silently substituting the generic horizon.

Equivalently, with finite retained memory h_b^{lock}, the bare translating binary hits a root-ledger wall at

$$u_{\text{crit}}=c_f-\frac{d_{\min}}{h_b^{\text{lock}}},$$

for any retained forward record with separation floor $d_{\min}$. At or above this wall that record exits the memory window, so the active causal-root ledger cannot be preserved on the same two-body chart. This is the binary-level version of the forward partner-root starvation theorem in Master Equation: the obstruction is kinematic/topological before it is an acceleration-balance residual.

Let $C_i(T_t)$ denote the causal wake surface emitted by architrino i at emission time T_t. For uniform circular motion, self-hit events are discrete intersections between the worldline and its own wake surfaces. Define the **principal self-delay angle** $\tilde{\delta}_s\in(0,\pi]$ as the minimal angular separation between the current position and the emission point that yields a hit. Additional self-hits occur at longer delays indexed by winding number $m\geq 0$, giving a discrete family $\delta_s(m)=\tilde{\delta}_s+2\pi m$.

Phase Angles and Delays

Let δ_s and δ_p denote the angular phase separations (measured along the circle) between:

- **Self** (same architrino): Current position -> its own past emission position that hits "now."
  - Causal delay: Δ_s; angular separation: $\delta_s=\omega\Delta_s$.
  - Chord length: $r_s=2R\sin(\delta_s/2)$.
- **Partner** (other architrino): Current position -> partner's past emission position that hits "now."
  - Causal delay: Δ_p; angular separation: $\delta_p=\omega\Delta_p$.
  - Chord length: $r_p=2R\cos(\delta_p/2)$.

Causal-Time Constraints in Normalized Field-Speed Units

For a signal to travel from emission point to reception point:

$$r=c_f\cdot\Delta\quad\Rightarrow\quad r=\Delta\quad(\text{in units where }c_f=1)$$

This yields two delay equations:

1. **Self-hit**:

$$\delta_s=\omega\Delta_s=\omega\cdot r_s=\omega\cdot 2R\sin(\delta_s/2)=2s\sin(\delta_s/2)$$

2. **Partner hit**:

$$\delta_p=\omega\Delta_p=\omega\cdot r_p=\omega\cdot 2R\cos(\delta_p/2)=2s\cos(\delta_p/2)$$

These two transcendental equations determine (δ_s,δ_p) as functions of speed s.

Circular-branch threshold: On this uniform circular branch, self-hit roots exist only when $s > 1$ (i.e., $\|\mathbf{V}\| > c_f$). For $s \le 1$, no self-hit roots occur on the circular chart. This is a branch-specific root result, not a general speed-only criterion for arbitrary histories.

Principal Partner-Root Certificate

For the partner branch, write the full delay angle as

$$\phi = \omega\Delta$$

and the chapter speed ratio as

$$\beta_f = \frac{\omega R}{c_f}$$

In this non-translating circular certificate, β_f is the same speed ratio denoted s elsewhere in the chapter.
The principal partner-root equation is

$$2\beta_f \cos\frac{\phi}{2} = \phi, \qquad 0 < \phi < \pi$$

The function $F(\phi) = 2\beta_f \cos(\phi/2) - \phi$ satisfies $F(0) = 2\beta_f > 0$, $F(\pi) = -\pi$, and

$$F'(\phi) = -\beta_f \sin\frac{\phi}{2} - 1 < 0$$

on $(0, \pi)$. Therefore the principal partner root exists and is unique for every $\beta_f > 0$.

The same conclusion gives a derived transversality floor. On the principal partner branch,

$$J_p = 1 + \beta_f \sin\frac{\phi}{2}$$

so the dimensional root-transversality quantity is

$$\kappa_{\text{hit}}^{\text{bin}} \equiv |c_f - \hat{\mathbf{r}} \cdot \mathbf{V}_j(T - \Delta)| = c_f \left(1 + \beta_f \sin\frac{\phi}{2}\right) > c_f$$

This floor is not an admissibility parameter for the principal branch; it is a computed property of the circular geometry. It certifies that the simple-root chart cannot fail by partner-root tangency on the principal partner branch.

The instantaneous radial-balance equation is also closed form. Setting the inward partner radial acceleration equal to the required centripetal acceleration gives

$$\frac{\beta_f^2 c_f^2}{R} = \frac{\kappa\epsilon^2}{4R^2 \cos(\phi/2) J_p}$$

and therefore, with $R_* = \kappa\epsilon^2 / c_f^2$,

$$\frac{R}{R_*} = \frac{1}{4\beta_f^2 \cos(\phi/2) J_p}$$

As $\beta_f \to 0$, the root satisfies $\phi \sim 2\beta_f$, and the balance reduces to

$$\omega^2 R^3 = \frac{\kappa\epsilon^2}{4}$$

which is the delayed Coulomb-Kepler scaling for the isolated opposite-polarity pair.

The same principal branch still cannot be a uniform orbit. The delayed partner line of action has a forward tangential projection, so

$$a_\theta^{(\mathrm{part})} = \frac{\kappa\epsilon^2 \sin(\phi/2)}{4R^2\cos^2(\phi/2)J_p} > 0$$

and the instantaneous work rate satisfies $A_\theta^{(\mathrm{part})} R\omega > 0$. Thus the principal branch has positive tangential work in the partner-only circular reduction: it gives the radial family above, but it also pumps tangential energy. A constant-speed circular binary therefore requires a signed multi-root tangential residual

$$\sum_{T_t \in \mathcal{C}_{12}(T)} A_\theta^{(12)}(T;T_t) + \sum_{T_t \in \mathcal{C}_{11}(T)} A_\theta^{(11)}(T;T_t) = 0$$

on the retained ledger, or an explicitly retained wake-flux channel in the finite-window energy ledger. Since circular self-hit roots require super-field-speed history on this branch, an MCB candidate using the self-hit barrier must live on the super-field-speed side of the circular ledger rather than on the principal partner branch alone.

Additional partner roots are not speculative. The full delay-angle equation is

$$\phi = 2\beta_f \left|\cos\frac{\phi}{2}\right|, \qquad \phi > 0,$$

and the retained ledger must record the sheet sign

$$\sigma_p = \operatorname{sign}\left(\cos\frac{\phi}{2}\right).$$

Positive-cosine and negative-cosine windows both contain admissible partner sheets. The principal root lies on the positive sheet in $(0,\pi)$. Higher positive-sheet pairs appear when the corresponding window maximum reaches zero:

$$\sqrt{\beta_f^2 - 1} + \arcsin\frac{1}{\beta_f} = 2\pi k$$

for $k \geq 1$. At equality the two roots are born at a tangency; above it they thicken the partner-hit ledger. Negative-sheet partner roots are represented by $\phi = 2\pi m - \alpha_p$ in the signed-sheet notation below. The first such branch is born at the minimum of

$$\beta_-(\alpha_p) = \frac{2\pi - \alpha_p}{2\cos(\alpha_p/2)}, \qquad 0 < \alpha_p < \pi,$$

whose tangency condition is $\tan(\alpha_p/2) = 2/(2\pi - \alpha_p)$. It carries the opposite tangential sign. The root census is therefore a computed signed branch diagram rather than a positive-window-only conjecture.

Signed Root Census and Speed Ladder

Root: An emission time $T_t < T_r$ (from either self or partner) that satisfies the causal constraint $r = c_f(T_r - T_t)$ and produces a hit at reception time T_r.

Integer-indexed older roots (winding numbers):

Let $\tilde{\delta}_s \in (0,\pi]$ and $\tilde{\delta}_p \in (0,\pi)$ denote the **minimal (principal) angular separations** that determine the chord lengths and acceleration directions. The partner endpoint is open because $\tilde{\delta}_p = \pi$ makes the partner chord length vanish and the inverse-square coefficient singular; the self endpoint remains closed and carries zero tangential projection.

In the same-sheet convention used for the first circular no-go, the full families of causal delays are:

- **Self**:

$$\delta_s(m) = \tilde{\delta}_s + 2\pi m = 2s\sin(\tilde{\delta}_s/2), \quad m = 0, 1, 2, \ldots$$

- **Partner**:

$$\delta_p(m) = \tilde{\delta}_p + 2\pi m = 2s\cos(\tilde{\delta}_p/2), \quad m = 0, 1, 2, \dots$$

Geometric interpretation:

- The minimal separations $\tilde{\delta}_s, \tilde{\delta}_p$ determine the **same-sheet principal geometry** (chord lengths, acceleration directions).
- The winding index m affects **timing/ordering** of multiple hits inside that same-sheet convention.

Signed-sheet completion: A full circular root certificate must also track whether the full delay angle is represented as $2\pi m + \alpha$ or $2\pi m - \alpha$, with $\alpha_s \in (0, \pi]$ for self roots and $\alpha_p \in (0, \pi)$ for partner roots. The same-sheet convention is the quotient that forgets the orientation of the delay direction; the signed sheet $\sigma \in \{+1, -1\}$ lifts the circular root to the orientation double cover of the retained delay strip. Opposite signed sheets can reverse the tangential projection of a self-hit line of action. The sign-invariant statements below are therefore certified only on the same-sheet principal branch chart unless the signed sheet has been explicitly included in the root ledger.

For the full signed ledger, write

$$\Delta_s^{\sigma,m} = 2\pi m + \sigma\alpha_s, \qquad \Delta_p^{\sigma,m} = 2\pi m + \sigma\alpha_p, \qquad \sigma \in \{+1, -1\}$$

with $\sigma = -1$ requiring $m \geq 1$. The signed circular root equations become

$$2\pi m + \sigma\alpha_s = 2s\sin(\alpha_s/2), \qquad 2\pi m + \sigma\alpha_p = 2s\cos(\alpha_p/2)$$

The corresponding tangential signs are $\sigma\cos(\alpha_s/2)$ for self roots and $\sigma\sin(\alpha_p/2)$ for partner roots, up to positive branch weights. The signed sheet is therefore not a cosmetic ledger choice: it is the first place the bare circular kernel can acquire a tangential contribution with the opposite sign from the same-sheet no-go record.

Transmitter identity	Sheet	Allowed winding	Tangential sign away from endpoints	First boundary
Partner	$\sigma = +1$	$m \geq 0$	positive	principal branch for all $s > 0$; first older positive-sheet representation at $s = \pi$
Partner	$\sigma = -1$	$m \geq 1$	negative	first interior tangency at $s = s_{p,-}^\star$
Self	$\sigma = +1$	$m \geq 0$	positive	principal branch at $s = 1$; first older branch at $s = s_1^\star$
Self	$\sigma = -1$	$m \geq 1$	negative	first boundary at $s = \pi/2$

The consolidated structural speed ladder of the circular atlas is therefore

Speed	Root-ledger event
$s = 1$	principal positive-sheet self root enters from $\alpha_s = 0$
$s = \pi/2$	first negative-sheet self root enters at $\alpha_s = \pi$
$s = s_{p,-}^\star \approx 2.97169$	first negative-sheet partner pair is born at an interior tangency
$s = \pi$	a negative-partner branch reaches $\alpha_p = 0$ and continues onto the first older positive-sheet representation
$s = s_1^\star \approx 4.60334$	first older positive-sheet self pair is born at an interior tangency

The negative-partner threshold and the first older positive-self threshold are fixed by

$$s_{p,-}^\star = \min_{0<\alpha<\pi} \frac{2\pi - \alpha}{2\cos(\alpha/2)} \approx 2.97169, \qquad \sqrt{(s_1^\star)^2 - 1} - \arccos\left(\frac{1}{s_1^\star}\right) = \pi.$$

The first negative self sheet, $m = 1, \sigma = -1$, obeys

$$2\pi - \alpha = 2s\sin(\alpha/2)$$

and appears at $s = \pi/2$ with $\alpha = \pi$. Equivalently, at the threshold a wake crosses the diameter $2R$ in time $2R/c_f$, while the transmitter advances half a circumference πR at speed sc_f; the equality $\pi R = sc_f(2R/c_f)$ gives $s = \pi/2$. For $s > \pi/2$ it contributes negative tangential drive. This does not prove circular closure, but it makes the $\sigma = -1$ sheet the first internal generator capable of carrying opposite period in the tangential cohomology class. A useful floor conjecture is:

> No isolated, bare, constant-speed circular MCB branch can close for $s < \pi/2$, because the first negative same-transmitter sheet is absent and the same-sheet tangential cohomology class has no internal cancellation generator. In cochain language, the space available to the retained two-body ledger has no opposite-period self-record before the $\sigma = -1$ wall at $s = \pi/2$.

The decision procedure is finite on any compact speed interval below $\pi/2$: enumerate the full signed partner and self-root ledger, certify the inactive gaps and positive $|J|$ floors, include the finite-window wake boundary term, and evaluate the signed tangential period. A retained negative-period root, a zero total period with closed wake flux, or a branch missed by the enumeration falsifies the floor conjecture.

For $s \geq \pi/2$, closure is still not automatic. The negative sheet must survive the finite-η branch chart, satisfy the Jacobian and inactive-gap floors, and balance the remaining tangential class through signed-root cancellation, wake escapement, or multi-body exchange.

Per-Hit Directions and Acceleration Components

Local Coordinate Frame at Receiver

- **Radial outward**: $\hat{e}_r$ (from rotation center toward receiver).
- **Tangential**: $\hat{e}_t$ (direction of motion along circle).

Unit Directions from Emission to Reception

Self-hit:

$$\hat{u}_s = \sin(\delta_s/2)\,\hat{e}_r + \cos(\delta_s/2)\,\hat{e}_t$$

Partner hit (geometric chord across circle):

$$\hat{u}_p = \cos(\delta_p/2)\,\hat{e}_r - \sin(\delta_p/2)\,\hat{e}_t$$

Canonical Per-Hit Accelerations

Using the delayed law with line-of-action direction and transmitter-side acceleration weight (where κ is a coupling constant and $\epsilon = |e|/6$), define the same-root factors

$$W_s^{\mathrm{acc}} = \frac{c_f}{|D_{t,s}|}, \qquad W_p^{\mathrm{acc}} = \frac{c_f}{|D_{t,p}|}.$$

The canonical per-hit acceleration contributions are

$$\mathbf{A}_s = +\kappa\epsilon^2\frac{W_s^{\mathrm{acc}}}{r_s^2}\hat{u}_s, \qquad \mathbf{A}_p = -\kappa\epsilon^2\frac{W_p^{\mathrm{acc}}}{r_p^2}\hat{u}_p.$$

On the non-translating symmetric circular benchmark, the equal-projection lemma gives $D_r = D_t$ on every retained self or partner chord, so signed root playback is one. The acceleration weights remain $W_s^{\mathrm{acc}} = 1/|J_s|$ and $W_p^{\mathrm{acc}} = 1/J_p$. The circular canonical contributions are

$$\mathbf{A}_s = +\kappa\epsilon^2 \frac{1}{r_s^2 |J_s|} \hat{u}_s, \qquad \mathbf{A}_p = -\kappa\epsilon^2 \frac{1}{r_p^2 J_p} \hat{u}_p.$$

The transmitter-side factors remain the root-density and transversality diagnostics:

$$J_s \equiv 1 - \frac{\mathbf{V}_{\text{self}}(T_t) \cdot \hat{u}_s}{c_f}, \qquad J_p \equiv 1 - \frac{\mathbf{V}_{\text{partner}}(T_t) \cdot \hat{u}_p}{c_f}.$$

Explicit Circular Jacobians

For the symmetric circular geometry, the transmitter velocities can be resolved exactly against the line-of-action directions:

$$\mathbf{V}_{\text{self}}(T_t) \cdot \hat{u}_s = s\cos(\delta_s/2), \qquad \mathbf{V}_{\text{partner}}(T_t) \cdot \hat{u}_p = -s\sin(\delta_p/2)$$

Hence the branch Jacobians reduce to

$$J_s = 1 - s\cos(\delta_s/2), \qquad J_p = 1 + s\sin(\delta_p/2)$$

Using the delay constraints gives equivalent forms

$$J_s = 1 - \frac{\delta_s}{2}\cot(\delta_s/2), \qquad J_p = 1 + \frac{\delta_p}{2}\tan(\delta_p/2)$$

These formulas make the transmitter-side transversality asymmetry between the two branch types explicit:

- The partner branch always satisfies $J_p > 1$, so its transmitter-side acceleration is diluted relative to a static inverse-square surrogate.
- The self branch can satisfy $J_s \to 0^+$, producing the causal bunching that sharpens self-hit into a null-separatrix wall for root density, action counting, and finite-η branch certification.

Transmitter-Side Radial and Tangential Diagnostics

Define **inward radial** as positive (toward center) and **tangential** as positive in direction of motion.

The projections in this subsection are transmitter-side circular diagnostics. They record root playback and root geometry, but they are not canonical Master EOM acceleration contributions until the same retained branches are recomputed with D_t, D_r, and $W^{\text{acc}} = c_f/|D_t|$.

Chord lengths:

$$r_s = 2R\sin(\delta_s/2), \quad r_p = 2R\cos(\delta_p/2)$$

Inward radial diagnostic components:

- **Self** (repulsive -> outward -> negative):

$$A^t_{s,\text{rad}} = -\kappa\epsilon^2 \frac{\sin(\delta_s/2)}{r_s^2\,|J_s|} = -\frac{\kappa\epsilon^2}{4R^2\sin(\delta_s/2)\,|J_s|}$$

- **Partner** (attractive -> inward -> positive):

$$A^t_{p,\text{rad}} = +\kappa\epsilon^2 \frac{\cos(\delta_p/2)}{r_p^2\,|J_p|} = +\frac{\kappa\epsilon^2}{4R^2\cos(\delta_p/2)\,|J_p|}$$

Net inward radial diagnostic:

$$A^t_{\text{rad}} = \frac{\kappa\epsilon^2}{4R^2}\left(\frac{1}{\cos(\delta_p/2)\,|J_p|} - \frac{1}{\sin(\delta_s/2)\,|J_s|}\right)$$

Tangential diagnostic components:

- **Self**:

$$T_s^t = +\kappa\epsilon^2 \frac{\cos(\delta_s/2)}{r_s^2\,|J_s|} = \frac{\kappa\epsilon^2 \cos(\delta_s/2)}{4R^2 \sin^2(\delta_s/2)\,|J_s|}$$

- **Partner**:

$$T_p^t = +\kappa\epsilon^2 \frac{\sin(\delta_p/2)}{r_p^2\,|J_p|} = \frac{\kappa\epsilon^2 \sin(\delta_p/2)}{4R^2 \cos^2(\delta_p/2)\,|J_p|}$$

Net tangential diagnostic:

$$T^t = T_s^t + T_p^t$$

Sub-Field-Speed Simplification

When $s \le 1$, self-hits do not occur (δ_s has no solution). Only the partner contributes to this transmitter-side diagnostic:

$$T^t(s \le 1) = T_p^t = \frac{\kappa\epsilon^2}{4R^2} \frac{\sin(\delta_p/2)}{\cos^2(\delta_p/2)\,|J_p|}$$

Using the delay relation $\delta_p = 2s\cos(\delta_p/2)$:

$$T^t(s \le 1) = \frac{\kappa\epsilon^2 s^2}{R^2} \frac{\sin(\delta_p/2)}{\delta_p^2\,|J_p|}$$

Because $J_p = 1 + s\sin(\delta_p/2) > 1$, the transmitter-side delay geometry weakens the canonical contribution relative to a stripped inverse-square surrogate by the factor $1/J_p$. Its tangential sign remains positive. For $s \le 1$, the full signed census contains only this principal partner root: no self root, older positive partner root, or negative sheet is active. A particle-only constant-speed circular orbit is therefore excluded on the full circular root ledger throughout the sub-field-speed regime. A causal retained-history account is still required for any broader conservation claim.

Requirements for True Circular Orbit (Working Hypothesis)

For uniform circular motion at fixed radius R and constant speed s:

1. **Receiver-side centripetal balance**:

$$A_{\text{rad}}^{\text{rec}} = \frac{s^2}{R}$$

2. **Finite-window energy balance**:

$$\left\langle \frac{dK_\mu}{dT} \right\rangle_W + \langle \Phi_{\text{wake},\partial W} \rangle_W = 0$$

Here K_μ is the chosen quadratic kinetic proxy and $\Phi_{\text{wake},\partial W}$ is the causal-wake energy flux through the boundary of the local window. The older shorthand $\langle T \rangle = 0$ is valid only for a particle-only closed window with no boundary wake flux.

On a declared branch chart b, this balance has an operational work record:

$$P_{b,\text{work}}^{(\eta)}(T) = \sum_i \mu_{\text{arch}}\, \mathbf{A}_{i,b}^{(\eta)}(T) \cdot \mathbf{V}_i(T)$$

For a circular constant-speed benchmark, $\mathbf{V}_i$ is tangent to the orbit and the radial record does no instantaneous work, so

$$\left\langle P^{(\eta)}_{b,\mathrm{work}} \right\rangle_{P_b} = \mu_{\mathrm{arch}}\, s_b\, \left\langle A^{\tan}_{\eta,b} \right\rangle_{P_b}$$

for the quadratic proxy. Thus the tangential term is not merely a geometric nuisance; it is the first constructive entry in the binary wake-energy ledger. If the primitive kinetic scalar is used instead, replace μ_{arch} by $\mu_K(\|\mathbf{V}_i\|)$ inside the summed power.

Tangential Drive and Wake Escapement

Theorem (Same-sheet no-go for constant-speed circular orbit in the bare two-body kernel).
In the symmetric, non-translating circular binary with canonical delayed radial acceleration contributions only, and with active roots restricted to the same-sheet principal branch chart defined above, the net tangential acceleration is strictly positive whenever at least one causal root contributes.

$$T_{\mathrm{net}} = \sum_{m\in\mathcal{M}_p} w_{p,m} T_{p,m} \ + \sum_{m\in\mathcal{M}_s} w_{s,m} T_{s,m} > 0$$

where $w_{p,m}, w_{s,m} \geq 0$ are same-root transmitter-side weights induced by $W^{\mathrm{acc}} = c_f/|D_t|$ and any declared regularization/time averaging, and $\mathcal{M}_p, \mathcal{M}_s$ are active partner/self root sets.

Proof.
For any active partner branch, the tangential contribution is

$$T_{p,m} = \frac{\kappa\epsilon^2}{4R^2} \frac{\sin(\tilde{\delta}_{p,m}/2)}{\cos^2(\tilde{\delta}_{p,m}/2)} > 0, \qquad \tilde{\delta}_{p,m} \in (0,\pi)$$

and for any active self branch (when present),

$$T_{s,m} = \frac{\kappa\epsilon^2}{4R^2} \frac{\cos(\tilde{\delta}_{s,m}/2)}{\sin^2(\tilde{\delta}_{s,m}/2)} \geq 0, \qquad \tilde{\delta}_{s,m} \in (0,\pi]$$

The sign is branch-invariant on this same-sheet chart because winding changes timing, not chord orientation. Therefore each summand in T_{net} is nonnegative. The always-present principal partner root is strictly positive, including when a self branch sits at its endpoint with zero tangential projection. Hence $T_{\mathrm{net}} > 0$ on the certified chart. □

Corollary.
Within the same-sheet bare isolated two-body kernel, an exact constant-speed circular orbit with no boundary wake-state exchange is impossible. Any MCB-like steady state must therefore close a finite-window balance: signed-root cancellation may reduce the local tangential drive, but any remaining forward kinetic-rate change must close against the causal wake state or genuinely multi-body Noether braid exchange.

Interpretation. The positive tangential component is not merely an obstruction to be erased. In a finite local window, partner and self wakes are continually emitted while only a subset of their causal isochrons later hit a local receiver. A local binary can be called conservative only if the retained causal wake state, its boundary exchange, and the active-root record close energy, momentum, and angular momentum on the same update.

Cohomology reading. On a closed circular branch, write θ for the receiver phase and let

$$\omega_T^{(b)} = R\, T^{(b)}_{\mathrm{net}}(\theta)\, d\theta$$

be the tangential torque one-form on the retained signed ledger b. Same-sheet records give a positive period integral,

$$\oint_{S^1} \omega_T^{(b)} > 0,$$

so $[\omega_T^{(b)}] \neq 0$ in $H^1(S^1)$ and $\omega_T^{(b)}$ is not an exact derivative of a single-valued mechanical angular-momentum potential on the particle-only chart. Closure requires a coboundary supplied by retained non-particle channels:

$$\left[\omega_T^{(b)} + \omega_{\partial W}^{(b)} + \omega_{\mathrm{wake}}^{(b)} + \omega_{\mathrm{multi}}^{(b)}\right] = 0$$

in the cycle cohomology of the branch chart. A compact escaped-action diagnostic is

$$N_{\mathrm{esc}}^{(b)} = \frac{\mu_{\mathrm{arch}}}{h_{\mathrm{act}}} \int_0^{P_b} R\,T_{\mathrm{net}}^{(b)}(T)\,dT = \frac{\mu_{\mathrm{arch}}}{h_{\mathrm{act}}\,\omega_b} \oint R\,T_{\mathrm{net}}^{(b)}(\theta)\,d\theta,$$

where h_{act} is the declared action unit used by the branch packet and the second equality assumes a uniform circular benchmark. It is distinct from the retained-history depth h. If the primitive kinetic scalar is used instead of the quadratic proxy, the same packet must replace μ_{arch} by the declared μ_K entry. A bare two-body circular closure can pass only when this class is cancelled by an explicitly retained signed sheet, causal wake-state, boundary, or multi-body exchange entry.

Plain language: On the same-sheet chart, the isolated pair shows persistent tangential drive at the per-hit level; cancellation is hard because every certified root accelerates the same way. The stable-branch question is whether one causal wake-state or multi-body update closes that drive without destroying the retained branch. This is a primary test of the MCB attractor hypothesis.

What “Maximum Curvature” Demands

Mechanism summary (self-hit balance): once $s > 1$, each self-hit contributes a **repulsive acceleration away from its own past emission point**. In the symmetric circular geometry that repulsion has a radial outward component and a signed tangential component. As the radius shrinks, both partner attraction and self-hit repulsion scale like $1/R^2$ times their transmitter-side weights $1/|J|$. Maximum curvature would require the outward self-hit radial component to balance the inward partner pull without the tangential sum destroying constant-speed closure, and the coincident self-root birth must first have a finite accepted event treatment.

The non-translating symmetric circular radial target is therefore the transmitter-side weighted acceleration contribution:

$$A_{\mathrm{rad}} = \frac{\kappa\epsilon^2}{4R^2}\left(\frac{1}{\cos(\delta_p/2)J_p} - \frac{1}{\sin(\delta_s/2)|J_s|}\right).$$

For translating, deformed, or non-circular branches, this target must be restored to the same-root form with $W_\bullet^{\mathrm{acc}} = c_f/|D_{t,\bullet}|$, with $D_{r,\bullet}/D_{t,\bullet}$ retained separately for root playback.

Increasing curvature ($1/R$ larger, so R smaller) requires **stronger inward radial acceleration**. This occurs when:

1. δ_p **increases** -> $\cos(\delta_p/2)$ decreases -> partner term $1/\cos(\delta_p/2)$ **increases** (stronger inward pull).
2. δ_s **increases** -> $\sin(\delta_s/2)$ increases -> the geometric part of the self term decreases, while the full outward response still depends on the same-root transmitter-side acceleration weight W_s^{acc}.

Two distinct balance mechanisms are now mathematically visible:

1. **Near-threshold inverse-distance hinge plus transmitter-side fold.**
   On the principal self branch, D_t loses its floor as $s \downarrow 1^+$, and the transmitter-side acceleration weight diverges as $1/|D_t|$. The coincident branch birth therefore remains a failed singular event until a finite regulator-independent transition is certified.

2. **Higher-speed multi-branch redistribution.**
   At larger s, additional self branches turn on and redistribute the outward response across several winding sectors. In that regime the detailed balance depends on the full transmitter-side weighted sum over all active branches rather than on the principal branch alone.

Current status: The same-sheet per-hit $T > 0$ result excludes only the restricted same-sheet chart. The complete unregularized signed simple-root ledger has algebraic circular candidates, beginning near $s = 3.07036$, so existence is measured rather than excluded on that chart. The maximum-curvature state remains uncertified for the isolated two-body system because finite-event continuation, retained-history persistence, wake-boundary closure, and return-map stability have not been established.

Because the desired MCB branch is expected to graze the $J = 0$ wall, the stability target is not only a smooth Floquet calculation. On smooth arcs with a fixed ledger, Floquet multipliers are the right local test. At the null separatrix itself, the branch is a caustic-grazing limit cycle: the appropriate theorem target is an isolating block in history space that straddles the $J = 0$ wall and has a persistent Conley index under finite-η continuation. The concrete target is uniform index persistence: for sufficiently small $\eta > 0$, the regularized return map must carry the same Conley index on one isolating neighborhood of the grazing orbit, with the finite-caustic impulse bound controlling the velocity jump through the wall. If the index changes as $\eta \to 0^+$, the MCB is not a robust attractor. In that reading, the MCB branch is stable only if the orbit returns through the grazing chart without escaping the isolating block or changing its declared signed ledger except at the certified fold records.

Emergent Properties and Measurement Standards

If a stable MCB exists, it provides a concrete **rod** and **clock** defined entirely by the two-body delay dynamics. Let

$$d_0 := R_{\mathrm{MCB}}, \qquad T_0 := \frac{2\pi}{\omega_{\mathrm{MCB}}}$$

The natural Layer-I two-body units are

$$R_* = \frac{\kappa\epsilon^2}{c_f^2}, \qquad T_* = \frac{R_*}{c_f}$$

so the first MCB outputs are the dimensionless ratios

$$\frac{R_{\mathrm{MCB}}}{R_*}, \qquad \frac{T_0}{T_*}, \qquad \beta_{\mathrm{MCB}}$$

rather than additional fitted constants. Once (c_f, κ, ϵ) fixes the length, time, and polarity units, the signed-root ledger and stability problem must compute those ratios as pure numbers.

Then d_0 is the candidate fundamental length scale of the architecture, and T_0 is the candidate fundamental time scale. Their comparison with the wake propagation speed is the dimensionless MCB speed factor

$$\beta_{\mathrm{MCB}} = \frac{R_{\mathrm{MCB}}\omega_{\mathrm{MCB}}}{c_f} = \frac{2\pi d_0}{c_f T_0}$$

so the wake propagation speed is not an imposed architrino-speed limit. It is the propagation reference used to compare the MCB rod and clock, while individual architrinos may enter super-field-speed regimes with

$$\|\mathbf{V}\| > c_f$$

In this view, any ruler or clock built from architrino assemblies ultimately reduces to multiples of (d_0, T_0). Measurement standards are therefore **dynamical invariants** of the two-body attractor: they persist because the underlying limit cycle (if realized) is stable and reproducible across assemblies.

A certified MCB would also define the first handedness marker. In the binary plane set

$$\hat{\mathbf{n}}_{\mathrm{MCB}} = \hat{\mathbf{r}} \times \hat{\mathbf{V}},$$

with $\hat{\mathbf{r}}$ pointing from the center to one chosen polarity record and $\hat{\mathbf{V}}$ its direction of motion. The two signs of $\hat{\mathbf{n}}_{\mathrm{MCB}}$ label two branch basins, B_+ and B_-, not two coordinate conventions. A branch-preserving deformation can rotate the plane, but it cannot flip this $\mathbb{Z}_2$ label without passing through a degeneracy where the circular plane, transmitter order, or signed causal-root ledger changes. Thus chirality is carried by the joint path-history and signed-root framing of the branch, not by a freely chosen drawing orientation.

This handedness claim is falsified by any continuous retained deformation from B_+ to B_- that preserves a nondegenerate plane, transmitter order, the signed causal-root ledger, and all declared Jacobian floors throughout the path. Such a deformation would show that the proposed $\mathbb{Z}_2$ label is a chart convention rather than a branch invariant.

If the MCB does not exist as a stable attractor, these emergent standards must be replaced by whatever stable limit structure the dynamics actually support.

Root Multiplicity vs. Speed

This section separates the two terminology axes used throughout the chapter:

- **Transmitter identity**: self-hit ($j = i$) or partner hit ($j \neq i$).
- **Root count**: single-root or multi-root on the current branch chart.

The self-hit onset is dynamically special because it introduces same-transmitter feedback and an outward self-repulsive channel. Partner multi-hit is still part of the same super-field-speed root topology: at higher speeds, older partner wake surfaces can also satisfy the causal-root condition and contribute additional inward channels.

In the same-sheet uniform circular, non-translating geometry, admissible self-roots are indexed by winding number $m \geq 0$ and minimal angular separation $\tilde{\delta}_s \in (0, \pi]$:

$$\delta_s = \tilde{\delta}_s + 2\pi m = 2s\sin(\tilde{\delta}_s/2)$$

Counting Self-Hits by Winding Index

For fixed winding $m \geq 0$, define

$$f_m(\delta; s) = 2s\sin(\delta/2) - \delta - 2\pi m, \qquad \delta \in (0, \pi]$$

An m-branch same-sheet self-hit exists exactly when $f_m(\delta; s) = 0$ has a solution in $(0, \pi]$.

- For the principal branch $m = 0$, the threshold is sharp:

$$s_0^\star = 1$$

- For higher winding numbers $m \geq 1$, the appearance threshold is determined by the tangency condition at the interior maximizer $f_m'(\delta; s) = 0$, namely

$$\cos(\delta_m^\star/2) = \frac{1}{s}, \qquad \sqrt{(s_m^\star)^2 - 1} - \arccos\left(\frac{1}{s_m^\star}\right) = \pi m$$

Thus the higher same-sheet self branches do not turn on at equally spaced speeds. Their onset is governed by a nonlinear sequence of tangencies of the delayed self-intersection curve. A full signed-root ledger must add the $\sigma = -1$ sheets described above; the first such negative self sheet appears at $s = \pi/2$, earlier than the first higher same-sheet self branch.

For large winding number m, the threshold has the asymptotic form

$$s_m^\star = \pi m + \frac{\pi}{2} + O\left(\frac{1}{m}\right)$$

so the equally spaced picture is recovered only as a high-speed approximation.

Note: Straight-line motion admits **no self-hits** even if $s > 1$; **curvature is required**. The above statements apply specifically to uniform circular, non-translating geometry.

The self-hit root count is therefore a genuine branch-bifurcation diagram for the circular benchmark. Here

$$s = \frac{\|\mathbf{V}\|}{c_f}$$

is the chapter's speed ratio, equivalent to β_f in the usual notation. Between neighboring branch-birth thresholds, the active self-root ledger $N_s(s)$ is constant and the same root labels can be transported. At the thresholds, the delay equation has a tangency and the newly born circular root lies on a Jacobian-null boundary. Thus the root census, the caustic locations, and the ledger-transition speeds are one computed object rather than three separate assumptions.

Root Ledger as a One-Parameter Morse Complex

For a fixed reception event on a one-parameter family of branch histories, write the root function as

$$F_{ij}(T_t; s) = \|\mathbf{X}_i(T; s) - \mathbf{X}_j(T_t; s)\| - c_f(T - T_t).$$

Active causal roots are the zeros of F_{ij}. A branch birth or death is a fold record:

$$F_{ij} = 0, \qquad \partial_{T_t} F_{ij} = 0, \qquad \partial^2_{T_t} F_{ij} \neq 0.$$

Away from those folds, the signed degree

$$D_{ij}(s) = \sum_{T_t \in \mathcal{C}_{ij}(T;s)} \operatorname{sign}(\partial_{T_t} F_{ij}(T_t; s))$$

is locally constant, while the unsigned counts N_s and M_p track the ranks of the same-transmitter and partner-root records. This is the binary version of the assembly topological charge: the later rank-three braid label (N_s, M_p, c_1) uses the two root-complex integers from this chapter and the phase-return degree data from the resonance-lock chart. A solver that reports only raw root counts loses the signed degree needed to distinguish a true branch fold from a harmless relabeling of records.

Parameter-Free Circular Branch Packet

The circular two-body benchmark can now be stated as a parameter-free branch packet. Use the Layer-I units

$$R_* = \frac{\kappa \epsilon^2}{c_f^2}, \qquad \rho = \frac{R}{R_*}, \qquad s = \frac{R\omega}{c_f}$$

and factor out the acceleration scale c_f^2/R_*. The remaining equations depend only on the dimensionless radius ρ, the speed ratio s, and the signed causal-root ledger.

For the principal partner branch, let $\xi_p = \delta_p/2$. The delay equation is

$$\cos \xi_p = \frac{\xi_p}{s}, \qquad 0 < \xi_p < \frac{\pi}{2}$$

with

$$J_p = 1 + s \sin \xi_p$$

as the transmitter-side transversality diagnostic. For a general signed partner branch $\alpha_p = (\xi, \sigma, m)$, use

$$2\pi m + 2\sigma\xi = 2s \cos \xi, \qquad J_p(\xi, \sigma; s) = 1 + \sigma s \sin \xi.$$

The canonically weighted circular acceleration coefficients are

$$P_{\mathrm{rad}}(\xi, \sigma; s) = \frac{1}{\cos \xi \, |J_p|}, \qquad P_{\tan}(\xi, \sigma; s) = \frac{\sigma \sin \xi}{\cos^2 \xi \, |J_p|}$$

where radial is measured inward and tangential is measured in the direction of motion.

For a signed self branch $\alpha_s = (\xi, \sigma)$ in the full circular ledger, use

$$\sigma \sin\xi = \frac{\xi}{s}, \qquad \sigma = \operatorname{sign}(\sin\xi)$$

with

$$J_s(\xi, \sigma; s) = 1 - s\sigma\cos\xi$$

as the transmitter-side transversality diagnostic. The outward radial and signed tangential canonical circular coefficients are

$$S_{\mathrm{rad}}(\xi, \sigma; s) = \frac{s}{\xi\,|J_s|}, \qquad S_{\tan}(\xi, \sigma; s) = \frac{s^2\sigma\cos\xi}{\xi^2\,|J_s|}$$

Higher self-root births occur at tangencies:

$$\tan\xi^\star = \xi^\star, \qquad s^\star = |\sec\xi^\star|$$

and these births are also Jacobian-null events, $J_s = 0$.

On a fixed signed ledger b, the dimensionless circular MCB candidate equations are therefore

$$\mathcal{G}^{(b)}_{\mathrm{rad}}(\rho, s) = \frac{1}{4\rho^2}\left(\sum_{\alpha_p \in b_p} P_{\mathrm{rad}}(\alpha_p; s) - \sum_{\alpha_s \in b_s} S_{\mathrm{rad}}(\alpha_s; s)\right) - \frac{s^2}{\rho} = 0$$

and

$$\mathcal{G}^{(b)}_{\tan}(\rho, s) = \frac{1}{4\rho^2}\left(\sum_{\alpha_p \in b_p} P_{\tan}(\alpha_p; s) + \sum_{\alpha_s \in b_s} S_{\tan}(\alpha_s; s)\right) = 0$$

Here b_p and b_s are the partner-hit and self-hit entries in the signed causal-root ledger. The equations are parameter-free because κ, ϵ, and c_f have already been absorbed into R_* and the acceleration scale. A common zero of these two residuals is only an algebraic circular MCB candidate; promotion to a stable branch still requires the finite-window return-map certificate, positive Jacobian floors, and energy packet described below.

Circular Self-Hit Sign Theorem and Complete-Ledger Measurement

The uniform-circular self-hit geometry supplies a derived sign result. For the full delay half-angle $\xi > 0$,

$$|\sin\xi| = \frac{\xi}{s}, \qquad \hat{\mathbf{u}}_s = |\sin\xi|\,\hat{\mathbf{e}}_r + \operatorname{sign}(\sin\xi)\cos\xi\,\hat{\mathbf{e}}_t$$

Every nondegenerate self-hit therefore has a strictly outward radial projection. On the principal branch $\xi \in (0, \pi)$, the tangential projection changes from forward to backward exactly at

$$\xi = \frac{\pi}{2}, \qquad s = \frac{\pi}{2}$$

This is exact on the uniform-circular chart, not a general threshold for non-circular histories. The derivation and falsifiers are given in Master Equation.

The absolute value in the root equation is essential. The first additional self-root pair is born at

$$\tan\xi_1^\star = \xi_1^\star, \qquad s_1^\star = \sqrt{1 + (\xi_1^\star)^2} \approx 4.6033388488$$

not near 7.8. The next pair is born at $s_2^\star \approx 7.7897057675$. At $s = 8$, the complete self ledger contains five roots, with full delay angles approximately $319.2409°$, $413.6433°$, $632.7112°$, $859.1794°$, and $911.8419°$. A three-root census at that speed has omitted the alternating-sine pair.

Claim grade: **derived** for the radial sign, principal $\pi/2$ threshold, and pair-birth equations; **measured** for the numerical root and residual values below. The independent analysis instrument is `scripts/equation-mapping/analyze-circular-self-hit-binary.mjs`. It brackets every monotone half-lobe, verifies roots against the direct Euclidean chord condition, and evaluates acceleration from the circular position and velocity vectors.

The principal partner formula reproduces the supplied tangential values through $s = 6$, including 0.7083439236 there, and confirms their positive sign. At $s = 10$ the canonical value is 1.1141796596, not 1.05588. The principal self value at $s = 10$ is -0.2782507206, while the sum over all five active self roots is -0.0902141750.

On $1 < s < 20$, the restricted ledger containing the principal partner root and every self root has no tangential zero. Its minimum is approximately 0.2389668633 in units $\kappa\epsilon^2/R^2$ at $s \approx 1.7972747766$. Its radial coefficient changes sign at $s \approx 1.8471246228$, not at $\pi/2$; the two values solve different balance equations, so their proximity has no derived significance.

The complete ledger gives the opposite existence verdict because older partner roots cannot be omitted. The measured simple-root zeros are:

s	Net radial coefficient, outward positive	Algebraic radius R/R_*
3.0703566254	-0.8196069638	0.0869416735
6.2184549634	-1.2902686401	0.0333668459
9.3764360282	-1.8001431321	0.0204753554

At each listed point the complete tangential coefficient is zero to the scan tolerance and the radial coefficient is inward, so the algebraic circular conditions have solutions inside the searched domain. This establishes measured existence on the current unregularized simple-root chart; it does not certify a periodic history. Each older branch descends from a $J = 0$ birth and still needs the common finite-event convention, retained root ledger, wake-boundary account, and return-map stability certificate.

The measurement is conditional on the canonical line of action from the transmitter's emission point to the receiver event. A counterfactual inertially extrapolated construction replaces only the acceleration direction by

$$\hat{\mathbf{d}}_{\text{ext}} = \frac{\mathbf{X}_r(T_r) - [\mathbf{X}_t(T_t) + \mathbf{V}_t(T_t)(T_r - T_t)]}{\|\mathbf{X}_r(T_r) - [\mathbf{X}_t(T_t) + \mathbf{V}_t(T_t)(T_r - T_t)]\|}$$

while retaining the actual causal roots, emission-site distance, and canonical transmitter-side acceleration weight. This convention isolates the line-of-action sensitivity without substituting a different wake-density law.

The recomputed complete ledger moves the first three emission-site candidates off both balance conditions:

Emission-site candidate s	Extrapolated-direction radial coefficient	Extrapolated-direction tangential coefficient
3.0703566254	$+0.1986630540$	-0.3350989817
6.2184549634	$+0.1969175233$	-0.1271086141
9.3764360282	$+0.1881554019$	-0.0742863069

The same counterfactual ledger has tangential zeros near $s = 3.2253960989$, 6.2226379612, and 9.3769260902, but their radial coefficients are respectively $+0.1357894119$, $+0.1768252822$, and $+0.1802347924$, with outward sign positive. The scan through $1 < s < 20$ finds six tangential zeros and no simultaneous inward-radial point. Claim grade: **measured counterfactual**, not canonical dynamics. The closed-form extrapolated direction independently checks the vector evaluator, while the causal roots remain checked against the Euclidean chord residual.

The equilibrium gate therefore fails before stability analysis: none of the extrapolated-direction zeros is a circular solution, so a Floquet multiplier or delayed-history spectrum about those rows would have no dynamical referent. This closes the requested counterfactual stability test as an acceleration-balance negative, not as a measured instability.

The autonomous wake-state reduction in Master Equation resolves the regular-domain ontology dependency under the present postulates. A fixed emission-site center with radius growing at absolute speed c_f has the canonical emission-site normal and the canonical $c_f/|D_t|$ weight. Redirecting only the acceleration is not a surface-normal response; moving the emitted center inertially changes absolute propagation speed, causal support, and root weight. The extrapolated calculation therefore remains a sensitivity diagnostic and does not eliminate the canonical emission-site candidates.

The circular result forecloses neither non-circular contraction nor the symmetric logarithmic spiral, multi-architrino braids, or Noether sea embedded configurations. It also does not yet establish the circular MCB: it promotes the current chart from an unanswered algebraic question to a measured candidate family while leaving finite-event persistence and stability open.

Discrete Azimuth Pattern of Circular Hits

Context: Non-translating, uniform circular binary at fixed speed s. Receiver "now" at azimuth $\theta = 0$.

The emission points on the circle that can produce hits "now" form a **finite, discrete set** of azimuths determined by the delay equations–**not arbitrary locations**. Because roots are indexed by winding number m and, in the full ledger, sheet sign σ, multiple hits at the same "now" can occur for different signed windings, but the admissible azimuths remain a finite comb and never fill the circle.

Partner Hits

- Minimal angular separation: $\tilde{\delta}_p \in (0, \pi)$.
- The signed causal delays and their allowed windings are those in the **Signed Root Census and Speed Ladder** above.
- **Emission azimuth** at reception:

$$\varphi_p^{\sigma,m}(s) = \pi - \sigma\tilde{\delta}_p^{\sigma,m}(s)$$

- **Existence thresholds**: each signed sheet is born when its delay equation first becomes tangent; the positive-sheet family has boundary threshold $s = m\pi$, while the negative-sheet family uses the interior minimum displayed above.
- As winding grows, the admissible azimuths approach the diametrically opposite point on their respective signed sheets.
- Partner multi-hit means $M_p(s) > 1$: the base partner branch plus one or more older partner roots. These additional roots affect the inward partner-root ledger, but they do not create same-transmitter feedback.

Self-Hits

- Minimal angular separation: $\tilde{\delta}_s \in (0, \pi]$.
- The signed causal delays and their allowed windings are those in the **Signed Root Census and Speed Ladder** above.
- **Emission azimuth** at reception:

$$\varphi_s^{\sigma,m}(s) = -\sigma\tilde{\delta}_s^{\sigma,m}(s)$$

- **Existence windows**:
- Principal branch ($m = 0$): exists for every $s > 1$, with $\tilde{\delta}_s \to 0^+$ as $s \downarrow 1$.
- The first negative sheet enters at $s = \pi/2$ through $\tilde{\delta}_s = \pi$.
- For older positive sheets with $m \geq 1$, the branch appears only when the self-delay equation develops an interior tangency. The exact threshold $s_m^\star$ is determined in **Counting Self-Hits by Winding Index** above.

- Within each branch, $\tilde{\delta}_s$ initially enters at a tangency angle and then decreases with s, so φ_s drifts toward $-\pi$ at high speed.

Super-Field-Speed Root Ledgers and Resonance Lock

The super-field-speed regime is not merely the same spiral at a larger speed. It changes the root topology of the binary. Once

$$\|\mathbf{V}\| > c_f$$

the receiver can intersect multiple older causal wake surfaces from both its own path and its partner's path. In the circular reduced model, these intersections are counted by two integer ledgers:

$$N_s(s) \equiv \#\{(m,\sigma) : \text{self branch } (m,\sigma) \text{ is active at speed } s\}$$

$$M_p(s) \equiv \#\{(m,\sigma) : \text{partner branch } (m,\sigma) \text{ is active at speed } s\}$$

The self-ledger

$$N_s$$

tracks outward self-hit channels. The partner-ledger

$$M_p$$

tracks inward partner-hit channels. Both are integer-valued because a causal root either exists or it does not. As

$$s$$

varies, these counts change only at branch birth/death thresholds where a causal delay equation develops a tangency.

A candidate stable super-field-speed bound state therefore cannot be described by a single smooth acceleration curve alone. It must satisfy a finite root-ledger balance:

$$\sum_{m\in\mathcal{M}_p(s)} A^{\text{rad}}_{p,m}(R,s) - \sum_{m\in\mathcal{M}_s(s)} A^{\text{rad}}_{s,m}(R,s) = \frac{s^2}{R}$$

together with whatever tangential closure condition is supplied by the full regularized dynamics. The radial equation says that partner-root accumulation supplies inward pull while self-root accumulation supplies outward response. On a fixed signed branch ledger b, the corresponding constant-speed closure target has the form

$$\left\langle \sum_{\rho\in b} T_\rho(R,s;\eta) \right\rangle_{P_b} = 0$$

where the average is taken over one candidate period P_b of the regularized history. The tangential condition remains the hard part: in the same-sheet bare isolated two-body kernel, the no-go result above shows that every active branch contributes positive tangential drive; in the full signed ledger, negative sheets must be included before any global no-go or closure theorem is claimed.

Equivalently, on a fixed signed ledger b, the circular MCB search is the intersection problem

$$G^{(b)}_{\text{rad}}(R,s) = 0, \qquad G^{(b)}_{\tan}(R,s) = 0$$

where

$$G^{(b)}_{\mathrm{rad}}(R,s) \equiv \sum_{\alpha_p \in b_p} A^{\mathrm{rad}}_{\alpha_p}(R,s) - \sum_{\alpha_s \in b_s} A^{\mathrm{rad}}_{\alpha_s}(R,s) - \frac{s^2}{R}$$

and

$$G^{(b)}_{\tan}(R,s) \equiv \left\langle \sum_{\alpha \in b} T_\alpha(R,s;\eta) \right\rangle_{P_b}$$

with b_p and b_s denoting the partner-hit and self-hit entries inside the signed ledger b.
The first curve enforces inward/outward radial balance, while the second enforces finite-window tangential closure. In the natural Layer-I units, the search lives in $(R/R_*, s)$, so any intersection is a parameter-free candidate point for that ledger. It is still only an algebraic MCB candidate until the fixed-ledger return map proves stability, positive Jacobian floors, and persistence under perturbation.

This gives a precise, conditional meaning to binary resonance lock. A stable slot would be a region of history space in which the integer pair

$$(N_s, M_p)$$

is fixed, the branch Jacobians stay transversal, and perturbations that approach a root threshold are pushed back into the same ledger rather than escaping to a neighboring one. If such a self-map certificate exists, the discreteness of

$$N_s \quad \text{and} \quad M_p$$

would provide a deterministic mechanism for quantized bound-state geometry: allowed radii and frequencies would be selected by integer causal-root ledgers rather than by a continuum of arbitrary circular orbits.

This statement is deliberately conditional. This chapter derives the discrete root ledgers and the radial balance target, but the stability and quantization claims require the missing full-history certificate: finite active branches, positive Jacobian floors, transmitter-side acceleration-weight floors, returned-history closure, and a monodromy or boundary-trapping argument. In practice, that certificate may close first in a collinear breather or Noether braid setting rather than in the bare circular two-body kernel.

Branch Stability Target (Hessian Bridge)

The standard equilibrium test in central-force mechanics uses the Hessian of an instantaneous effective potential. If $q_\star$ is an equilibrium, the matrix

$$H_{ab}(q_\star) = \partial_a \partial_b V_{\mathrm{eff}}(q_\star)$$

tests local stiffness in the non-symmetry directions. This is useful as comparison language, but it is not yet a stability proof for an architrino binary because the acceleration law depends on path-history, the active signed causal-root ledger, the transmitter-side acceleration weight, and the branch Jacobian floors.

The $\mathbb{AAA}$ branch-stability target is therefore a cycle-averaged stiffness matrix on a fixed branch chart. Let b denote a fixed signed causal-root ledger and let $\mathbf{X}_b(T)$ be a candidate periodic history with period P_b. For reduced branch coordinates y^a transverse to time shift, period reparameterization, Euclidean motions, and any phase-locked flat-connection moduli retained by an enclosing assembly chart, define the diagnostic stiffness target

$$K^{(b)}_{ab} = \frac{1}{P_b} \int_0^{P_b} \left. \frac{\delta^2 U^{\mathrm{hist}}_{\eta,b}}{\delta y^a \, \delta y^b} \right|_{\mathbf{X}_T = \mathbf{X}_{b,T}} dT$$

where $U^{\mathrm{hist}}_{\eta,b}$ is the action-compatible history potential, or the corresponding diagnostic reconstruction when the regularization has not yet been derived from the delayed action. Negative stiffness in this matrix is a local instability signal; positive stiffness is only a necessary reduced-coordinate check, not a certificate.

The actual branch certificate must be delayed-history and Floquet-style. Let

$$\mathcal{P}_b : \mathcal{N}_b \subset \mathcal{H} \to \mathcal{H}$$

advance an admissible history by one candidate cycle while the signed causal-root ledger remains fixed. A stable branch requires the return map to stay inside the same branch neighborhood,

$$\mathcal{P}_b(\mathcal{N}_b) \subset \mathcal{N}_b, \qquad \inf_{\phi \in \mathcal{N}_b} |J(\phi)| \geq J_{\min} > 0$$

and the non-symmetry Floquet multipliers of $D\mathcal{P}_b[\mathbf{X}_b]$ to satisfy

$$|\mu_\alpha| < 1$$

Only that return-map condition would upgrade the Hessian-style stiffness picture into branch stability. If the candidate touches a branch-fold or $J = 0$ wall, this smooth Floquet test must be supplemented by the Conley-index isolating-block certificate named above; otherwise the multiplier calculation has evaluated the smooth arcs while missing the grazing transition. Until those certificates are supplied, MCB stability remains a conditional target rather than a completed proof.

Finite-dimensional projection caveat

The circular formulas below use reduced coordinates; stability in the full history space remains a separate proof obligation.

Two-Body Closure Packet (Theorem Target)

The practical standard is replayability. A binary branch is not accepted because the picture is circular, compact, or suggestive. It is accepted only when the same finite record supplies the motion, active roots, excluded roots, return map, energy packet, and residuals needed to reproduce the branch under the delayed law.

A nontrivial electrino:positrino binary is promoted only by a replayable finite-η packet, not by the circular ansatz alone. For a fixed signed causal-root ledger b, the binary closure packet is

$$\mathfrak{C}_{2\mathrm{B}}^{(\eta)} = (b, \mathbf{X}_b, P_b, R_b, s_b, \mathfrak{B}_b, \mathcal{P}_b, \mathcal{E}_b)\,,$$

where $\mathbf{X}_b(T)$ is the two-body history, P_b is its return period, R_b and s_b are the circular benchmark radius and speed when that reduction is valid, $\mathfrak{B}_b$ is the branch chart of active and excluded roots, $\mathcal{P}_b$ is the history-space return map, and $\mathcal{E}_b$ is the constructive energy packet of Delay-Dynamics Energy. The packet must report the following residuals before the branch can be used as a closed result.

This chapter owns the normative two-body residual tuple:

$$\mathsf{Res}_{2\mathrm{B}}^{(\eta)} = \left(\mathcal{R}_{\mathrm{EOM}}^{2\mathrm{B}}, \mathcal{R}_{\mathrm{per}}^{2\mathrm{B}}, \mathcal{R}_{\mathrm{bal}}^{2\mathrm{B}}, \nu_J^{2\mathrm{B}}, \nu_{\mathrm{rec}}^{2\mathrm{B}}, \Delta_{\mathrm{gap}}^{2\mathrm{B}}, \lambda_{\mathrm{sec}}^{2\mathrm{B}}, \epsilon_E^{(\eta)}, \Delta_{\mathrm{E,cross}}^{(\eta)}, \mathcal{R}_\omega^{2\mathrm{B}}\right).$$

Simulation recipes consume this tuple by reference; they must not define shorter or reordered variants.

The equation-of-motion residual is

$$\mathcal{R}_{\mathrm{EOM}}^{2\mathrm{B}}(b, \eta) = \frac{1}{P_b} \int_0^{P_b} \frac{\left\| \frac{d^2 \mathbf{X}_b}{dT^2}(T) - \mathcal{A}_{\eta,b}[\mathbf{X}_{b,T}] \right\|}{1 + \|\mathcal{A}_{\eta,b}[\mathbf{X}_{b,T}]\|}\, dT,$$

where $\mathcal{A}_{\eta,b}$ is the regularized two-body branch acceleration obtained from the active self and partner records in b. The period residual is

$$\mathcal{R}_{\mathrm{per}}^{2\mathrm{B}}(b, \eta) = \frac{\|\mathbf{X}_{b,P_b} - \mathbf{X}_{b,0}\|_{\mathcal{H}}}{\|\mathbf{X}_{b,0}\|_{\mathcal{H}} + \epsilon_{\mathcal{H}}},$$

with $\mathcal{H}$ the declared history norm and $\epsilon_{\mathcal{H}} > 0$ a fixed normalization floor.

The packet must also report the signed-degree record

$$\deg_s^{2B}(b) = \sum_{\rho\in b_s} \operatorname{sign} J_\rho, \qquad \deg_p^{2B}(b) = \sum_{\rho\in b_p} \operatorname{sign} J_\rho,$$

where b_s and b_p are the retained self-hit and partner-hit entries. On a smooth certified window these integers must be constant. If the branch crosses a fold inside the window, the packet must log the corresponding $\Delta N = \pm 2, \Delta D = 0$ surgery rather than treating the unsigned root counts as conserved data.

The branch-chart admissibility certificate is

$$\nu_J^{2B}(b,\eta) = \inf_{\rho\in b,\, 0\le T\le P_b} |J_\rho(T)| > 0, \qquad \Delta_{\rm gap}^{2B}(b,\eta) = \inf_{\rho\in b^{\rm off},\, 0\le T\le P_b} |g_\rho(T)| > 0.$$

Here J_ρ is the root Jacobian for an active record and g_ρ is the signed gap of a declared inactive record in the finite branch complement $b^{\rm off}$. The certificate fails if either floor tends to zero under refinement or under the advertised η-continuation.

The same active records must also certify a nonvanishing lower acceleration-weight margin

$$\nu_{\rm rec}^{2B}(b,\eta) = \inf_{\rho\in b,\, 0\le T\le P_b} W_\rho^{\rm acc}(T) > 0.$$

Together with $\nu_J^{2B} > 0$, this keeps the canonical transmitter-side acceleration weight inside a finite positive interval on the retained branch chart.

For a circular benchmark the radial and tangential balance residual is

$$\mathcal{R}_{\rm bal}^{2B} = \frac{\left|\left\langle A_{\eta,b}^{\rm rad}(R_b,s_b)\right\rangle_{P_b} - s_b^2/R_b\right|}{1 + s_b^2/R_b + \left|\left\langle A_{\eta,b}^{\rm rad}\right\rangle_{P_b}\right|} + \frac{\left|\left\langle A_{\eta,b}^{\rm tan} + A_{\partial W}^{\rm tan}\right\rangle_{P_b}\right|}{1 + \left\langle |A_{\eta,b}^{\rm tan}| + |A_{\partial W}^{\rm tan}|\right\rangle_{P_b}}.$$

The boundary term is not optional bookkeeping: it is required by the constructive finite-window wake-energy account. If it is absent, verification is incomplete and the packet is not advanced; tangential work cannot be hidden in an undefined reservoir.

The stability certificate is a secular Floquet margin in history space,

$$\lambda_{\rm sec}^{2B}(b,\eta) = 1 - \rho\Big(D\mathcal{P}_b[\mathbf{X}_b]\big|_{E_\perp}\Big) > 0,$$

where $E_\perp$ removes the neutral phase and symmetry directions. A numerical orbit without this projected return-map certificate is an existence candidate, not a stable binary certificate.

For a standalone circular binary, the neutral quotient includes the global time phase, the period-reparameterization direction, and Euclidean translations and rotations of the complete history. When the same two-body packet is embedded into a phase-locked rank-three braid or larger assembly chart, a neutral-direction audit is required: a direction may be removed from $E_\perp$ only if it is neutral for the full enclosing chart, not merely for the isolated subsystem. The flat-connection moduli declared by the enclosing chart are physical lock variables unless the full chart proves them neutral. Otherwise a slow drift of relative phase can be hidden as an allowed symmetry even though it breaks the lock.

The energy packet is

$$\mathcal{E}_b = \Big(\epsilon_E^{(\eta)}(W_b;\mathfrak{B}_b), \Delta_{\rm E,cross}^{(\eta)}(W_b;\mathfrak{B}_b), U_{b,\rm work}^{(\eta)}(T), U_{\min,b}^{(\eta)}\Big),$$

and must satisfy

$$\epsilon_E^{(\eta)}(W_b;\mathfrak{B}_b) \le \epsilon_E^\star, \qquad \Delta_{\rm E,cross}^{(\eta)}(W_b;\mathfrak{B}_b) \le \epsilon_{\rm cross}^\star, \qquad E_{{\rm wake},b}^{(\eta)}(T) \ge U_{\min,b}^{(\eta)}$$

on the same window, branch chart, and regulator used for the motion residuals. The work reconstruction is

$$U_{b,\mathrm{work}}^{(\eta)}(T) = U_b(T_*) - \int_{T_*}^{T} \sum_i \mu_{\mathrm{arch}}\, \mathbf{A}_{i,b}^{(\eta)}(T') \cdot \mathbf{V}_i(T')\, dT'$$

for the quadratic proxy, with $\mu_K(\|\mathbf{V}_i\|)$ replacing μ_{arch} when the primitive kinetic scalar is used. The lower-bound entry applies to the constructed action-level wake charge when that route is available, or to the compatible work reconstruction when that is the declared route. This is the handoff point to the constructive delay-energy chapter: ordinary Noether language is not sufficient until $E_{\mathrm{wake},b}^{(\eta)}$ or its compatible work-integral reconstruction has been constructed for the chosen chart.

Finally, the characteristic frequency is extracted from the return period,

$$\omega_b = \frac{2\pi}{P_b}, \qquad \mathcal{R}_{\omega}^{2\mathrm{B}} = \frac{|2\pi/P_b - s_b/R_b|}{|2\pi/P_b| + |s_b/R_b| + \epsilon_\omega},$$

when the circular reduction is claimed. For a noncircular branch, $\omega_b = 2\pi/P_b$ remains the fundamental return frequency, but the s_b/R_b comparison is inadmissible unless an effective radius and speed have been independently defined. A breather or spiral candidate must instead report its harmonic-extraction rule on the retained history record and compare the extracted fundamental or locked harmonic to $2\pi/P_b$.

The theorem target is therefore:

> If a finite-η branch supplies $\mathfrak{C}_{2\mathrm{B}}^{(\eta)}$ with $\mathcal{R}_{\mathrm{EOM}}^{2\mathrm{B}}$, $\mathcal{R}_{\mathrm{per}}^{2\mathrm{B}}$, $\mathcal{R}_{\mathrm{bal}}^{2\mathrm{B}}$, and $\mathcal{R}_{\omega}^{2\mathrm{B}}$ below declared tolerances, $\nu_J^{2\mathrm{B}}$, $\nu_{\mathrm{rec}}^{2\mathrm{B}}$, and $\Delta_{\mathrm{gap}}^{2\mathrm{B}}$ bounded away from zero, $\lambda_{\mathrm{sec}}^{2\mathrm{B}} > 0$, and the constructive energy residuals closed on the same branch chart, then that branch is a certified local electrino:positrino two-body binary at that finite regulator.

No such finite-η packet is supplied in this chapter yet. The status is a theorem target and simulation closure contract, not a closed proof. The $\eta \to 0$ limit, the basin measure of the branch, and the later use of the binary as a universal clock or matter standard remain separate obligations.

State Space and Well-Posedness of the Two-Body Delay System

Introduction and Scope

The master equation of motion for the architrino system constitutes a system of **State-Dependent Neutral Delay Differential Equations (SD-NDDEs)**. Unlike ordinary differential equations (ODEs) where the state is a point in $\mathbb{R}^{6N}$, the state of this system is a **function segment** representing the past history of the architrinos.

We denote the position of the i-th architrino as $\mathbf{X}_i(T) \in \mathbb{R}^3$. We work in the **Euclidean void** with fixed metric δ_{ij}.

Functional Phase Space

To define the evolution at time T, we require knowledge of the trajectory over an interval $[T - \Delta_{\max}, T]$, where $\Delta_{\max}$ is the maximum causal lookback time relevant to the current dynamics.

Definition 1 (The History Space)

Let $h > 0$ be a history horizon (sufficiently large to capture all active causal roots). On a smooth simple-root branch, the **smooth history space** $\mathcal{H}_{\mathrm{sm}}$ is the Banach space of continuously differentiable functions mapping the delay interval to the configuration space:

$$\mathcal{H}_{\mathrm{sm}} = C^1\left([-h, 0]; (\mathbb{R}^3)^N\right).$$

For a trajectory $\mathbf{X} : [-h, \infty) \to (\mathbb{R}^3)^N$, the **state at time** T, denoted $\mathbf{X}_T$, is the element of $\mathcal{H}_{\mathrm{sm}}$ on smooth charts, or of $\mathcal{H}_*$ on caustic-extension charts, given by:

$$\mathbf{X}_T(\theta) = \mathbf{X}(T + \theta), \quad \theta \in [-h, 0]$$

The norm on the smooth chart is the standard C^1 sup-norm: $\|\phi\|_{\mathcal{H}_{\mathrm{sm}}} = \sup_{\theta \in [-h,0]}(\|\phi(\theta)\| + \|\dot{\phi}(\theta)\|)$.

Remark: We require C^1 rather than C^0 because the causal delay Δ depends on the state. In such systems, the vector field is typically not Lipschitz continuous in the C^0 topology, endangering uniqueness.

For caustic-grazing packets this smooth space is not the whole story. The working extension is

$$\mathcal{H}_* = W^{1,\infty}\left([-h,0];(\mathbb{R}^3)^N\right),$$

with C^1 regularity retained on smooth arcs and finite impulse transitions handled by the finite-η kernel before any $\eta \to 0$ statement is made. The existence theorem below is a smooth-chart theorem. A branch that crosses a $J = 0$ wall must supply a separate impulse lemma or isolating-block continuation certificate showing that the finite-η solutions converge in $\mathcal{H}_*$ with bounded velocity and finite total impulse. This makes $\mathcal{H}_*$ the common functional-analytic home for caustic-grazing two-body packets, doubling-frequency middle-carrier caustics, and any later breather packet that relies on finite impulse rather than a globally C^1 path.

Below, $\mathcal{H}$ denotes the declared history chart for the packet being tested. Unless a caustic-extension certificate is explicitly named, $\mathcal{H} = \mathcal{H}_{\rm sm}$.

The Regularized Interaction Functional

We formalize the acceleration term derived in the master equation.

Definition 2 (Causal Constraint Functional)

For a receiver architrino i at reception time T_r and transmitter j, the delay $\Delta_{ij}(T_r)$ is implicitly defined by the causal-isochron condition. Let $\phi \in \mathcal{H}$ be the history. A **causal root** is a value $\Delta > 0$ satisfying:

$$g_{ij}(\Delta, \phi) \equiv \|\phi_i(0) - \phi_j(-\Delta)\| - c_f\Delta = 0$$

Lemma 1 (Regularity of the Delay Map)

Assumption: The velocities are sub-field-speed relative to the separation, i.e., $\|\mathbf{V}_j\| < c_f$ (single-root regime) OR we isolate a specific branch of the multi-root solution where the relative radial velocity is not c_f.

Statement: If $\phi \in \mathcal{H}$ and Δ^* is a simple root of $g_{ij}(\Delta, \phi) = 0$ (i.e., $\partial_\Delta g_{ij} \neq 0$), then there exists a neighborhood $U \subset \mathcal{H}$ of ϕ and a continuously differentiable functional $\Delta : U \to \mathbb{R}^+$ such that $\Delta(\phi) = \Delta^*$.

Proof.
Define

$$g_{ij}(\Delta, \phi) = \|\phi_i(0) - \phi_j(-\Delta)\| - c_f\Delta$$

Because $\phi \in C^1$, the evaluation maps $\phi \mapsto \phi_i(0)$ and
$(\Delta, \phi) \mapsto \phi_j(-\Delta)$ are C^1, hence g_{ij} is C^1 on
$\mathbb{R}^+ \times \mathcal{H}$. At a root (Δ^*, ϕ),

$$\partial_\Delta g_{ij} = \hat{\mathbf{r}}_{ij} \cdot \dot{\phi}_j(-\Delta^*) - c_f, \quad \hat{\mathbf{r}}_{ij} \equiv \frac{\phi_i(0) - \phi_j(-\Delta^*)}{\|\phi_i(0) - \phi_j(-\Delta^*)\|}$$

Equivalently, $\partial_\Delta g_{ij} = -D_{t,ij}$ on this root.
The simple-root condition is exactly $\partial_\Delta g_{ij} \neq 0$, i.e. no
delayed tangency/causal-shock degeneracy. Therefore, by the Banach-space
Implicit Function Theorem, there exist a neighborhood U of ϕ and a
unique C^1 map $\Delta : U \to \mathbb{R}^+$ with
$g_{ij}(\Delta(\psi), \psi) = 0$ and $\Delta(\phi) = \Delta^*$. $\square$

Definition 3 (Regularized Acceleration Functional)

To ensure the vector field is Lipschitz, we replace the distributional Dirac delta of the master equation with the mollifier δ_η (see Master Equation). The acceleration functional $F_i : \mathcal{H} \to \mathbb{R}^3$ is:

$$F_i(\phi) = \sum_j \kappa\sigma_{ij}|q_i q_j| \int_{-h}^{0} \frac{\phi_i(0) - \phi_j(\theta)}{\|\phi_i(0) - \phi_j(\theta)\|^3} \, \delta_\eta \left(\|\phi_i(0) - \phi_j(\theta)\| + c_f\theta\right) \, d\theta$$

Crucial Property: For $\eta > 0$ and smooth δ_η, this integral operator maps C^1 histories to continuous accelerations.

This finite-η functional is a certification surrogate until its sharp-limit
branch reduction reproduces the canonical transmitter-side acceleration weight.
Each retained simple root must carry $W^{\mathrm{acc}}_{ij} = c_f/|D_{t,ij}|$.
The same record also carries $D_{r,ij}/D_{t,ij}$ for signed root playback, but that
ratio does not multiply the instantaneous acceleration.

On $\mathcal{H}_*$ this same formula is interpreted through the finite-η integral first. The admissibility claim is weaker: the packet must show bounded velocity and finite total impulse across the grazing chart before it can pass to the $\eta \to 0$ limit.

Local Well-Posedness

Theorem 1 (Local Existence and Uniqueness)

Assumptions:

1. $\eta > 0$, and δ_η is C^1 with bounded value and bounded derivative.
2. Initial history $\phi^0 \in \mathcal{H}$ is admissible: there exists $d_{\min} > 0$ such that all interaction channels used by Definition 3 satisfy

$$\|\phi_i(0) - \phi_j(\theta)\| \geq d_{\min}, \qquad \theta \in [-h, 0]$$

on a neighborhood of ϕ^0.
3. Delay roots used in channel construction are simple (transversal), i.e. no causal-shock degeneracy (Lemma 1).
4. Active branches are uniformly finite on the considered history neighborhood.
5. Couplings and polarity magnitudes are finite.
6. Optional higher-smoothness gluing condition at $T = T_{\text{init}}$ (needed for C^2 at the junction, not for C^1 well-posedness).

Statement:
Let $\mathbf{Y} = (\mathbf{X}, \mathbf{V})$ and write the system in first-order form

$$\frac{d\mathbf{Y}}{dT} = \mathcal{G}(\mathbf{Y}_T), \qquad \mathbf{Y}_{T_{\text{init}}} = \phi^0$$

Then there exists $\Delta T > 0$ and a unique C^1 solution on $[T_{\text{init}} - h, T_{\text{init}} + \Delta T)$.
Equivalently, there is a unique maximal solution interval

$$[T_{\text{init}} - h, T_{\max}), \qquad T_{\max} > T_{\text{init}}$$

If the optional gluing condition holds, the solution is C^2 at T_{init}.

Proof.
Define

$$\mathcal{G}(\phi) = (\phi_v(0), F(\phi))$$

with F from Definition 3.

1. By Assumption 2, every denominator in the interaction kernel is bounded away from zero on the admissible neighborhood; therefore the map

$$(\mathbf{u}, \mathbf{w}) \mapsto \frac{\mathbf{u} - \mathbf{w}}{\|\mathbf{u} - \mathbf{w}\|^3}$$

is C^1 there with bounded derivative.
2. By Assumption 1, composition with δ_η preserves C^1 regularity and bounded derivatives.
3. By Lemma 1 and Assumption 3, delay branches (where used) depend C^1 on history; thus branch-evaluation maps are locally Lipschitz in ϕ.
4. Finite sums over channels and integration over finite interval $[-h, 0]$ preserve local Lipschitz continuity; hence $\mathcal{G}$ is locally Lipschitz on an open subset of $\mathcal{H}$ containing ϕ^0.
5. Apply the standard Banach-space existence/uniqueness theorem for state-dependent DDEs: a unique local C^1 solution exists and extends uniquely to a maximal interval.

Therefore Theorem 1 holds. □

Global Existence vs. Blow-Up

Unlike Newtonian gravity, global existence is **not guaranteed** simply by avoiding collisions, because the delay equation can harbor “runaway” modes where self-acceleration diverges.

Theorem 2 (Continuation Principle)

The solution $\mathbf{X}(T)$ can be extended as long as the state $\mathbf{X}_T$ remains within a compact subset of the phase space where causal roots are simple.

Definition 4 (Blow-Up Criteria)

The solution ceases to exist at finite time T^* if:

1. **Collision:** $\inf_{i,j} \|\mathbf{X}_i(T) - \mathbf{X}_j(T')\| \to 0$ inside the regularization kernel support.
2. **Infinite Speed:** $\sup_i \|\mathbf{V}_i(T)\| \to \infty$.
3. **Causal Shock:** The derivative of the delay $d\Delta/dT$ diverges because the transmitter-side factor becomes singular. The branch condition is $\mathbf{V}_j(T_t) \cdot \hat{\mathbf{r}}_{ij} = c_f$ at emission, not merely $\|\mathbf{V}_j\| = c_f$.

Symmetry, Conservation, and Lyapunov Functionals

Introduction

Standard conservation laws (energy, momentum, angular momentum) rely on the application of Noether’s theorem to local Lagrangian densities. In this delayed setting, the acceleration at absolute time T depends on the phase-space trajectory over the interval $[T - h, T]$.

For an action-derived, symmetry-preserving delayed model, symmetries of the substrate (Euclidean void + absolute time) imply conservation laws, but the conserved quantities are no longer simple functions of the instantaneous state $(\mathbf{X}, \mathbf{V})$. Instead, they are **functionals on the history space** $\mathcal{H}$. For a working regularized kernel not yet derived from an action, the same expressions function as validation diagnostics rather than established Noether charges.

This section derives these functionals, establishes the exact symmetry group of the regularized dynamics ($\eta > 0$), and provides the *a priori* bounds required to ensure physical well-posedness (preventing unphysical runaway acceleration).

The Global Symmetry Group

We consider the regularized two-body system in the Euclidean void $\mathbb{R}^3$ with metric δ_{ij} and absolute time T.

In this symmetry proof, bare T is intentionally the generic absolute-time parameter transformed by time translation. When one delayed term is read as a causal hit, that evaluation event has reception time T_r and the retained earlier root has emission time T_t.

Definition (The Fundamental Symmetry Group)

The background substrate and the master equation interaction kernel

$$\mathbf{A}_{ij}(T) \propto \frac{W_{ij}^{\mathrm{acc}}(T;T_t)}{\|\mathbf{X}_i(T)-\mathbf{X}_j(T_t)\|^3}\,(\mathbf{X}_i(T)-\mathbf{X}_j(T_t))$$

(regularized by η) respect the group:

$$G_{\mathrm{fund}} = E(3)\times\mathbb{R}_{\mathrm{time}}$$

where $E(3)=\mathbb{R}^3\rtimes O(3)$ is the Euclidean group of spatial translations and rotations, and $\mathbb{R}_{\mathrm{time}}$ denotes time translation.

Theorem (Invariance of the Equations of Motion)

Let $\mathbf{X}(T)$ be a solution to the master equation.

1. **Time Translation:** For any $\Delta T\in\mathbb{R}$, $\mathbf{Y}(T)=\mathbf{X}(T+\Delta T)$ is also a solution.
2. **Spatial Isometry:** For any $R\in O(3)$ and $\mathbf{b}\in\mathbb{R}^3$, $\mathbf{Y}(T)=R\mathbf{X}(T)+\mathbf{b}$ is also a solution.

Proof.
For time translation, set $\mathbf{Y}_i(T)=\mathbf{X}_i(T+\Delta T)$. If $T_t\in\mathcal{C}_{ij}^X(T+\Delta T)$ for the original solution, then $T_t-\Delta T\in\mathcal{C}_{ij}^Y(T)$ because

$$\|\mathbf{Y}_i(T)-\mathbf{Y}_j(T_t-\Delta T)\| = \|\mathbf{X}_i(T+\Delta T)-\mathbf{X}_j(T_t)\| = c_f[(T+\Delta T)-T_t] = c_f[T-(T_t-\Delta T)]$$

Hence the same branch contributions appear with shifted times, and $\frac{d^2\mathbf{Y}_i}{dT^2}(T)=\frac{d^2\mathbf{X}_i}{dT^2}(T+\Delta T)$ satisfies the same acceleration law.

For spatial isometries, set $\mathbf{Y}_i(T)=R\mathbf{X}_i(T)+\mathbf{b}$, $R\in O(3)$. Distances are preserved:

$$\|\mathbf{Y}_i(T)-\mathbf{Y}_j(T_t)\| = \|R(\mathbf{X}_i(T)-\mathbf{X}_j(T_t))\| = \|\mathbf{X}_i(T)-\mathbf{X}_j(T_t)\|$$

so causal-root times are unchanged. Unit directions transform covariantly: $\hat{\mathbf{r}}_{ij}^Y=R\hat{\mathbf{r}}_{ij}^X$. The dot products defining D_t, D_r, and W^{acc} are preserved by the same spatial isometry. Therefore each acceleration term transforms as $\mathbf{A}_{ij}^Y=R\mathbf{A}_{ij}^X$, and

$$\frac{d^2\mathbf{Y}_i}{dT^2}(T) = R\frac{d^2\mathbf{X}_i}{dT^2}(T) = \sum_j\sum_{T_t\in\mathcal{C}_{ij}(T)}\kappa\sigma_{ij}\frac{|q_iq_j|\,W_{ij}^{\mathrm{acc}}(T;T_t)}{r_{ij}^2}\,\hat{\mathbf{r}}_{ij}^Y$$

Thus $\mathbf{Y}$ solves the same equations. $\square$

Implication: In an action-derived regularization, these symmetries correspond to exact history-space integrals of motion. Because the interaction is non-local in time, those integrals must account for momentum and energy carried by causal wake surfaces rather than only by the instantaneous mechanical coordinates.

Conservation of Generalized Momentum

As a standard instantaneous-interaction comparison, equal bookkeeping weights would give $\mu_{\mathrm{arch}}\mathbf{A}_{12}(T)=-\mu_{\mathrm{arch}}\mathbf{A}_{21}(T)$. The delayed system does not generally satisfy that equal-time relation: $\mathbf{A}_{12}(T)$ samples architrino 2 at $T-\Delta_1$, while $\mathbf{A}_{21}(T)$ samples architrino 1 at $T-\Delta_2$. This comparison does not introduce force as a substrate quantity; the Master Equation remains acceleration-first.

Definition (Mechanical Momentum)

The instantaneous mechanical momentum is:

$$\mathbf{P}_{\text{mech}}(T) = \sum_i \mu_{\text{arch}} \mathbf{V}_i(T)$$

Because of the delay, $\frac{d}{dT}\mathbf{P}_{\text{mech}} \neq 0$ generally.

Conservation Target (Total Momentum Functional)

For an action-derived delayed model with translation symmetry, there exists a functional $\mathbf{P}_{\text{wake}}[\mathbf{X}_T]$ representing the momentum flux encoded in the active causal wake surfaces such that the total momentum:

$$\mathbf{P}_{\text{tot}} = \mathbf{P}_{\text{mech}}(T) + \mathbf{P}_{\text{wake}}[\mathbf{X}_T]$$

is conserved. For working regularized models, this same expression is a validation diagnostic unless the chosen regularization preserves the translation symmetry of the underlying action.

Explicit Form (Weak Coupling Limit):
For $\eta \to 0$, the wake momentum can be approximated by integrating the acceleration impulse over the delay time:

$$\mathbf{P}_{\text{wake}} \approx \sum_{i \neq j} \int_{T-\Delta_{ij}(T)}^{T} \mu_{\text{arch}} \mathbf{A}_{ij}^{\text{emit}}(T')\, dT'$$

Physical interpretation: The "missing" momentum is accounted for by the causal wake surfaces currently traversing the space between transmitters and receivers in an action-derived model; otherwise this balance is the momentum diagnostic to verify.

Corollary (Center of Response Motion):
For an isolated binary, the center of mass $\mathbf{X}_{\text{cm}}$ need not move at constant velocity in the mechanical coordinates alone. Instead, it can oscillate around a mean trajectory while wake momentum carries the compensating history term. This is the two-body version of the center-of-response theorem target: in an exactly symmetric circular binary, the exposed-energy response center $\mathbf{X}_{\text{resp}}$ is pinned to the circle center by symmetry, while the particle-only mechanical center can still show finite-window oscillatory bookkeeping if wake momentum is not included. A runaway center-of-mass self-acceleration is forbidden only in an action-derived model whose regularization preserves translation symmetry; in working regularized models this is a conservation diagnostic to be checked.

Energy and The Lyapunov Functional

Energy conservation is the critical constraint preventing runaway solutions.

Definition (The History Hamiltonian)

For an action-derived delayed model with time-translation symmetry, the target conserved quantity $\mathcal{H}$ is a history functional. For state-dependent delays, the useful comparison object is a **Lyapunov-Krasovskii-style functional**:

$$\mathcal{H}(\mathbf{X}_T) = K(T) + \mathcal{U}_{\text{history}}(\mathbf{X}_T)$$

1. **Kinetic Energy:** $K(T) = \sum \frac{1}{2}\mu_{\text{arch}} \|\mathbf{V}_i(T)\|^2$.
2. **Potential Functional:** $\mathcal{U}_{\text{history}}$ accumulates the assembly-level work bookkeeping from the delayed acceleration contributions. Unlike an instantaneous potential $V(r)$, this depends on the configuration of all active wake surfaces.

Trajectory Identity (Energy Balance)

$$\frac{dK}{dT} = \sum_i \mu_{\text{arch}} \mathbf{V}_i(T) \cdot \mathbf{A}_i(T)$$

We define the **Interaction Potential Functional** $\mathcal{W}(T)$ such that:

$$\mathcal{W}(T) = -\int_{T_{\text{init}}}^{T} \sum_i \mu_{\text{arch}} \mathbf{V}_i(T') \cdot \mathbf{A}_i(T')\, dT'$$

This functional is nonlocal in time: it accumulates deferred work along the path-history of wakes and is not an instantaneous potential $U(r)$.
Then, by construction along the realized trajectory, $\mathcal{E}_{\text{tot}} = K(T) + \mathcal{W}(T)$ is constant. It is an exact Noether charge only when $\mathcal{W}$ is the boundary term of the same symmetry-preserving delayed action; otherwise it is a diagnostic reconstruction.

That distinction is decisive for the circular tangential channel. A $\mathcal{W}$ obtained by integrating the same $\mathbf{A} \cdot \mathbf{V}$ record cannot test whether the record contains persistent forward tangential acceleration; it assigns the opposite change to $\mathcal{W}$ by definition. Independent circular energy closure requires the action-derived boundary charge or a separately derived finite-window wake account.

Lemma (Boundedness of the Potential)

Assumption: The interaction is regularized with width $\eta > 0$ such that the per-hit acceleration is bounded: $\|\mathbf{A}_{ij}\| \leq A_{\max}(\eta)$.
Statement: For a bound system (architrinos confined to a finite volume V), the magnitude of the assembly-level work rate is bounded by $N\mu_{\text{arch}} A_{\max} V_{\max}$.

Conditional Target (No-Runaway Criterion)

This criterion is not a completed theorem until the same symmetry-preserving regularized action supplies $\mathcal{W}$ on the retained branch chart and a lower bound is proven for that branch. Under those hypotheses, in an action-derived master-equation branch with fixed $\eta > 0$, an isolated binary cannot undergo runaway acceleration ($\|\mathbf{V}\| \to \infty$) *unless* the action-compatible potential energy functional $\mathcal{W}(T)$ diverges to $-\infty$.

Proof Logic:
Since $\mathcal{E}_{\text{tot}}$ is constant:

$$K(T) = \mathcal{E}_{\text{tot}} - \mathcal{W}(T)$$

For $K(T)$ to diverge, $\mathcal{W}(T)$ must decrease without bound.

1. **Partner attraction:** $q_1 q_2 < 0$. The potential is negative (attractive). As $r \to 0$, $V \to -\infty$. Collapse leads to infinite kinetic energy in the standard Kepler singularity pattern; in this architecture, self-hit is the proposed counter-channel.
2. **Self-hit repulsion:** $q_1 q_1 > 0$. The acceleration is **repulsive**. The potential contribution is **positive**.

- Work done by self-hit: If an architrino is pushed “from behind” by its own wake, it gains K.
- However, this energy must come from the $\mathcal{W}$ term.
- Since self-hit potential is repulsive (positive energy hill), converting it to kinetic energy lowers the total potential.
- **Crucial bound:** The deferred work encoded in a self-wake is finite when the emitted causal-wake budget is finite. An architrino cannot extract infinite energy from its own past unless the history functional has already assigned an infinite budget to that causal wake.

Conclusion: A self-acceleration runaway, where an architrino accelerates itself indefinitely using self-acceleration contributions, is excluded only on branches satisfying the action-derived conservation and lower-bound hypotheses. In other working models, the same statement is a validation target: the system can oscillate or settle, but an apparent explosion to $\|\mathbf{V}\| = \infty$ must be traced either to singular collapse, transversality loss, or a broken conservation diagnostic.

Summary

The circular atlas establishes exact delay equations, signed-sheet root thresholds, and canonically weighted radial and tangential coefficients. The principal partner branch cannot form a particle-only constant-speed circle because its tangential acceleration is positive. The complete unregularized canonical simple-root ledger does contain algebraic radial/tangential balance points, so the circular ansatz is not excluded at that level. Redirecting the acceleration toward an inertially extrapolated emission site removes those candidates and supplies no replacement equilibrium on $1 < s < 20$, but the autonomous fixed-speed wake state rejects that construction as the local response of the present causal surfaces. A maximum-curvature binary remains conditional: the canonical candidates must survive one finite singular-event convention, retained-history transport, wake-boundary exchange, return-map stability, Jacobian floors, and the action-derived conservation charges on one retained history record.

Causal Action Functional

This chapter explains how action-like scalar summaries are allowed to enter delayed dynamics with transmitter-side acceleration weight. The Master Equation remains the vector law. The causal action functional is a branch statistic used to compare retained histories, estimate barriers, and feed stability or mass-response tests without replacing the line-of-action acceleration.

The central warning is simple: a scalar action value is valid only on the same retained branch record that supplies the causal roots, transmitter-side factor, receiver-side factor, and transmitter-side acceleration weight. Otherwise the statistic has lost the causal information that made the branch physical.

Problem Statement and Goal

This chapter gives the action-functional side of the canonical transmitter-side Master EOM. Its job is not to preserve a separate scalar law. Its job is to define which retained branch records may be used for action, stability, mass-response, and transition-cost calculations after the branch has been rebuilt with transmitter-side acceleration weight.

The active branch strength is

$$W_{ij}^{\mathrm{acc}}(T_r;T_t) = \frac{c_f}{|D_{t,ij}(T_r;T_t)|},$$

with

$$D_{t,ij} = c_f - \mathbf{V}_j(T_t)\cdot\hat{\mathbf{r}}_{ij}(T_r;T_t), \qquad D_{r,ij} = c_f - \mathbf{V}_i(T_r)\cdot\hat{\mathbf{r}}_{ij}(T_r;T_t).$$

Plain language: a retained hit must say how densely the transmitter laid down the arriving wake surface. The receiver-side quantity is recorded separately through the signed playback derivative D_r/D_t.

A branch record that contains D_t but omits D_r can still define the instantaneous acceleration weight, but it cannot certify root continuation through reception time. Action, power, wake-history, mass-response, and conservation claims must state whether they consume transmitter-side acceleration, signed root playback, or both; they may not multiply the two by default.

Core Functional Definitions

On a retained chart $\mathfrak{B}$ with active causal roots $T_t \in \mathcal{C}_{ij}(T_r)$, the receiver-side scalar branch statistic over a native-time window T_{win} is

$$\bar{\mathcal{A}}_{\mathrm{rec}}[\mathfrak{B}] = \frac{1}{T_{\mathrm{win}}}\int_0^{T_{\mathrm{win}}} \sum_{i,j} \sum_{T_t\in\mathcal{C}_{ij}(T_r)} \frac{W_{ij}^{\mathrm{acc}}(T_r;T_t)}{r_{ij}^2(T_r;T_t)+\epsilon_c^2}\,dT.$$

This statistic is sign-blind and coupling-normalized: it suppresses κ, $|q_i q_j|$, and the polarity sign $\sigma_{ij} = \mathrm{sign}(q_i q_j)$. Attractive and repulsive records therefore add by received magnitude rather than canceling by direction. After the

native-time average, $\bar{A}_{\rm rec}$ has inverse-area units;
it is action-like only in the sense that it accumulates receiver-side branch-magnitude density on the retained causal record. It is not automatically the exact Fokker-type variational action, whose causal kernel is tested separately in Master Equation.

Plain language: this number asks how much same-record causal-hit magnitude a branch carries over the window after signs, coupling scale, and push direction have been stripped off.

This is a scalar statistic, not the vector Master EOM itself. It keeps the same causal roots and transmitter-side acceleration weight while discarding the line-of-action direction. Its use is limited:

1. compare candidate branch classes,
2. define transition-cost and barrier targets,
3. supply scalar records for later mass or medium-response tests,
4. hand candidates back to the Master EOM for vector acceleration and conservation checks.

The exact vector acceleration/action consumer must use

$$\frac{W_{ij}^{\rm acc}}{r_{ij}^2}\hat{\mathbf{r}}_{ij}$$

on the same retained branch record. A scalar extremum of $\bar{A}_{\rm rec}$ is therefore only a candidate branch label until the vector residuals close.

Geometric/Topological Framework

The causal root locus is defined by

$$g_{ij}(T_r,T_t)=\|\mathbf{X}_i(T_r)-\mathbf{X}_j(T_t)\|-c_f(T_r-T_t)=0.$$

Plain language: the root condition says that a wake emitted by transmitter j at T_t reaches receiver i exactly at reception time T_r.

On a simple retained root, $D_t\neq 0$ supplies the local inverse-function condition. A retained record is the branch-local data packet that binds the root, transmitter identity, receiver identity, regulator state, and acceleration/action entries to one history chart. A retained box is an interval or chart neighborhood that encloses those entries together; outward-rounded intervals have endpoints rounded away from the computed value so the true entry remains enclosed. The branch label persists as long as the same retained record keeps:

Row	Required status
root residual	zero on the retained box
transmitter-side factor	bounded away from zero except declared caustic routing
receiver-side factor	present on the same retained record
transmitter-side acceleration weight	outward-rounded $W^{\rm acc}$ interval
inactive gaps	positive on the retained complement
finite memory	declared finite horizon

Row	Required status
regulator state	declared η and ϵ_c limits or finite values

Branch labels may change only at declared boundaries: a root enters or leaves the memory window, an inactive gap closes, D_t reaches a caustic boundary, a collision regulator is invoked, or the retained records no longer occupy the same box.

Causal Writhe and Topological Use

Topological quantities such as causal writhe remain admissible only as branch geometry:

$$Wr_c(\mathfrak{B}) = \sum_{\alpha,\beta} \operatorname{sgn}(\alpha,\beta)\,\chi_{\text{causal}}(\alpha,\beta).$$

This notation records signed causal-locus crossings or linkages in the retained record. Here α and β index oriented retained causal-locus strands or strand segments in the declared projection. The indicator $\chi_{\text{causal}}(\alpha,\beta)$ equals 1 only when the two strands form an admissible crossing or linkage event on the same retained record, and equals 0 otherwise. The sign $\operatorname{sgn}(\alpha,\beta)$ is the orientation sign of the ordered strand pair relative to the declared branch framing; it is not defined at a fold, framing slip, or unresolved collision record.

Wr_c is therefore a causal-locus crossing statistic, not a replacement for the canonical framed-topology records such as $Lk = \mathrm{Wr} + \mathrm{Tw}$ in Constructing the Absolute Frame and Architrino. It does not supply acceleration strength. Any use of Wr_c in spin, chirality, confinement, or horizon-interface arguments must also state the branch record on which D_t, D_r, and W^{acc} are available.

Circular Benchmark (Branch-Count Theorem)

The circular branch-count benchmark is topology only. Circular self-hit births, Jacobian-null thresholds, and inactive-gap ledgers may classify causal-root structure, but they do not imply a circular no-go, acceleration-balance result, action minimum, or mass scale.

The theorem spine is the circular no-proliferation result already used by the delayed dynamics stack. In the symmetric circular benchmark, write

$$\beta_f(T) = \frac{\omega(T)R(T)}{c_f}.$$

If $|\beta_f(T)| \leq \beta_{\max} < \infty$ uniformly, then the active circular self-hit count is uniformly bounded:

$$N_{\text{self}}(T) \leq \frac{\beta_{\max}}{\pi} + C_{\text{circ}},$$

where C_{circ} is an absolute endpoint-count constant for the circular root equation. On a one-sign subchart this has the sharper asymptotic form

$$N_{\text{self}}^{(+)}(\beta_f) = \frac{\beta_f}{\pi} + O(1).$$

The branch births occur at tangencies of the circular root equation, so the root census, Jacobian-null thresholds, and inactive-gap changes are one topological ledger. On the non-translating circular chart, $D_r = D_t$, so the playback ratio is one. The acceleration weight is instead $W^{\text{acc}} = c_f/|D_t| = 1/|J|$ in normalized units and is not generally one. The branch-count theorem therefore uses the root structure and does not certify acceleration balance, action closure, or stability. The detailed circular derivations are in Master Equation and the winding-index census in Binary Dynamics.

A current circular benchmark must emit:

Evidence record	Required content
retained roots	partner/self labels and windows
D_t	nonzero denominator floor or declared caustic route
D_r	receiver-side factor interval
W^{acc}	same-record branch strength interval
vector residual	radial and tangential Master EOM residuals
scalar statistic	$\bar{\mathcal{A}}_{\text{rec}}$ on the same record
negative control	Not advanced disposition: verification is incomplete when D_r is absent and failed when D_r is mismatched

Until those records exist, circular material is not evidence for action closure.

Branch Barrier and Transition Cost

For a path $\Gamma : \lambda \mapsto \mathfrak{B}_\lambda$ of retained charts with endpoints $\mathfrak{B}_{\lambda_0}$ and $\mathfrak{B}_{\lambda_1}$, define the candidate receiver-side barrier by the reparametrization-invariant saddle height

$$B_{\text{rec}}(\lambda_0, \lambda_1) = \inf_{\Gamma:\mathfrak{B}_{\lambda_0}\to\mathfrak{B}_{\lambda_1}} \sup_{\lambda\in[\lambda_0,\lambda_1]} \left[\bar{\mathcal{A}}_{\text{rec}}[\mathfrak{B}_\lambda] - \max\left(\bar{\mathcal{A}}_{\text{rec}}[\mathfrak{B}_{\lambda_0}], \bar{\mathcal{A}}_{\text{rec}}[\mathfrak{B}_{\lambda_1}]\right)\right]_+$$

This is a transition-cost target, not a proof of stability. A promoted barrier must state the retained branch path, the root identity across the path, the regulator state, and the same-record transmitter-side acceleration-weight records. If a later certificate uses an integral barrier instead, the promoted record must also declare the path measure, for example arclength in a stated metric on chart space.

Reduced Branch-Certificate Targets

A branch certificate that consumes this chapter must report:

Certificate entry	Required content
branch identity	retained roots, inactive gaps, finite memory
transmitter-side acceleration weight	D_t, D_r, and W^{acc} enclosed on the same retained box
scalar stationarity	first-variation or discrete comparison record for $\bar{\mathcal{A}}_{\text{rec}}$

Certificate entry	Required content
vector consistency	Master EOM residual on the same retained record
Noether pullback	energy, momentum, and angular-momentum wake-history records from the same action or realized-trajectory record; see Energy and Delay Dynamics Energy
negative controls	rejection of missing, mismatched, or incomplete records

The branch certificate is not promoted if any of those entries are supplied by different root boxes, different regulator states, or different history records.

Summary and Status

The current action-functional program is a receiver-side rebuild target. It keeps causal-root topology, branch labels, caustic routing, and scalar comparison targets, but action evidence requires complete transmitter-side branch records. The next useful mathematical artifact is one retained branch packet that binds root topology, D_t, D_r, W^{acc}, vector residuals, scalar statistic, Noether pullback, and negative controls required before advancement on the same record.

Effective Lagrangian

This chapter asks whether the delayed Master EOM can be recovered from an action principle. In ordinary mechanics, a Lagrangian is useful because varying one scalar history functional gives the equations of motion. In $\mathbb{AAA}$ the target is harder: the functional must remember delayed causal roots, transmitter identities, boundary terms, and transmitter-side acceleration weight.

The validity condition is simple. Any variational scaffold in this chapter that does not produce transmitter-side acceleration weight is invalid as closure evidence. The current target is to vary a path-history functional whose branch-reduced acceleration law carries $W^{\mathrm{acc}} = c_f/|D_t|$ on the same retained roots as the Master EOM. Transmitter-side factors remain transversality diagnostics until paired with the receiver-side factor and checked by the stated residuals.

Variational proof work therefore begins from this canonical receiver-side target. No prior action stationarity, energy balance, or Noether wake-history verdict is inherited unless the same derivation reproduces the receiver-side branch law on the retained record.

The bridge is deliberately conditional. The Master EOM remains the primary dynamics at the substrate level; an action or Lagrangian chart becomes theorem-grade only after its variation, boundary, and conservation residuals close on the retained branch chart. Until then, the effective Lagrangian is a disciplined inference device rather than an independent ontology.

Ordinary Lagrangian Orientation

In a standard comparison form for ordinary local mechanics, one chooses generalized coordinates $q^a_{\mathrm{std}}(t_{\mathrm{std}})$ and writes a Lagrangian $L_{\mathrm{std}}(q_{\mathrm{std}}, dq_{\mathrm{std}}/dt_{\mathrm{std}}, t_{\mathrm{std}})$, often in the simple form

$$L_{\mathrm{std}} = K - V$$

where K is kinetic energy and V is potential energy. The corresponding action is

$$S_{\mathrm{std}}[q_{\mathrm{std}}] = \int_{t_{\mathrm{std},a}}^{t_{\mathrm{std},b}} L_{\mathrm{std}}\left(q_{\mathrm{std}}, \frac{dq_{\mathrm{std}}}{dt_{\mathrm{std}}}, t_{\mathrm{std}}\right)\, dt_{\mathrm{std}}$$

and fixed-endpoint stationarity,

$$\delta S_{\mathrm{std}} = 0$$

gives the Euler-Lagrange equation

$$\frac{d}{dt_{\rm std}}\frac{\partial L_{\rm std}}{\partial(dq^a_{\rm std}/dt_{\rm std})}-\frac{\partial L_{\rm std}}{\partial q^a_{\rm std}}=0$$

for each coordinate $q^a_{\rm std}$. This equation is not a separate force postulate. It is the recovery condition that the chosen scalar $L_{\rm std}$ must satisfy if the action is to generate the equations of motion.

Operationally, stationarity is tested by nearby trial paths $q^a_{{\rm std},\epsilon}(t_{\rm std})=q^a_{\rm std}(t_{\rm std})+\epsilon\xi^a(t_{\rm std})$ with $\xi^a(t_{{\rm std},a})=\xi^a(t_{{\rm std},b})=0$. Because ξ^a is otherwise arbitrary, setting the first variation of $S_{\rm std}$ to zero forces the Euler-Lagrange expression itself to vanish. The action is therefore a history functional with units of energy times time, not an instruction to minimize instantaneous energy.

A minimal recovery check is the one-dimensional harmonic oscillator. In the standard comparison form, for a mass m attached to an ideal spring of stiffness k with displacement $x_{\rm std}(t_{\rm std})$,

$$L_{\rm std}\left(x_{\rm std},\frac{dx_{\rm std}}{dt_{\rm std}}\right)=\frac{1}{2}m\left(\frac{dx_{\rm std}}{dt_{\rm std}}\right)^2-\frac{1}{2}kx^2_{\rm std}$$

so the Euler-Lagrange equation gives

$$\frac{d}{dt_{\rm std}}\left(m\frac{dx_{\rm std}}{dt_{\rm std}}\right)-(-kx_{\rm std})=0$$

or equivalently

$$m\frac{d^2x_{\rm std}}{dt^2_{\rm std}}=-kx_{\rm std}$$

which is the same equation obtained from Newton’s law and Hooke’s law. The value of the example is not that Lagrangian mechanics replaces the tested motion, but that it recovers the same equation from an energy scalar and generalizes cleanly to many coordinates.

The $\mathbb{AAA}$ correction to this toy example is more informative than the recovery itself. A real assembly-level spring is a delayed restoring channel, so the first effective model is not exactly $m_{\rm eff}d^2x_{\rm eff}/dt^2_{\rm eff}=-k_{\rm eff}x_{\rm eff}$ but

$$m_{\rm eff}\frac{d^2x_{\rm eff}}{dt^2_{\rm eff}}(t_{\rm eff})=-k_{\rm eff}\,x_{\rm eff}(t_{\rm eff}-\Delta_{\rm eff})+\cdots$$

for an effective causal-wake delay $\Delta_{\rm eff}$ across the assembly. Expanding the delayed displacement gives

$$\left(m_{\rm eff}+\frac{1}{2}k_{\rm eff}\Delta^2_{\rm eff}\right)\frac{d^2x_{\rm eff}}{dt^2_{\rm eff}}-k_{\rm eff}\Delta_{\rm eff}\frac{dx_{\rm eff}}{dt_{\rm eff}}+k_{\rm eff}x_{\rm eff}=O\left(k_{\rm eff}\Delta^3_{\rm eff}\frac{d^3x_{\rm eff}}{dt^3_{\rm eff}}\right)$$

on a slowly varying branch. The leading correction is therefore sign-definite once the branch delay orientation is fixed. For the causal restoring convention displayed above it is anti-damping, an analogous local pattern to the one that appears as positive tangential work in the circular binary. The mass-like coefficient is also shifted by the delayed response. This does not prove the full assembly mass map, but it shows in the simplest chart why inertia and dissipation-like terms are delayed-response quantities rather than primitive architrino constants.

The two displayed corrections are not independent parameters. They are the first even and odd moments of the same delayed restoring channel:

$$m_{\rm delay}\sim\frac{1}{2}k_{\rm eff}\Delta^2_{\rm eff},\qquad\Gamma_{\rm delay}\sim k_{\rm eff}\Delta_{\rm eff}$$

where m_{delay} denotes the mass-like shift and Γ_{delay} denotes the signed anti-damping coefficient for this convention. On a fixed branch, their ratio is a kernel-shape consequence of the same causal-wake delay, not two fitted material constants. This toy calculation is the finite-dimensional seed of the continuum statement below: even-frequency kernel moments feed inertia-like response, while odd-frequency moments feed dissipation or anti-damping channels.

Historically, the route into this form matters. Newtonian force balance can be projected along fixed-endpoint variations as virtual work. For conservative interactions, $\mathbf{F} = -\nabla V$ turns the work term into a variation of potential energy, while the inertial term supplies a variation of kinetic energy plus an endpoint term. When the endpoint variation vanishes, Hamilton's construction turns that differential relation into the stationary action of $K - V$. The useful condition is therefore stationarity of the action, not a literal minimum in every case.

The same idea survives in $\mathbb{AAA}$ only after changing the object being varied. The Master EOM is not local in the instantaneous native variables $(\mathbf{X}_i(T), \mathbf{V}_i(T))$: receiver acceleration depends on delayed transmitter coordinates, causal-root branches, transmitter-side acceleration weights, and the retained causal-wake history. A local expression $L(\mathbf{X}, \mathbf{V}, T)$ therefore cannot be the substrate-level action for the exact law. The appropriate candidate is a multi-time path-history functional whose variation must reproduce the delayed receiver-side branch law.

The operational bridge is:

1. ordinary mechanics uses $L_{\text{std}}(q_{\text{std}}, dq_{\text{std}}/dt_{\text{std}}, t_{\text{std}})$ and tests $\delta S_{\text{std}} = 0$;
2. $\mathbb{AAA}$ uses a regularized delayed action $S_\eta[\{\mathbf{X}_i\}]$ over path history;
3. the action is promoted only if its variation yields the Master EOM on the retained branch chart;
4. failure is measured by the variation residual $\mathbf{R}_i^{(\eta)}(T)$ and the window diagnostic $\epsilon_{\text{var}}^{(\eta)}(W)$ defined below.

Thus the Lagrangian question in $\mathbb{AAA}$ is not whether one can write a familiar-looking $T - V$ expression. The question is whether a delayed action with the same causal-root, transmitter-side factor, transmitter-side acceleration-weight, boundary, and wake-history conventions as the Master EOM has a stationary variation whose residual closes. Only then do Noether-style energy, momentum, and angular-momentum statements become theorem-grade rather than diagnostic.

Ordinary Hamiltonian Orientation

Hamiltonian mechanics repackages the same standard comparison dynamics into coordinates and canonical momenta. Starting from a local Lagrangian $L_{\text{std}}(q_{\text{std}}, dq_{\text{std}}/dt_{\text{std}}, t_{\text{std}})$, define the canonical momentum

$$p_a \equiv \frac{\partial L_{\text{std}}}{\partial(dq^a_{\text{std}}/dt_{\text{std}})}$$

and, when the velocity-momentum map can be inverted, define the Hamiltonian by the Legendre transform

$$H_{\text{std}}(q_{\text{std}}, p, t_{\text{std}}) = p_a \frac{dq^a_{\text{std}}}{dt_{\text{std}}} - L_{\text{std}}\left(q_{\text{std}}, \frac{dq_{\text{std}}}{dt_{\text{std}}}, t_{\text{std}}\right)$$

with the velocities rewritten in terms of $(q_{\text{std}}, p, t_{\text{std}})$. Hamilton's equations are

$$\frac{dq^a_{\text{std}}}{dt_{\text{std}}} = \frac{\partial H_{\text{std}}}{\partial p_a}, \qquad \frac{dp_a}{dt_{\text{std}}} = -\frac{\partial H_{\text{std}}}{\partial q^a_{\text{std}}}$$

so one second-order equation in q^a_{std} becomes a first-order flow on phase space (q^a_{std}, p_a). In simple time-independent mechanical systems H_{std} is often the total energy $K + V$, but the defining statement is the Legendre transform and the canonical flow, not the energy slogan by itself.

The same equations can also be read from the phase-space action

$$S_H[q_{\text{std}}, p] = \int_{t_{\text{std},a}}^{t_{\text{std},b}} \left(p_a \frac{dq^a_{\text{std}}}{dt_{\text{std}}} - H_{\text{std}}(q_{\text{std}}, p, t_{\text{std}})\right) dt_{\text{std}}$$

when variations in both q^a_{std} and p_a are admitted and endpoint variations of q^a_{std} vanish. Variation with respect to p_a gives $dq^a_{\mathrm{std}}/dt_{\mathrm{std}} = \partial H_{\mathrm{std}}/\partial p_a$, while variation with respect to q^a_{std} gives $dp_a/dt_{\mathrm{std}} = -\partial H_{\mathrm{std}}/\partial q^a_{\mathrm{std}}$. This is the action-level form of the canonical flow, and it is the part that matters when asking whether a reduced $\mathbb{AAA}$ chart is genuinely Hamiltonian rather than only an energy-like fit.

The conjugate momenta are more than bookkeeping in ordinary mechanics. When a coordinate is cyclic, the corresponding conjugate momentum is conserved; the same coordinate-momentum pairing later becomes the classical object used in Bohr-Sommerfeld action integrals and in canonical commutation rules. In $\mathbb{AAA}$ these are recovery targets for a reduced effective chart, not permission to quantize the substrate variables directly.

This matters for $\mathbb{AAA}$ because the exact Master EOM is a delayed path-history law, not an ordinary finite-dimensional phase-space law. The instantaneous pair $(\mathbf{X}_i(T), \mathbf{P}_i(T))$ does not contain all active causal-root, boundary, and wake-history data. A Hamiltonian chart is therefore an effective reduction: it is admissible only when a coarse-graining compresses the retained path history into coordinates and momenta while preserving the comparison invariants. The test is not merely that an expression called H_{eff} can be written, but that the induced return map preserves the relevant measure, symplectic form, or Poisson-bracket structure to the declared tolerance.

Canonical transformations sharpen the same test. In ordinary Hamiltonian mechanics, a change from (q, p) to (Q, P) is not automatically an equivalent mechanics; it is canonical only when the new variables preserve Hamilton's equation form, equivalently the symplectic form or Poisson brackets on the admitted phase-space functions. Generating functions are useful because they construct such transformations and can expose cyclic coordinates, conserved momenta, action-angle variables, or Hamilton-Jacobi constants. In $\mathbb{AAA}$ this remains an effective-chart claim: a reduced chart may be transformed for calculation only while the same branch record keeps the canonical-chart, bracket, or symplectic residual controlled. Otherwise the transformation is a coordinate fit that has lost causal-wake history, not a bridge to operator recovery.

For $\mathbb{AAA}$, the strongest phase-space use case is therefore not an arbitrary instantaneous snapshot. It is a replayable or phase-locked branch chart: a reduced description in which the retained internal motion returns to a comparable section despite bounded surrounding influences. If a retained assembly is modeled by coarse coordinates Q^A and by phase-bearing sub-assemblies indexed by $\alpha = 1, \ldots, N_{\mathrm{ph}}$, the candidate chart has the form

$$z_{\mathfrak{B}} = (Q^A, \Pi_A, \theta^\alpha, I_\alpha)$$

where θ^α records the sub-assembly phase and I_α is the conjugate action variable for that phase. Each retained phase-locked sub-assembly adds its own phase-action pair. Surrounding influences are admissible only when they are represented as fixed branch data, slow parameters, or additional coordinates over the comparison window; otherwise the chart is a driven open system rather than a closed Hamiltonian phase space.

On a single periodic channel, the action variable is not an arbitrary label once the chart is required to be canonical and the angle is required to advance uniformly. With the local 2π convention, the reduced action is the closed-cycle integral of the canonical one-form,

$$I_\alpha = \frac{1}{2\pi} \oint_{\gamma_\alpha} \Pi \, dQ$$

and the frequency readout is

$$\omega_\alpha = \frac{\partial H_{\text{eff}}}{\partial I_\alpha}$$

on that reduced chart. The value of this comparison is methodological: a replayable branch can expose frequency and harmonic content before the full path-history solution is written, but only if the same causal-root ledger and retained branch record make the closed-cycle integral and canonical residual stable.

The action variables are local objects unless the phase torus is globally unobstructed. For a three-binary Family-A chart, the indexed phase circles need not form a trivial T^3 bundle over the retained branch family. Choose any declared ordering (a, b, c) of the persistent binary indices. A retained return cycle of binary a can carry a phase-entry degree pair rather than a single scalar winding. With $\rho_a : S^1_a \to \mathfrak{B}$ denoting that return cycle,

$$c_1[\theta^a, \theta^b, \theta^c] = \big(\deg(\theta^b \circ \rho_a),\, \deg(\theta^c \circ \rho_a)\big) = (m, n) \in \mathbb{Z}^2$$

when the relative phase connection closes on the branch. This is the topological content of integer resonance lock: the lock ratios (m, n) in A3.3 Doubling-Frequency Resonance Lock make the phase-entry data integral rather than irrationally drifting. The symbol c_1 is retained as the established phase-entry notation, but here it means return-map degree data, not a scalar curvature integral. The effective Hamiltonian chart is therefore globally promotable only on resonance-locked branches where the returned phase torus and causal-root ledger close together. Off-lock, the same I_α may exist on a local patch but acquires monodromy under return, so quantization and measure preservation become local fitting statements rather than global chart facts.

More precisely, the action variables I_α are sections of a flat action bundle over the retained branch family. They are globally defined only when the return holonomy is trivial on the admitted observables; equivalently, the phase-return degree pair closes by integer multiples of 2π on the same causal-root ledger. A Bohr-Sommerfeld-like condition is therefore admissible only on this trivial-holonomy locus:

$$\oint_{\gamma_\alpha} \Pi \, dQ \in 2\pi\hbar_{\text{eff}}\mathbb{Z}$$

Outside that locus, the action integral is multivalued under the return map, so the apparent integer is a local chart artifact rather than a branch invariant.

Regularized Nonlocal Action and Variation

The Master Equation of Motion for architrinos is non-Markovian, driven by intersections between receiver trajectories and past causal wake surfaces. Consequently, any action-level scaffold for this law cannot be a local integral over instantaneous states. It must be a multi-time functional over path history, and its variation residual must be identified before the scaffold is treated as an exact action derivation. If that residual does not vanish or reduce to a declared boundary term, the proposed action does not derive the Master EOM.

For a finite, isolated set of architrinos parameterized by absolute time T in the Euclidean void, use the $\eta > 0$ regularized delayed action below. The exact causal wake kernel is recovered in the weak branch limit as $\eta \to 0^+$. The admissible interaction sum excludes trivial self-coincidence: $i \neq j$ terms are retained, and $i = j$ terms are retained only on nontrivial self-hit branches with $T - T_t \geq \Delta_{\min} > 0$ or with an explicitly declared core regularization.

The $\eta \to 0^+$ statement is a weak or distributional scaling claim over declared observables unless a stronger topology is explicitly supplied. A finite-regulator trend supports this action scaffold only after the observable map, normalization, admissible test functions, and uniform control needed for the limit are stated. It is not by itself a proof of the exact causal-wake action.

$$S_\eta[\{\mathbf{X}_i\}] = \int dT \sum_i \frac{1}{2}\mu_{\rm arch}\|\mathbf{V}_i(T)\|^2 - \frac{1}{2}\sum_{i,j}^{\rm adm} \mu_{\rm arch}\kappa\, \sigma_{ij}|q_i q_j| \int dT \int_{-\infty}^{T} dT_t\, \frac{\phi_\eta\big(\tilde{g}_{ij}(T,T_t)\big)}{r_{ij}(T;T_t)}$$

$$\tilde{g}_{ij}(T,T_t) \equiv T - T_t - \frac{r_{ij}(T;T_t)}{c_f}, \qquad r_{ij}(T;T_t) = \|\mathbf{X}_i(T) - \mathbf{X}_j(T_t)\|, \qquad \phi_\eta \equiv \delta_\eta$$

With $[\tilde{g}] = T$ and $[\delta(\tilde{g})] = T^{-1}$, the coefficient $\mu_{\rm arch}\kappa$ gives the interaction term the same action dimension as the quadratic bookkeeping term. A factor κ/c_f would instead leave the kernel with acceleration dimensions before time integration.

Plainly: the same universal conversion used in the kinetic row must also multiply the interaction row; dividing by the wake speed does not repair the units.

Here:

- $\mathbf{X}_i(T)$ is the trajectory of architrino i.
- T is the generic dummy variable of the action integral. At a retained causal hit it takes the receiver role T_r, while T_t remains the transmitter emission time.
- $\mu_{\rm arch}$ is the universal force/energy bookkeeping constant, not a particle-specific inertial mass.
- $r_{ij}(T;T_t)$ is the Euclidean separation between reception and emission events.
- δ_η is a mollified delta function of width $\eta > 0$. It supports Lipschitz control only together with the collision floor, finite-branch, transversality, and integrability assumptions below.
- $\sigma_{ij} = \mathrm{sign}(q_i q_j)$ enforces attraction for opposite polarities and repulsion for like polarities.

Regularization and Admissibility Assumptions

The derivation below is valid under:

- **(EL1)** $\mathbf{X}_i \in C^2([T_a,T_b];\mathbb{R}^3)$ and variations $\boldsymbol{\xi}_i$ are C^1 with $\boldsymbol{\xi}_i(T_a) = \boldsymbol{\xi}_i(T_b) = 0$.
- **(EL2)** ϕ_η is a normalized C^1 approximate identity: either $\phi_\eta \in C_c^1(\mathbb{R})$, $\phi_\eta \geq 0$, $\int \phi_\eta(s)\,ds = 1$, or a Gaussian/sufficiently fast-decaying mollifier with an explicit tail bound on the chosen analysis window.
- **(EL3)** Collision and trivial-self exclusion on active support, or on the tail-controlled analysis window for noncompact mollifiers: $r_{ij}(T;T_t) \geq r_{\min} > 0$ whenever the retained window admits $\phi_\eta(\tilde{g}_{ij}(T,T_t))$, and for $i = j$ the retained window also satisfies $T - T_t \geq \Delta_{\min} > 0$ unless a separate core regularization supplies the same lower-bound control.
- **(EL4)** Delay-root transversality on active branches: $\partial_{T_t}\tilde{g}_{ij}(T,T_t) \neq 0$ when $\tilde{g}_{ij}(T,T_t) = 0$.
- **(EL5)** Integrability on the chosen history window, either by finite support or sufficient tail falloff, so differentiation under the time integrals is justified.
- **(EL6)** Delayed branch convention: only $T_t \leq T$ contributes (equivalently, the $\Theta(T - T_t)$ branch of the causal selector).

Kernel Variation and Branch Reduction

This subsection isolates the exact step at which a variational scaffold can fail. Set $\mathbf{X}_i^\varepsilon = \mathbf{X}_i + \varepsilon\boldsymbol{\xi}_i$ and differentiate at $\varepsilon = 0$.

Kinetic term:

$$\delta S_{\eta,\rm kin} = \sum_i \int_{T_a}^{T_b} \mu_{\rm arch}\mathbf{V}_i \cdot \frac{d\boldsymbol{\xi}_i}{dT}\, dT = -\sum_i \int_{T_a}^{T_b} \mu_{\rm arch}\mathbf{A}_i \cdot \boldsymbol{\xi}_i\, dT$$

For the interaction kernel

$$\mathcal{K}_{ij}(T,T_t) \equiv \frac{\phi_\eta(\tilde{g}_{ij}(T,T_t))}{r_{ij}(T;T_t)}, \qquad \hat{\mathbf{r}}_{ij} \equiv \frac{\mathbf{X}_i(T) - \mathbf{X}_j(T_t)}{r_{ij}(T;T_t)}$$

the receiver-coordinate gradient is

$$\nabla_{\mathbf{X}_i(T)}\mathcal{K}_{ij} = -\hat{\mathbf{r}}_{ij}\left[\frac{\phi_\eta(\tilde{g}_{ij})}{r_{ij}^2} + \frac{\phi_\eta'(\tilde{g}_{ij})}{c_f\, r_{ij}}\right]$$

This receiver-side gradient is one ingredient in the full first variation, but it is not the complete Euler-Lagrange expression. In the double-time action, each varied worldline appears both as a receiver coordinate $\mathbf{X}_i(T)$ and as a transmitter coordinate inside transposed kernels. The full branch-resolved variation is carried out in Master Equation. The term proportional to $\phi_\eta'(\tilde{g}_{ij})$ is an action-variation residual. It is not an independently justified architrino acceleration. The action candidate succeeds only if the complete variation cancels this term or converts it into a declared boundary contribution while retaining the transmitter-side acceleration law.

On charts where the constraint-variation residual is boundary-only, or is cancelled by an explicitly declared regularized action-level term, the branch-reduced target is the transmitter-side delayed acceleration law

$$\mu_{\text{arch}}\mathbf{A}_i(T) = \sum_j \kappa\,\sigma_{ij}|q_iq_j| \sum_{T_t\in\mathcal{C}_{ij}(T)} \frac{W_{ij}^{\text{acc}}(T;T_t)\,\hat{\mathbf{r}}_{ij}(T;T_t)}{r_{ij}(T;T_t)^2}$$

where $W_{ij}^{\text{acc}} = c_f/|D_{t,ij}|$ is computed on the same retained root record.
This includes nontrivial self-hit branches $j=i$ when the trivial coincidence root is excluded.

The branch collapse used here is an $\eta\to 0^+$ simple-root statement, not an identity at arbitrary finite η. Since

$$\partial_{T_t}\tilde{g}_{ij}(T,T_t) = -\left(1 - \frac{\hat{\mathbf{r}}_{ij}(T;T_t)\cdot\mathbf{V}_j(T_t)}{c_f}\right)$$

any branch-local smooth f satisfies

$$\lim_{\eta\to 0^+}\int_{-\infty}^{T} f(T_t)\phi_\eta\big(\tilde{g}_{ij}(T,T_t)\big)\,dT_t = \sum_{T_t\in\mathcal{C}_{ij}(T)} \frac{f(T_t)}{|1-\hat{\mathbf{r}}_{ij}(T;T_t)\cdot\mathbf{V}_j(T_t)/c_f|}$$

provided the active roots are simple and separated from collision support.

Equivalently, in the finite-η branch-selector form one may write

$$\mu_{\text{arch}}\mathbf{A}_i(T) = \sum_j \kappa\,\sigma_{ij}|q_iq_j| \int_{-\infty}^{T} dT_t\,\frac{\hat{\mathbf{r}}_{ij}(T;T_t)}{r_{ij}(T;T_t)^2}\,\phi_\eta\big(\tilde{g}_{ij}(T,T_t)\big)$$

with the understanding that the displayed finite-η integral is a branch-selector surrogate. Its weak limit must be recomputed so that the retained branch law carries the transmitter-side factor W^{acc}. The derivative term in $\nabla_{\mathbf{X}_i}\mathcal{K}_{ij}$ is cleared only after the full delayed variation is assembled and the branch reduction is performed. If it survives in the interior, this action candidate fails to derive the Master EOM.

A derivation, reduction, or simulation that claims action-derived dynamics must therefore report the variation residual

$$\mathbf{R}_i^{(\eta)}(T) = \mu_{\text{arch}}\mathbf{A}_i(T) - \sum_j \kappa\,\sigma_{ij}|q_iq_j|\mathbf{F}_{ij,\text{scale}}^{(\eta)}(T)$$

using the scale term and constraint residual defined in Master Equation. The dimensionless window diagnostic is

$$\epsilon_{\text{var}}^{(\eta)}(W) = \frac{\sum_i\int_W \|\mathbf{R}_i^{(\eta)}(T)\|\,dT}{\sum_i\int_W\left(\mu_{\text{arch}}\|\mathbf{A}_i(T)\| + \|\mathbf{F}_{i,\text{act}}^{(\eta)}(T)\|\right)dT + \varepsilon}$$

The transmitter-side branch target is theorem-grade on W only when this residual tends to zero with the declared branch floors and boundary convention. Otherwise the local effective Lagrangian remains a fitted chart. The surviving derivative-of-constraint term is evidence against this action candidate; it does not license a new acceleration term, a vector potential, or a magnetic-like mechanism.

The same-support local scalar route and its finite delta-jet extension are ruled out under the restricted assumptions in master-equation: cancelling the derivative residual forces the counterterm to change the accepted inverse-square scale term. The currently minimal known scale-only repair is the delayed-interior characteristic-tail kernel stated there. With

$$u = \tilde{g} + \frac{r}{c_f}$$

the endpoint-clear candidate is

$$K_{\text{eff}}^{(\eta)}(r, \tilde{g}) = \int_{-\infty}^{\tilde{g}} \frac{\delta_\eta(s)}{c_f(u-s)^2} ds$$

or the finite-endpoint variant with lower limit $-h_+$ after the characteristic gauge has cancelled the endpoint-clearance term. It satisfies

$$\left(\partial_r - \frac{1}{c_f}\partial_{\tilde{g}}\right) K_{\text{eff}}^{(\eta)} = -\frac{\delta_\eta(\tilde{g})}{r^2}$$

so it cancels the derivative-of-constraint residual without changing the accepted inverse-square scale term. Effective Lagrangian reductions should still inherit the Master EOM directly unless they explicitly choose the normalized characteristic-tail kernel and carry its boundary-increment convention on the retained chart.

The operator in this identity is the derivative along the causal characteristic. With

$$D_{\text{char}} \equiv \partial_r - \frac{1}{c_f}\partial_{\tilde{g}}, \qquad u = \tilde{g} + \frac{r}{c_f},$$

one has $D_{\text{char}} u = 0$. The tail kernel is therefore the characteristic integral of the regularized hit density along $u = \text{const}$. This is why it carries an endpoint convention: the repair is energy-conserving only when the endpoint boundary is characteristic to the same order as the retained chart. If the endpoint cuts across the characteristic foliation, the endpoint term is an interior Euler source and the repair has changed the acceleration law rather than merely clearing a boundary.

The normalized characteristic-tail kernel carries explicit energy, momentum, and angular-momentum wake-history increments in master-equation. An effective Lagrangian reduction may therefore choose that kernel only when it also carries the same boundary-increment convention and reports the corresponding variation and conservation residuals on its branch chart. Without those residuals, the reduced Lagrangian remains a scaffold for the Master EOM rather than an independent proof of the branch acceleration.

Symmetries and History-Aware Conservation Laws

The regularized action S_η is invariant under the fundamental symmetry group of the substrate when the mollifier, history window, and self-branch cutoff preserve those symmetries: the Euclidean group $E(3)$ and absolute time translations $\mathbb{R}_{\text{time}}$; the exact statement is recovered in the $\eta \to 0^+$ limit. If the regularization is inserted only at the equation-of-motion level or uses a non-invariant window, the associated energy, momentum, and angular-momentum expressions become diagnostics rather than proved Noether charges.

Because the Lagrangian is nonlocal in time, the corresponding Noether charges are path-history functionals tracking interactions that are still carried by causal wakes between emission and reception.

Here symmetry means an active transformation of the retained physical record, not merely a passive relabeling of coordinates. A passive relabeling is a representation check: the same assembly, causal-wake history, and Noether sea record should not acquire a different physical meaning because the chart changed. An active transformation asks whether the transformed branch record obeys the same action principle. Only the active question produces a Noether conservation statement.

The ordinary boundary-term identity makes the recovery burden precise. For a local action, the first variation splits into an interior Euler-Lagrange term and an endpoint term,

$$\delta S_{\mathrm{std}} = \int_{t_{\mathrm{std},a}}^{t_{\mathrm{std},b}} \left(\frac{\partial L_{\mathrm{std}}}{\partial q^a_{\mathrm{std}}} - \frac{d}{dt_{\mathrm{std}}} \frac{\partial L_{\mathrm{std}}}{\partial (dq^a_{\mathrm{std}}/dt_{\mathrm{std}})} \right) \delta q^a_{\mathrm{std}}\, dt_{\mathrm{std}} + [p_a \delta q^a_{\mathrm{std}} - H_{\mathrm{std}} \delta t_{\mathrm{std}}]_{t_{\mathrm{std},a}}^{t_{\mathrm{std},b}}$$

with

$$p_a = \frac{\partial L_{\mathrm{std}}}{\partial (dq^a_{\mathrm{std}}/dt_{\mathrm{std}})}, \qquad H_{\mathrm{std}} = p_a \frac{dq^a_{\mathrm{std}}}{dt_{\mathrm{std}}} - L_{\mathrm{std}}.$$

On a stationary path, the interior term vanishes. Spatial translation symmetry then compares endpoint momentum, while absolute-time translation symmetry compares the Hamiltonian energy. This is the standard Noether route: a conserved quantity is the boundary charge induced by a continuous symmetry of the action, not an independently imposed storage rule.

In $\mathbb{AAA}$ this identity is a recovery template, not a substrate replacement. A delayed action is promoted only if the same split appears on the retained causal-root chart: the interior term must reduce to the Master EOM residual, and the endpoint term must become the wake-history boundary functional on the same branch record. Spatial translation invariance then protects $\mathbf{P}_{\mathrm{mech}} + \mathbf{P}_{\mathrm{wake}}$ only when the wake momentum record is retained, and absolute-time translation protects $K + E_{\mathrm{wake}}$ only when the endpoint leakage record is declared. Dropping the interior residual, the wake-history endpoint term, or the boundary flux turns the Noether statement back into a diagnostic comparison.

The more general local Noether form also matters. For an infinitesimal active transformation

$$q^a_{\mathrm{std}} \mapsto q^a_{\mathrm{std}} + \epsilon X^a(q_{\mathrm{std}}, t_{\mathrm{std}})$$

the action variation is unchanged when the Lagrangian changes at most by a total time derivative,

$$\delta L = \epsilon \frac{dG}{dt_{\mathrm{std}}}$$

On stationary paths this gives the conserved charge

$$\frac{d}{dt_{\mathrm{std}}} (p_a X^a - G) = 0$$

Spatial translations have $G = 0$ and recover momentum. Rotations recover angular momentum. Time translations are the case where the total-derivative term supplies the Hamiltonian energy. In the delayed chart, the same pattern is admissible only after X^a, G, and the boundary functional are replaced by history-aware branch quantities from the retained causal-root record.

Energy Functional:
Invariance under absolute time translation yields a conserved total energy only for the symmetry-preserving action-derived model:

$$E_{\mathrm{tot}}(T) = K(T) + E_{\mathrm{wake}}(T)$$

where the action-level nonlocal Noether charge can be written with the weighted causal kernel from Master Equation. To avoid confusing the receiver-gradient kernel above with the Noether-energy kernel, write

$$\mathcal{K}^E_{ij}(T_1, T_t) = \mu_{\mathrm{arch}} \kappa\, \sigma_{ij}\, |q_i q_j| \Theta(T_1 - T_t) \frac{\delta\big(\tilde{g}_{ij}(T_1, T_t)\big)}{r_{ij}(T_1, T_t)}$$

For the delayed-interior characteristic-tail candidate, the Noether-energy kernel must instead be built from the same normalized action kernel,

$$\mathcal{K}^E_{ij,\text{eff}}(T_1,T_t)=\mu_{\text{arch}}\kappa\,\sigma_{ij}\,|q_iq_j|\Theta(T_1-T_t)K^{(\eta)}_{\text{eff}}(r_{ij}(T_1,T_t),\tilde{g}_{ij}(T_1,T_t))$$

The scalar $1/r$ expression remains the diagnostic scaffold only when this replacement has not been declared for the chart. Then:

$$E_{\text{wake}}(T)=-\frac{1}{2}\sum_{i,j}\int_{-\infty}^{T}dT_t\int_{T}^{\infty}dT_1\,\partial_{T_1}\mathcal{K}^E_{ij}(T_1,T_t)$$

The outer minus sign matches the action convention $S=S_{\text{kinetic}}-\frac{1}{2}\sum S_{ij}$ and makes the sharp static like-polarity pair charge positive. Reversing that sign would contradict the positive work required to bring a repelling like-polarity pair closer.

Plainly: the boundary charge must inherit both the units and the sign of the same action kernel.

For compatible trajectory reconstruction one may use the work-integral form

$$U(T)=U_*-\int_{T_*}^{T}\sum_i\mu_{\text{arch}}\,\mathbf{A}_i(T')\cdot\mathbf{V}_i(T')\,dT'$$

when it is derived from the same action-level acceleration law and boundary convention. Otherwise $U(T)$ is a diagnostic history functional, not an independently proved Noether charge.

The corresponding finite-window energy residual is

$$\epsilon^{(\eta)}_E(W)=\frac{\left|\Delta_W\left(K+E^{(\eta)}_{\text{wake}}\right)-\int_W\sum_i\mathbf{V}_i\cdot\mathbf{R}^{(\eta)}_i\,dT-\int_W\mathcal{B}^{(\eta)}_E\,dT\right|}{|\Delta_WK|+\left|\Delta_WE^{(\eta)}_{\text{wake}}\right|+\varepsilon}$$

Here $\mathcal{B}^{(\eta)}_E$ is the declared endpoint or period-cut leakage. For isolated period-matched tests, $\epsilon^{(\eta)}_{\text{var}}\to0$, $\mathcal{B}^{(\eta)}_E\to0$, and $\epsilon^{(\eta)}_E\to0$ are the minimal conservation checks before the effective Hamiltonian is promoted beyond a diagnostic fit.

For a branch chart that explicitly chooses the normalized delayed-interior characteristic-tail kernel, the conservation object is not the generic scalar $1/r$ scaffold above but the pullback

$$K_{\mu,\mathfrak{B}}+E^{(\eta)}_{\text{wake,eff},\mathfrak{B}},\qquad\mathbf{P}_{\text{mech},\mathfrak{B}}+\mathbf{P}^{(\eta)}_{\text{wake,eff},\mathfrak{B}},\qquad\mathbf{J}_{\text{mech},\mathfrak{B}}+\mathbf{J}^{(\eta)}_{\text{wake,eff},\mathfrak{B}}$$

defined on the same retained branch records that enter the acceleration residual. The energy residual above is theorem-level only after this chart declares the action-level $\tilde{g}$, endpoint convention, branch floors, and endpoint or period-cut leakage terms. The work-integral reconstruction $U(T)$ remains a trajectory diagnostic unless it is derived from that same normalized kernel and boundary convention.

Generalized Momentum:
Spatial translation invariance guarantees the conservation of total momentum, $\mathbf{P}_{\text{tot}}=\mathbf{P}_{\text{mech}}(T)+\mathbf{P}_{\text{wake}}(T)$, where the mechanical momentum of the architrinos is balanced by the momentum flux propagating within the causal wake surfaces. Boundedness of the history-aware energy is therefore the natural diagnostic against runaway behavior, not a separate postulate.

For an effective reduction to promote a retained chart rather than fit it, it must also report vector residuals for the same branch pullback:

$$\epsilon^{(\eta)}_P(W)=\frac{\left\|\Delta_W\left(\mathbf{P}_{\text{mech}}+\mathbf{P}^{(\eta)}_{\text{wake,eff}}\right)-\int_W\sum_i\mathbf{R}^{(\eta)}_i\,dT-\int_W\mathcal{B}^{(\eta)}_P\,dT\right\|}{\|\Delta_W\mathbf{P}_{\text{mech}}\|+\left\|\Delta_W\mathbf{P}^{(\eta)}_{\text{wake,eff}}\right\|+\varepsilon}$$

and

$$\epsilon_J^{(\eta)}(W) = \frac{\left\| \Delta_W \left(\mathbf{J}_{\text{mech}} + \mathbf{J}_{\text{wake,eff}}^{(\eta)} \right) - \int_W \sum_i \mathbf{X}_i(T) \times \mathbf{R}_i^{(\eta)}\, dT - \int_W \mathcal{B}_J^{(\eta)}\, dT \right\|}{\|\Delta_W \mathbf{J}_{\text{mech}}\| + \left\| \Delta_W \mathbf{J}_{\text{wake,eff}}^{(\eta)} \right\| + \varepsilon}$$

Small $\epsilon_E^{(\eta)}$, $\epsilon_P^{(\eta)}$, and $\epsilon_J^{(\eta)}$ are conservation diagnostics when the regularization is inserted at the equation-of-motion level. They become Noether-charge tests only when the action regularization itself preserves time translation, spatial translation, and rotation symmetry on the retained chart.

Coarse-Graining: The Effective Continuum Lagrangian

The continuum Lagrangian belongs to a coarse-grained level. To describe emergent behavior of the Noether sea and complex assemblies, the description passes from discrete trajectories to continuum densities on native slices. Define a coarse-grained architrino polarity density $\rho_q(\mathbf{X}, T)$ and current density $\mathbf{j}_q(\mathbf{X}, T)$, smoothed over a scale much larger than the Noether braid scale but smaller than macroscopic gradients. This notation is deliberately distinct from Noether braid density variables such as ρ_{NS} and n.

At the level of a branch-collapsed delayed causal action, the exact multi-time interaction double sum suggests the continuum delayed functional

$$S_{\text{int}}^{\text{cg}} = -\frac{\kappa}{2c_f} \int dT \int d^3X \int d^3X' \, \frac{\rho_q(\mathbf{X}, T)\rho_q(\mathbf{X}', T - \|\mathbf{X} - \mathbf{X}'\|/c_f)}{\|\mathbf{X} - \mathbf{X}'\|}$$

with delayed transmitter time

$$T' = T - \frac{\|\mathbf{X} - \mathbf{X}'\|}{c_f}$$

propagation direction

$$\hat{\mathbf{n}}(\mathbf{X}, \mathbf{X}') = \frac{\mathbf{X} - \mathbf{X}'}{\|\mathbf{X} - \mathbf{X}'\|}$$

coarse transport velocity

$$\mathbf{u}(\mathbf{X}', T') = \frac{\mathbf{j}_q(\mathbf{X}', T')}{\rho_q(\mathbf{X}', T')} \qquad (\rho_q \neq 0)$$

This Eulerian double-space functional is a continuum inheritance target for the discrete delayed causal $1/r$ action kernel. It contains no additional transmitter-side factor: the delayed density $\rho_q(\mathbf{X}', T')$ already carries the transmitter-side compression or dilation produced by the Lagrangian-to-Eulerian coarse-graining. For a point transmitter, the familiar transmitter-velocity factor appears when the particle delta is collapsed through its emission-time root; it is not an extra denominator to multiply into the Eulerian density kernel. A corrected delayed action must reproduce the canonical inverse-square acceleration density weighted by $W^{\text{acc}} = c_f/|D_t|$. Receiver velocity may enter the full variation, root playback, and conserved accounts, but it may not reappear as an extra multiplier on the instantaneous acceleration.

The remaining action correction is also one continuum location where delayed pairwise mechanical acceleration fails to cancel. The branch chart must distinguish transmitter-side acceleration weight from receiver-side root playback, so the receiver/transmitter exchange is not represented by a symmetric mechanical stress alone. Translation invariance still protects total momentum when the wake momentum is included, but the mechanical current must split as

$$\Pi_q^{ij} = \Pi_{q,\text{sym}}^{ij} + \Pi_{q,J}^{ij}, \qquad \Pi_{q,J}^{[ij]} \equiv \frac{1}{2}\left(\Pi_{q,J}^{ij} - \Pi_{q,J}^{ji} \right)$$

where $\Pi_{q,J}^{[ij]}$ is a candidate antisymmetric branch-correction contribution. It is not a new substrate acceleration term. A continuum simulation may test this effective description only after $\Pi_{q,J}^{[ij]}$ has been derived from the same delayed branch record and shown to close the relevant wake-history account.

The continuum variables are admitted only through balance laws inherited from resolved histories. A coarse polarity density and current must satisfy

$$\partial_T \rho_q + \nabla_{\mathbf{X}} \cdot \mathbf{j}_q = R_\rho^{\mathrm{cg}}$$

and the first two kinetic moments must close through a declared momentum-current tensor and energy-flux vector,

$$\partial_T (\rho_q u^i) + \partial_{X^j} \Pi_q^{ij} = f_q^i + R_{P,q}^i$$

$$\partial_T e_q + \nabla_{\mathbf{X}} \cdot \mathbf{J}_{e,q} = \mathbf{f}_q \cdot \mathbf{u} + R_{E,q}$$

Here Π_q^{ij} and $\mathbf{J}_{e,q}$ are coarse-history summaries of the retained causal-wake record, not new substrate fields. The effective action is a promoted continuum chart only when R_ρ^{cg}, $R_{P,q}^i$, and $R_{E,q}$ are small under history, spatial, and regulator refinement. Otherwise the chart has reproduced only low-order moments while leaving unresolved memory in the omitted kinetic hierarchy.

For near-equilibrium reductions, a constitutive response may be written schematically as

$$\Pi_q^{ij} = \Pi_{\mathrm{rev}}^{ij} - 2\eta_{\mathrm{cg}} \left(E^{ij} - \frac{1}{3} (\nabla_{\mathbf{X}} \cdot \mathbf{u}) h^{ij} \right) - \zeta_{\mathrm{cg}} (\nabla_{\mathbf{X}} \cdot \mathbf{u}) h^{ij} + \Pi_{\mathrm{mem}}^{ij}$$

where $E^{ij} = \frac{1}{2}(\partial_{X^i} u^j + \partial_{X^j} u^i)$ and $\mathring{E}^{ij} = E^{ij} - \frac{1}{3}(\nabla_{\mathbf{X}} \cdot \mathbf{u}) h^{ij}$ is the deviatoric strain-rate tensor. This is a comparison form borrowed from continuum mechanics and kinetic theory. In $\mathbb{AAA}$ it becomes native only after η_{cg}, ζ_{cg}, and Π_{mem}^{ij} are derived from the same delayed branch record that supplies the acceleration law. The subscript in η_{cg} marks a coarse-grained viscosity-like coefficient and is distinct from the regulator η in δ_η.

The constructive route is to read the transport coefficients as low-frequency moments of the delayed response kernel, not as independent material constants. If $\widetilde{K}_{\mathrm{shear}}(\omega)$ and $\widetilde{K}_{\mathrm{bulk}}(\omega)$ are the shear and bulk projections of the same branch-derived causal kernel, then the leading near-equilibrium coefficients have the schematic form

$$\eta_{\mathrm{cg}} \sim \lim_{\omega \to 0} \frac{\mathrm{Im}\, \widetilde{K}_{\mathrm{shear}}(\omega)}{\omega}, \qquad \zeta_{\mathrm{cg}} \sim \lim_{\omega \to 0} \frac{\mathrm{Im}\, \widetilde{K}_{\mathrm{bulk}}(\omega)}{\omega}$$

and Π_{mem}^{ij} carries the finite-frequency remainder. This makes the viscosity-like channel an odd-frequency readout of the delayed acceleration kernel. The ratio between η_{cg}, ζ_{cg}, and the acceleration-law coupling κ is therefore a kernel-shape consequence on a certified branch, not an additional parameter family.

This is the continuum version of the delayed oscillator expansion. A branch-derived response kernel has one Taylor structure:

$$\widetilde{K}(\omega) = \widetilde{K}_{\mathrm{even}}(\omega) + \widetilde{K}_{\mathrm{odd}}(\omega)$$

Its even part supplies candidate inertia-like and mass-renormalization coefficients; its odd part supplies candidate anti-damping, viscosity-like response, and antisymmetric stress. Ratios such as $\eta_{\mathrm{cg}}/m_{\mathrm{eff}}$ or $\eta_{\mathrm{cg}}/\kappa$ become branch invariants only after the same delayed kernel and comparison window have been independently certified.

The corresponding dissipation residual is

$$\mathcal{R}_{\mathrm{diss}}(W) = \frac{\left| \Delta_W K_{\mathrm{cg}} + \int_W \left(2\eta_{\mathrm{cg}} \mathring{E}_{ij} \mathring{E}^{ij} + \zeta_{\mathrm{cg}} (\nabla_{\mathbf{X}} \cdot \mathbf{u})^2 \right) \, dT \, dV + \Delta_W E_{\mathrm{wake}} \right|}{|\Delta_W K_{\mathrm{cg}}| + \int_W \left(2\eta_{\mathrm{cg}} \mathring{E}_{ij} \mathring{E}^{ij} + \zeta_{\mathrm{cg}} (\nabla_{\mathbf{X}} \cdot \mathbf{u})^2 \right) dT \, dV + |\Delta_W E_{\mathrm{wake}}| + \varepsilon}$$

This residual prevents ordinary viscous loss language from replacing the exact wake-history energy ledger. A nonzero positive quadratic term is allowed as a coarse channel for coherent-to-incoherent transfer, but the transferred content must appear in the retained wake, heat, or medium-response record.

By defining an effective scalar potential $\Phi_{\mathrm{wake}}(\mathbf{X}, T)$ and a vector transport potential $\mathbf{A}_{\mathrm{wake}}(\mathbf{X}, T)$ that track the integrated causal wakes of the continuous medium, the system maps locally onto an effective field theory. These potentials are bookkeeping variables for delayed transport, not additional ontological primitives. The resulting local Lagrangian density $\mathcal{L}_{\mathrm{eff}}$ therefore belongs to a further closure step beyond the exact delayed causal action.

At the standard local-field level, the action principle changes the object being varied rather than the logic of stationarity. A particle path in the recognition form is replaced by effective fields $\varphi^A_{\mathrm{eff}}(x^i_{\mathrm{eff}}, t_{\mathrm{eff}})$, and the local action has the layer-explicit schematic form

$$S[\varphi] = \int dt_{\mathrm{eff}}\, d^3x_{\mathrm{eff}}\, \mathcal{L}\left(\varphi^A_{\mathrm{eff}}, \partial_{t_{\mathrm{eff}}}\varphi^A_{\mathrm{eff}}, \partial_{x^i_{\mathrm{eff}}}\varphi^A_{\mathrm{eff}}, \ldots\right).$$

Fixed-boundary variation gives the field Euler-Lagrange expression

$$\frac{\partial \mathcal{L}}{\partial \varphi^A_{\mathrm{eff}}} - \partial_{t_{\mathrm{eff}}} \frac{\partial \mathcal{L}}{\partial(\partial_{t_{\mathrm{eff}}}\varphi^A_{\mathrm{eff}})} - \partial_{x^i_{\mathrm{eff}}} \frac{\partial \mathcal{L}}{\partial(\partial_{x^i_{\mathrm{eff}}}\varphi^A_{\mathrm{eff}})} = 0.$$

This is the common effective grammar behind Maxwell, Einstein-Hilbert, and Standard Model action formulations. For $\mathbb{AAA}$ it is not a license to treat fields as substrate objects. It is the recovery grammar a local chart must satisfy after the delayed branch record has been coarse-grained into admitted fields and after its Euler-Lagrange residual has been checked against the same causal-wake, boundary, and transmitter-side acceleration-weight records.

Effective Hamiltonian Domain Gate

A local Hamiltonian or local Lagrangian description is admissible only after the path-history law has been reduced to a finite set of coarse variables that preserve the relevant state-counting measure over the comparison window. This is an inference condition: it tests whether exact histories can be represented by local canonical coordinates without losing the invariants under comparison. Let $\mathcal{Q}$ be the coarse-graining from exact histories $\Gamma(T)$ to effective coordinates $z = (\rho_q, \mathbf{j}_q, \ldots)$, and let $\mathcal{P}^{\mathrm{eff}}_{\Delta T}$ be the induced effective flow. The local canonical approximation must supply a measure $\mu_{\mathcal{Q}}$ such that

$$(\mathcal{P}^{\mathrm{eff}}_{\Delta T})_* \mu_{\mathcal{Q}} = \mu_{\mathcal{Q}} + O(\epsilon_{\mathcal{Q}})$$

on the retained regime. This measure condition is necessary but not sufficient for canonical mechanics. The same handoff must also control a bracket or symplectic residual, for example

$$\left\|(\mathcal{P}^{\mathrm{eff}}_{\Delta T})^* \omega_{\mathcal{Q}} - \omega_{\mathcal{Q}}\right\| \le \epsilon_\omega$$

for the retained two-form $\omega_{\mathcal{Q}}$, or an equivalent Poisson-bracket residual on the admitted observables. If $\epsilon_{\mathcal{Q}}$ or ϵ_ω is not controlled, the local Hamiltonian is only a fitting chart, not a derived mechanics.

For a replayable branch chart, this measure condition is the $\mathbb{AAA}$ analogue of Liouville's theorem. In ordinary finite-dimensional Hamiltonian mechanics the phase-space flow is divergence-free, $\nabla_z \cdot \dot{z} = 0$, so a phase-space volume element may stretch and fold but is not compressed by the exact flow. In the delayed setting, the analogous statement is valid only after $\mathcal{Q}$ retains the phase variables, causal-root ledger, wake-history record, and surrounding context that actually control the return map. Dropping an active sub-assembly phase can make a closed chart look dissipative or probabilistic merely because the chart has thrown away one of the variables that carries the recurrence.

The preserved two-form is likewise not the naive instantaneous form alone. On a delayed branch the candidate symplectic structure is posited to carry a memory correction,

$$\omega_{\mathcal{Q}} = \omega_0 + \omega_{\text{mem}}, \qquad \omega_0 = \sum_A dQ^A \wedge d\Pi_A + \sum_\alpha d\theta^\alpha \wedge dI_\alpha$$

with

$$\omega_{\text{mem}} = \int_{-h}^{0} \mathcal{K}_{\text{symp}}(\vartheta)\, \delta\mathbf{X}(\vartheta) \wedge \delta\mathbf{V}(\vartheta)\, d\vartheta$$

where h is the retained memory depth and $\mathcal{K}_{\text{symp}}$ is built from the same branch causal kernel that supplies the acceleration. The explicit construction of $\mathcal{K}_{\text{symp}}$ and the boundary-flux identity below are open obligations of the Hamiltonian-promotion gate. The residual ϵ_ω is small only when this memory term is replayable: after one return, the retained history segment $[-h, 0]$ must map to a congruent segment with the same branch records and boundary convention. This is why phase-locked branches are the natural Hamiltonian domain. They replay the history window that carries ω_{mem}, while off-lock branches leak symplectic content through the memory boundary and can look dissipative after projection.

Equivalently, ω_{mem} is the symplectic flux through the boundary of the retained memory interval. A Hamiltonian-promotable branch must make that boundary periodic under the return map:

$$\oint_{\text{return}} \omega_{\text{mem},\partial[-h,0]} = O(\epsilon_\omega)$$

after quotienting only true zero-Floquet neutral directions. If the memory-boundary flux has a secular component, the projected chart can conserve neither the corrected symplectic form nor the apparent energy ledger without adding the missing history variable. This is the same branch-symplectic promotion condition used by the scalar causal-action return-map residual and by binary or doubling-frequency return-map packets: preserve $\omega_0 + \omega_{\text{mem}}$ on the retained delayed chart, not merely the instantaneous phase volume.

This gate keeps the exact and effective levels separate. The Master Equation owns the delayed causal dynamics; the effective Hamiltonian owns only those regimes where internal wake memory, branch changes, and unresolved Noether sea exchange have been compressed without losing the observer-level invariants being compared.

The same domain restriction applies before translating an effective Hamiltonian chart into quantum operators. The admissible observable set in Quantum Operator Mapping must be derived from this retained coarse-graining and record window, not chosen afterward as a free quantization convention.

The positive selection rule is that the quantizable algebra is generated by the globally defined branch variables,

$$\{Q^A, \Pi_A\} \cup \{e^{i\theta^\alpha}, I_\alpha\}$$

not by arbitrary functions on a projected chart. The phases enter through the single-valued observables $e^{i\theta^\alpha}$, while I_α records the corresponding action. A Bohr-Sommerfeld-like integer is admissible only when it is forced by single-valuedness around the resonance-locked phase bundle,

$$\oint_{\gamma_\alpha} \Pi\, dQ \in 2\pi\hbar_{\text{eff}}\mathbb{Z}$$

with the integer tied to the phase-return degree pair above. Thus quantization in this reduction is a topological single-valuedness condition on a retained phase-locked bundle, not a global quantization convention imposed on every smooth effective observable.

Topological Constraints and Assembly Stability

The delayed action, after branch reduction to causal-locus and root-ledger data, constrains the allowed topological configurations of architrino assemblies in the Noether sea. Stable assemblies, such as maximum-curvature candidates inside Family-A braids, should therefore be treated as theorem targets for localized, phase-locked causal-locus classes rather than as already-proved vortices or continuum topological defects.

The stability of these assemblies must be checked by the nonlinear self-hit feedback embedded in the interaction functional. When internal circulation velocities exceed c_f, the non-Markovian repulsion supplies a candidate outward branch barrier, not the centripetal binder. It becomes part of a robust geometric attractor only after the complete signed acceleration ledger, a branch chart, Lyapunov or Floquet diagnostic, and history-aware energy bound are supplied. Likewise, mass-gap language is a closure target tied to discrete admissible branch classes, not an automatic consequence of writing the effective action.

The native topological sector is the stabilized causal-root ledger, not a borrowed field-theory vortex number. The canonical definition is given in Noether Braid Topological Charge; in the effective-action chart, the same assembly topological charge is the retained sector

$$[\mathfrak{B}] = (N_s,\, M_p,\, c_1[\theta_1, \theta_2, \theta_3]) \in \mathbb{Z}_{\geq 0} \times \mathbb{Z}_{\geq 0} \times \mathbb{Z}^2$$

where N_s counts active self-hit roots, M_p counts active partner-hit roots, and $c_1[\theta_1, \theta_2, \theta_3]$ is the phase-return degree pair of the resonance-locked Noether braid chart in persistent-index order. This class is deformation-stable only inside the nondegenerate branch domain: a causal-root fold, reconnection, or loss of phase-bundle closure changes the sector.

The corresponding mass-gap target is therefore native and computable. The gap is the minimum action cost to change $[\mathfrak{B}]$ by an admissible branch transition, such as a $\Delta N_s = \pm 2$ root birth or death under the same Jacobian floor and boundary convention. In a caustic-grazing transition this cost should be estimated from the finite impulse and wake-history increment across the fold. If that minimum vanishes under refinement, the action chart has no protected assembly gap; if it remains positive, the gap is a property of the branch ledger and delayed action, not an imported continuum-defect assumption.

In the action-counting notation of Causal Action Functional, let $\mathfrak{B}_{\lambda_0(\eta)}$ and $\mathfrak{B}_{\lambda_1(\eta)}$ be retained finite-regulator branch charts on opposite sides of a path that crosses the specific codimension-one wall Σ_{fold}. The same target is

$$\Delta_{\text{gap}} = \liminf_{\eta \to 0^+} B_{\text{rec}}(\lambda_0(\eta), \lambda_1(\eta)) > 0$$

for the wall that changes the targeted entry of the assembly topological charge. The wall may be a causal-root fold, a phase-lock wall, or a frame-degeneracy wall. The mass gap is positive exactly when the receiver-side fold-crossing cost survives regulator refinement with the finite memory and regulator state declared by those charts; this is the action view of the same uniform-in-η fold-survival problem that stability packets test through Conley, Lyapunov, or Floquet data.

Closure Interface: Action-to-Envelope Reduction

This chapter supplies the variational bridge used by the quantum closure chain. The bridge remains effective and comparative: it tests when a signed polarity/current history can be compressed into a nonnegative envelope without erasing memory terms.

From the regularized nonlocal action, the first step is to derive a continuum effective action in terms of coarse variables $(\rho_q, \mathbf{j}_q)$. The second step tests a phase-amplitude closure ansatz for the retained nonnegative envelope channel:

$$\rho_{\text{env}} = |\psi|^2, \qquad \mathbf{j}_{\text{env}} = \frac{\hbar_{\text{eff}}}{m_{\text{eff}}} \Im(\psi^* \nabla_{\mathbf{X}} \psi)$$

Here m_{eff} is the retained envelope mass parameter of the benchmark chart, not a primitive architrino mass. The projection from the signed polarity/current data $(\rho_q, \mathbf{j}_q)$ to the nonnegative envelope channel must be declared before ρ_{env} is interpreted as $|\psi|^2$.

That projection has a topological cost. The signed polarity density carries a polarity-sign sheet

$$\sigma(\mathbf{X}, T) = \operatorname{sign} \rho_q(\mathbf{X}, T) \qquad (\rho_q \neq 0)$$

and the interfaces $\rho_q = 0$ are polarity domain walls. The envelope map is faithful only on a region where σ is constant. When a loop γ encloses domain-wall crossings, the phase chart must carry the lost sign sheet as a $\mathbb{Z}_2$ bundle datum:

$$\oint_{\gamma} \nabla_{\mathbf{X}} S_{\mathrm{env}} \cdot d\boldsymbol{\ell} = \pi\, N_{\mathrm{wall}}(\gamma) \pmod{2\pi}$$

where $N_{\mathrm{wall}}(\gamma)$ is the parity count of enclosed polarity-domain-wall intersections in the retained projection. The memory current is therefore not generic residue in this regime. Its circulation classifies the polarity-domain-wall topology that the nonnegative envelope has forgotten. A spin-$\frac{1}{2}$-like double-valued envelope can be promoted only if this $\mathbb{Z}_2$ sign-sheet circulation is recovered from the same $(\rho_q, \mathbf{j}_q)$ history and persists under branch-preserving deformation.

This is a hard wall for the spinor and exchange-statistics program and is the action-side realization of the exchange-loop hard wall. The nonnegative envelope forgets an orientation double cover of the signed-density configuration space; the polarity domain walls are the branch locus of that cover. If the parity $N_{\mathrm{wall}}(\gamma) \pmod 2$ can change without crossing a certified fold, reconnection, or declared surgery event in the retained branch record, then the half-integer envelope response has been fitted rather than derived. Conversely, a deformation-stable $\mathbb{Z}_2$ holonomy gives a concrete substrate carrier for the -1 sign under an exchange cycle, provided the exchange cycle is computed from the same signed polarity/current history rather than from an imposed quantum label.

The handoff must report the continuity residual

$$R_{\mathrm{cg}} = \partial_T \rho_{\mathrm{env}} + \nabla_{\mathbf{X}} \cdot \mathbf{j}_{\mathrm{env}}, \qquad \epsilon_{\mathrm{cg}} = \frac{\|R_{\mathrm{cg}}\|}{\|\partial_T \rho_{\mathrm{env}}\| + \|\nabla_{\mathbf{X}} \cdot \mathbf{j}_{\mathrm{env}}\| + \varepsilon}$$

and keep the memory current

$$\mathbf{j}_{\mathrm{mem}} = \mathbf{j}_q - \mathbf{j}_{\mathrm{env}}$$

as an explicit residual rather than absorbing it into fitted constants. Equivalently, with $\Delta\rho = \rho_q - \rho_{\mathrm{env}}$,

$$\partial_T \rho_q + \nabla_{\mathbf{X}} \cdot \mathbf{j}_q = R_{\mathrm{cg}} + \partial_T \Delta\rho + \nabla_{\mathbf{X}} \cdot \mathbf{j}_{\mathrm{mem}}$$

Thus a small R_{cg} by itself does not prove envelope closure; the projection mismatch and memory-current divergence must be controlled as well.

For the non-relativistic, fixed-particle-number benchmark, the same envelope must also admit a phase chart

$$\psi = \sqrt{\rho_{\mathrm{env}}}\, e^{iS_{\mathrm{env}}/\hbar_{\mathrm{eff}}}, \qquad \mathbf{j}_{\mathrm{env}} = \frac{\rho_{\mathrm{env}}}{m_{\mathrm{eff}}} \nabla_{\mathbf{X}} S_{\mathrm{env}}$$

Define

$$K_{\mathrm{env}} = \frac{\|\nabla_{\mathbf{X}} S_{\mathrm{env}}\|^2}{2m_{\mathrm{eff}}}, \qquad Q_{\mathrm{env}} = -\frac{\hbar_{\mathrm{eff}}^2}{2m_{\mathrm{eff}}} \frac{\nabla_{\mathbf{X}}^2 \sqrt{\rho_{\mathrm{env}}}}{\sqrt{\rho_{\mathrm{env}}}}$$

and test the corresponding Hamilton-Jacobi residual

$$R_{\mathrm{HJ}} = \partial_T S_{\mathrm{env}} + K_{\mathrm{env}} + V_{\mathrm{eff}} + Q_{\mathrm{env}}$$

This is the current form-level quantum recovery. The residual-controlled envelope chart reproduces the Madelung/Hamilton-Jacobi structure of the non-relativistic Schrödinger equation, and the action-bundle single-valuedness condition above supplies the Bohr-Sommerfeld integer on a resonance-locked branch. Those statements are chart recoveries, not full quantum closure: the Born rule still requires the finite-window basin measure to push forward to $|\psi|^2$ on record-forming apparatus channels, and spin-$\frac{1}{2}$ exchange still requires the polarity-domain-wall $\mathbb{Z}_2$ holonomy to remain deformation-stable on the same retained branch.

The effective Schrödinger/Madelung chart is licensed on a retained window only when

$$\mathcal{R}_{\mathrm{env}} = \max\left(\epsilon_{\mathrm{cg}}, \frac{\|R_{\mathrm{HJ}}\|}{\|\partial_T S_{\mathrm{env}}\| + \|K_{\mathrm{env}}\| + \|V_{\mathrm{eff}}\| + \|Q_{\mathrm{env}}\| + \varepsilon}, \frac{\|\mathbf{j}_{\mathrm{mem}}\|}{\|\mathbf{j}_q\| + \varepsilon} \right) \le \epsilon_{\mathrm{env}}$$

This is a comparison residual, not a new ontology. If it fails, the wave function and Hamiltonian remain useful fitting charts for that window rather than promoted quantum closure.

The interface is closed only when:

- the Euler-Lagrange equations of the coarse action reproduce the effective envelope equation used in pilot-wave-character;
- the phase-amplitude chart reports $\mathcal{R}_{\mathrm{env}}$ rather than assuming the Schrödinger limit;
- memory contributions $\mathbf{j}_{\mathrm{mem}}$ remain explicit as controlled correction terms rather than hidden parameter absorbs.

Noether Braid

Noether Braid

The **Noether braid** is the reader-facing class of neutral assembly scaffolds used by the Noether sea chapters and particle-architecture chapters. Families A and B begin with a six-architrino branch; Family C extends the class to a twelve-worldline coaxial branch. This is the first place where the reader should think in terms of a retained many-body branch rather than a pair, point particle, or ordinary orbit.

A Noether braid is not assumed at the outset to be a set of exact binaries. The base object is a polarity-neutral six-body branch whose architrino paths lie on closed support curves with speed factors bounded above and below. In that branch, three negative-polarity architrinos (electrinos) and three positive-polarity architrinos (positrinos) maintain a persistent causal-return ledger.

For the base neutral braid, the simple idea is six persistent strands plus one shared ledger. Family C carries twelve persistent strands on its own declared ledger. The hard question in either case is whether the delayed dynamics can keep that ledger coherent: the same identities, the same active root structure, compatible action and wake rows, and enough stability to serve as a reusable assembly scaffold.

This question is the crux of the theory. The Noether sea, the particle architecture, the mass-response program, and the effective-metric recovery all rest first on a retained base branch, so the retained-branch question is the central open obligation of this scene. The chapters here define the braid families, carry the shared mathematics, explain the configuration-space hypotheses, and state the requirements a retained branch must satisfy, each at its stated claim level. These chapters do not track the search: status, run results, and candidate rankings are not textbook content, and a result enters only once it is established at its stated claim level.

One working principle of this scene deserves stating openly. When two statements derived along independent routes turn out to describe the same limit — the horizon-alignment condition and the vanishing of the axial polarity dipole, or the same moment cancellation appearing in both a braid record and an Accessory Configuration — that coincidence is treated as a seam of the underlying ontology, not as an accident to admire. In a correct substrate theory one mechanism surfaces in many observer-level places precisely because it is one mechanism, so each multi-route convergence is logged, the common cause is hunted, and the identified mechanism is then required to make at least one new prediction beyond the statements it unified. Convergences that resist unification are equally valuable, because they mark places where the ontology is still missing a part.

Neutral-Braid Base

The neutral braid is the broad six-architrino case before a family member imposes a binary partition or geometric relation. Its polarity inventory contains three electrinos and three positrinos, indexed by $i \in \{1, \ldots, 6\}$ with signs $\sigma_i \in \{+1, -1\}$ satisfying

$$\#\{i : \sigma_i = +1\} = \#\{i : \sigma_i = -1\} = 3, \qquad \sum_{i=1}^{6} \sigma_i = 0.$$

Equivalently, the compact inventory is $3\epsilon_+ + 3\epsilon_-$. This ledger is imposed before any binary partition, member assignment, or reference fixture. Each architrino has three attractive opposite-polarity channels and two repulsive same-polarity channels among the other five sites. The $3 + 2$ count is an inventory fact, not a compressed acceleration law; the net acceleration must still be assembled from the retained causal roots and path history.

Before a family chart is selected, the intrinsic path of architrino i may be represented by a closed arclength curve

$$\mathbf{Y}_i : \mathbb{R}/L_i\mathbb{Z} \to \mathbb{R}^3, \qquad \|\mathbf{Y}_i'(s)\| = 1,$$

with physical trajectory

$$\mathbf{X}_i(T) = \mathbf{Y}_i(\lambda_i(T)), \qquad \frac{d\lambda_i}{dT}(T) = \nu_i(T), \qquad 0 < \nu_- \le \nu_i(T) \le \nu_+ < \infty.$$

Thus the base class permits changing support geometry, nonuniform speed, changing local curvature, and delayed multi-channel response without first reducing the motion to exact binary rows. A retained neutral braid must still return to a closed causal ledger within the declared recovery tolerance. Families A and B inherit this six-site neutral inventory before adding member coordinates.

Family C instead declares a twelve-worldline neutral inventory, while each exact B1 or B1.3 component on its C3–C6 loci inherits the six-site base inventory.

The prescribed geometry is organized by Braid Taxonomy. Its current map is:

Term	Definition	Additional structure
neutral braid	The broad six-architrino neutral case before any required binary grouping or radial organization.	Polarity balance and causal-return bookkeeping.
Family A	One braid whose three binary axes are orthogonal at the near-rest endpoint and converge toward the group-translation direction under the prescribed response.	`A1` is the zero-axial-offset subset, `A2` is the fully symmetric member, and `A3` carries the general axial/transverse decomposition.
Family B	One braid whose three binary midpoints and axes coincide.	`B1` is the fixed-coordinate common-frequency co-rotating member.
Family C	A twelve-worldline coaxial braid family containing six neutral binaries.	`C1` and `C2` are general co-rotating and counter-rotating members; `C3` and `C4` constrain the record to two B1 components; `C5` and `C6` further constrain both components to B1.3.

These definitions name prescribed coordinate classes, not retained-branch existence. Stable all-pairs roots, recovery after perturbation, and observer-export behavior are theorem targets that must be certified by the branch ledger rather than read back into a family identifier. The broader diagnostic axes and search variables remain in Noether Braid Configuration Space.

The word **braid** names the family-declared retained worldline strands together with their shared causal-return ledger: six strands in the base and Family-A/B cases, and twelve in Family C. It does not by itself assert that the branch already carries a protected mathematical braid-group class. A protected braid, linking, framing, or chirality class is extra structure to be certified by the assembly topological charge program.

Canonical reader-facing prose uses **Noether braid** for the assembly class, **neutral braid** for the base case, and the family/member identifiers for prescribed geometry. Durable symbols and internal runtime identifiers may still contain `NS`, `noether_braid`, or `nested-shell-braid`; those strings are stable implementation identifiers, not a second taxonomy. The braid's dynamic envelope geometry is developed separately in Braid Envelope Geometry, while metric-level translation belongs to Emergent Metric.

Simple Picture

A Noether braid is a candidate way for a declared neutral architrino inventory to keep coming back into a repeatable causal relationship. The important object is not a drawn knot or a fixed material ring. It is the full branch record: which architrinos are present, which causal wakes return, which root identities stay active, and which conserved or nearly conserved quantities survive around the cycle.

That is why the family identifiers are deliberately neutral. `A1` through `A3`, `B1`, and `C1` through `C6` point to explicit table rows; the identifiers do not themselves imply stability, mass response, photon behavior, or Noether sea dominance. Those claims require retained branch certificates and downstream export rows.

Document Role

This chapter is the overview and family map for the Noether braid stack. It defines the word **braid**, routes the coordinate taxonomy, and explains why family identifiers are geometry classes rather than retained-branch results.

It does not carry the detailed family derivations, select a frequency family, assign proof dispositions, compute assembly topological charge, or export Lorentz clock/ruler deformation by itself. Neighboring chapters consume the branch record named here, and they play distinct roles. The taxonomy defines the coordinate system and member rows; the requirements chapter states the realization-independent proof contract; the mathematics chapter carries the machinery shared by every realization; the configuration-space chapter carries broader diagnostic axes and search variables; the analysis chapter works one candidate frequency family exactly; the export chapters describe what a retained branch would hand to the rest of the theory.

Role	Chapter	What it owns
Requirements	Braid Recovery Requirements	The realization-independent retention-certificate shape, its base-family instantiation, proof-burden order, and recovery-target inventory.
Taxonomy	Braid Taxonomy	The canonical coordinates, family/member identifiers, master tables, and prescribed response endpoints.
Family definition	Braid Family A	The shared Family-A geometry, A1 and A3 variants, the A2 definition, and their coordinate-locus relations.

Role	Chapter	What it owns
Family definition	Braid Family B	The exact B1 path geometry, coordinate boundaries, axial-translation specialization, and Family-A boundary.
Family definition	Braid Family C	The general twelve-worldline coaxial chart, the C1/C2 circulation relation, the C3/C4 two-B1 loci, the C5/C6 two-B1.3 loci, and the physical-mapping boundary.
Configuration space	Noether Braid Configuration Space	The evidence-level terms and supplementary rank-three angular-momentum-frame diagnostics outside the canonical taxonomy.
Braid A1 dynamics and interpretation	Braid A1 Dynamics and Interpretation	A1 retention questions, closure labels, cadence retuning, scaling, alignment, and downstream hypotheses.
A2 symmetry and return response	A2 Symmetry and Return Response	The A2 invariant-channel theorem, two-ring geometry, dipole identity, momentum screw, and return-response analysis.
Mathematics	Braid Mathematics	The shared machinery: transverse speed-budget lemmas, eigen-braid spectrum framing, fold-set action quantization as hypothesis, and Accessory Configuration moment analysis.
Analysis methodology	Candidate Braid Analysis Methodology	The common causal-wake map, internal and external probes, energy-ledger interface, sampling method, and candidate-grading rules.
Analysis	A3.3 Doubling-Frequency Resonance Lock	The A3.3 $4{:}2{:}1$ candidate, including its zero-axial-offset A1.3 locus, and its lock analysis.
Export	Braid Envelope Geometry	The family-general envelope and observer-export interface: dynamic exclusion envelope, sea-interface diagnostic, canonical geometry variables, and the Lorentz projection.
Export	Noether Braid Topological Charge	Classification of retained branch charts.

A first reading should follow the table order: what a retained braid must satisfy, then the coordinate taxonomy and Family-A, Family-B, and Family-C definitions, then the broader configuration space and member specialists, then shared mathematics, the common analysis method, and candidate analyses, with the export chapters as the interface layer. Search progress is not tracked in these chapters.

Medium-Selection Burden

Branch retention is not the same question as Noether sea primacy. A retained Noether braid branch would show that one neutral assembly class can persist. It would not yet show that this class is the dominant ambient structure in the universe, because many other architrino assemblies might also be imagined.

The stronger claim is a selection theorem over candidate assembly classes. A class can serve as the ambient Noether sea population only if it can be retained as a branch and also form a dense, locally neutral, convergent, transparent, pressure-bearing, and constitutively useful medium. In the notation of Noether sea, any proposed Family-A route must pass the ambient selection residual while competing assembly classes either fail, remain local matter or reaction branches, or appear only as higher-energy, short-lived, or environment-specific excitations.

This distinction protects the proof order. The neutral-braid row asks whether the six-site architecture can close; each family/member row adds its own coordinate constraints. The Noether sea selection row asks why one retained member should dominate the weak homogeneous medium rather than a different assembly population. A particle-like success, a metric-like export, or an appealing exclusion volume is therefore not enough by itself; the same branch class must also supply the statistical abundance, far-field cancellation, packing, and shared-response properties needed by the Noether sea.

Braid Recovery Requirements

Before any particular braid geometry is featured, the theory owes the reader a contract: what must a candidate braid actually deliver? This chapter states that contract once, independently of which realization — one support band, three ordered bands, or another family member — eventually satisfies it. The requirements come in two layers. The retention layer asks whether the family-declared neutral inventory can persist as one coherent causal-return record. The recovery layer asks what a retained branch must then hand to the rest of physics: the clocks, rulers, masses, charges, spectra, statistics, forces, and cosmological histories that general relativity, quantum theory, the Standard Model, and the ΛCDM-era observations already describe at the observer level.

Stating the requirements realization-independently protects the proof order. A realization chapter may carry beautiful exact structure and still leave every row below open; a recovery chapter may state a sharp observer-level target that no current branch can yet consume. Keeping the contract in one place prevents both failure modes from hiding: every claim in the braid scene can be checked against this chapter's ladder, and every ladder row names the chapter where its detailed burden lives.

Nothing in this chapter is a retained-branch result. Every row below is an obligation — a theorem target, closure target, or comparison target at its stated level — and proof dispositions are not carried in this chapter.

Document Role

This chapter owns the realization-independent statement of the braid proof burden: the retained-branch certificate row structure, the first-failure reporting discipline, the ordered proof-burden ladder, and the full recovery-target inventory consumed by the downstream theory. It deliberately owns no geometry and no evidence. The neutral six-body base lives in Noether Braid; prescribed member definitions live in Braid Taxonomy, Braid Family A, and Braid Family B. The shared mathematical machinery lives in Braid Mathematics. Proof dispositions are not carried in this chapter; broader diagnostic axes live in Noether Braid Configuration Space.

A reader should use this chapter the way an engineer uses a requirements specification: to know what any proposed design must eventually satisfy, and to recognize when a reported success addresses one row while leaving the blocking rows untouched.

The Retained-Branch Certificate

The retention question has the same row structure for every family member. A candidate branch B over a test window W is a claim that the family-declared neutral inventory keeps returning to one repeatable causal relationship: the same identities, the same active root structure, compatible action and wake rows, and enough stability to serve as a reusable assembly scaffold. The base and Family-A/B cases use six architrinos with inventory $3\epsilon_+ + 3\epsilon_-$; Family C uses twelve worldlines grouped into six neutral binaries. The certificate makes that claim auditable by splitting it into rows that must all close on one ledger identity:

$$\mathsf{R}(B,W) = (\mathsf{Inventory}, \mathsf{Curves}^\nu, \mathsf{Support}, \mathsf{Root}^\nu, \mathsf{Tail}^\nu, \mathsf{Dynamics}^\nu, \mathsf{Action}^\nu_\Gamma, \mathsf{Noether}^\nu, \mathsf{Framing}^\nu, \mathsf{Event}^\nu, \mathsf{Stability}^\nu, \mathsf{Convergence}, \mathsf{Status})$$

The inventory row fixes which architrinos are present and their polarity balance. The curve and support rows fix the closed support geometry and its declared band structure — this is the only place where the family member enters, as the declared support descriptor. The root row demands the actual retained causal roots for all ordered distinct source pairs, thirty in the six-body case, with delays, Jacobian floors, transmitter-side acceleration weights, and lines of action assembled from the true path histories rather than from a compressed acceleration law. The tail, dynamics, action, and Noether rows demand that the delayed accelerations, the action bookkeeping, and the conserved-quantity ledger all balance on the same record. The framing row carries the deformation-stable framed-path record, including the declared relation $Lk = \mathrm{Wr} + \mathrm{Tw}$, the framing sign, and its positive conditioning floor. The event and stability rows demand that framing-wall or root-topology crossings are logged and that the branch returns after perturbation, and the convergence row demands that the far-population wake sums the record depends on actually converge.

Retention is the conjunction, never a partial credit:

$$\mathrm{Retain}(B,W) \iff P_{\mathrm{inventory}} \wedge P_{\mathrm{curves}} \wedge P_{\mathrm{support}} \wedge P_{\mathrm{root}} \wedge P_{\mathrm{tail}} \wedge P_{\mathrm{dyn}} \wedge P_\Gamma \wedge P_{\mathrm{Noether}} \wedge P_{\mathrm{framing}} \wedge P_{\mathrm{event}} \wedge P_{\mathrm{stab}} \wedge P_{\mathrm{conv}}$$

Every predicate must use the same source-pair policy, same-transmitter policy, memory depth, support descriptor, action convention, framing convention, event interval, and inventory ledger. If any row changes those conventions, the result is a ledger mismatch, not a retention result. The neutral-braid statement of this certificate, with the base-family notation, is given in Base-Family Certificate Instantiation; any prescribed taxonomy member inherits the same rows and may compress the all-pairs ledger only after its reduction map proves how the compressed entries are inherited.

The First-Failure Ladder

A certificate that fails should fail informatively. The reporting discipline is to identify the first blocking row, in the fixed row order above, together with the data needed to act on it:

$$\mathsf{F}(B,W) = (\mathrm{first\_failed\_row}, \mathrm{ledger\_id}, \mathrm{margin}, \mathrm{blocking\_packet}, \mathrm{repair\_or\_rejection})$$

The ladder shape carries the scene's central reading rule. Rows through convergence block branch retention; case-reduction and observer-export rows classify downstream structure only after the required rows close. A favorable Lorentz, photon, topology, mass-map, or envelope-geometry diagnostic therefore cannot rescue an open root, tail, dynamics, action, event, stability, or convergence row — and symmetrically, a negative diagnostic remains scoped to the branch chart and assumptions that produced it. The margin entry keeps quantitative failures honest: a row that fails by a certified interval is worth more to the program than a row that merely lacks evidence, because it either rejects a chart or names the exact quantity a repair must move.

Proof-Burden Order

The retention certificate is the first rung of a longer ladder. The burdens close in a fixed order, and a packet can supply evidence for one rung while leaving the next rung open. The realization-independent ladder is:

Order	Burden	What must close on the same record
1	Rest branch retention	The full certificate conjunction in the declared rest environment.
2	Noether sea embedded retention	The rest rows plus the local population-response row from like assemblies, for branches whose stability is supplied by the ambient medium rather than by isolation.
3	Moving observer export	Transport, response-center, clock, ruler, energy/action, and preferred-frame-leakage rows for nonzero group velocity.
4	Assembly consumer rows	The recovery-target inventory below, each target consuming the retained branch record rather than substituting for it.

Two consequences of this ordering deserve emphasis. First, isolation is a limiting seed chart, not the physical situation: a branch that fails in the Euclidean void and closes only with the embedded population-response row is still a physical success, because the universe supplies the medium. Second, consumer success never travels backward. A recovered spectrum, acceleration law, or metric export classifies a retained branch; it does not retroactively prove retention, and it earns no claim-level promotion for the rungs beneath it.

Recovery-Target Inventory

A retained, transportable braid branch is the theory's proposed common cause for a wide inventory of observer-level physics. This section states that inventory once. Each row names the target, the requirement in realization-independent form, and the chapter that owns the detailed derivation burden. The rows are stated from the perspective of the working theory; their individual claim levels — derivation, closure target, effective summary, or comparison target — are carried by the owning chapters.

Relativistic and Gravitational Targets

Target	Requirement	Owning chapters
Lorentz clock/ruler export	A moving retained branch must retune its internal record so that clock rate and envelope contraction collapse to the observer-calibrated $\gamma_0(v_{\text{eff}}) = (1 - v_{\text{eff}}^2/c_0^2)^{-1/2}$ in the homogeneous weak-field limit, with preferred-frame leakage bounded below current test sensitivity.	Lorentz Kinematics, Proper Time and Time Dilation
Effective metric and weak-field gravity	The braid-bearing Noether sea must export an effective metric whose weak clock row reproduces $d\tau_A/dt \approx 1 - U_N/c_0^2 - \lVert\mathbf{w}\rVert^2/(2c_0^2)$, with the Newtonian potential match, effective coupling, and PPN coefficients derived from one same-record constitutive response rather than fit separately.	Emergent Metric, General Relativity, PPN Parameters
Strong-field and horizon behavior	The terminal-alignment condition of the braid family must recover horizon phenomenology — darkness, entropy counting over alignment-restricted closure labels, and singularity resolution — as branch-boundary behavior rather than as imported geometry.	Black Holes, Singularity Resolution
Decay-rate dilation and the clock hypothesis	A moving unstable retained branch must dilate its decay and transaction rates by the same $1/\gamma_0(v_{\text{eff}})$ as its clock export — the storage-ring muon-lifetime record and rotor time-dilation measurements are the tested benchmarks — with the candidate mechanism that internal cadence, and therefore the pacing of action-transaction events, slows with the clock. The residual acceleration dependence of decay rates must remain below the clock-hypothesis bounds (pure $1/\gamma$ behavior verified at accelerations of order $10^{18}\,g$ in storage rings), which bounds how much braid-geometry strain per unit acceleration may leak into transaction rates.	Proper Time and Time Dilation, Lorentz Kinematics

Quantum and Standard-Model Targets

Target	Requirement	Owning chapters
Mass map	Observed particle masses must be extracted as effective inertial response of retained branches — small observed mass from large shielded interior energy — with the extraction rule derived from the same branch record used for retention.	Particle Masses
Fermion generations	The three-generation ladder must be recovered as a structural ladder of the braid family — the working reading is a shielding-tier ladder — with the generation count derived from the delayed dynamics rather than postulated.	A1 Shielding, Muon and Tau
Spin-statistics and exchange	Fermionic antisymmetry and bosonic shared occupation must be recovered from braid envelope geometry plus an exchange sign consumed from the same retained row that supplies spinor closure, not from a separately selected bookkeeping sign.	Fermi-Dirac and Bose-Einstein Statistics, Angular Momentum and Spin

Target	Requirement	Owning chapters
Photon and Maxwell recovery	The photon channel must be recovered as a propagating assembly of released action history whose superposed delayed potentials reproduce Maxwell behavior, transverse polarization, and propagation at the recovered signal speed.	Electroweak Bosons, Radiation
Strong force and color	Color bookkeeping, gluon-like exchange, and confinement must be recovered from braid substructure and its interaction channels, including why isolated color-carrying assemblies are unstable.	Color Charge and SU(3), Gluons, Nucleon Structure
Weak channel	Weak-interaction phenomenology — short range, flavor change, mixing structure — must be recovered from near-field braid interactions without a primitive massive mediator, with the mediator masses and mixing angle emerging as assembly properties.	Electroweak Bosons, Weak Mixing Angle
Net-charge quantization	Observer-level electric charge must arrive in the observed quantized units as a consequence of admissible dressing inventories over the braid's net polarity inventory, not as a primitive label.	Quantum Number Mapping, Architrino
Atomic spectra	Atomic energy levels and spectral lines must be recovered as electron-assembly resonance envelopes in the structured nuclear and Noether sea wake environment, with level spacing inherited from the action-transaction ledger.	Atomic Spectra, Atomic Structure

Cosmology-Era Targets

The fixed-void discipline makes the cosmological rows unusually sharp: with no expanding void available, every redshift-linked observable must be recovered from transport through the evolving Noether sea.

Target	Requirement	Owning chapters
Redshift transport rows	Surface-brightness dimming $(1+z)^{-4}$, light-curve time dilation $(1+z)$, and $T_{\rm CMB}(z) = T_0(1+z)$ must be recovered from transport physics rather than from tired-light energy loss.	Expansion Mechanism, Cosmology Reconstruction
Era ladder	The observationally anchored era sequence — nucleosynthesis abundances, recombination and the CMB, structure formation — must be recovered with an effective scale history derived from the mass map and Noether sea response coefficients.	BBN Constraints, CMB, Structure Formation
Dark-sector accounting	The phenomena attributed to dark matter and dark energy must be recovered as Noether sea population, response, and gradient effects, or explicitly scoped as open residuals.	Dark Matter, Dark Energy

Noether Sea Selection Burdens

The recovery rows above mostly consume one retained branch. The medium rows consume a population, and they add a burden that no single-branch success can discharge: the featured braid class must be shown to dominate the ambient medium. A class can serve as the Noether sea population only if it passes every entry of the selection residual defined in Noether Sea: retained-branch closure, local polarity neutrality, convergence of the far-population wake sum, dense packing without uncontrolled branch disruption, weak homogeneous transparency, a shared constitutive response across the refractive, clock, stress, and metric channels, compatibility with the particle-building program, and a production or recycling route that supplies sufficient abundance.

Transparency is a bounded-response condition, not zero coupling: the medium must keep direct loss, scattering, and preferred-frame visibility small while still supplying the constitutive response that clocks, photon transport, matter response, and neutrino-like propagation are recovered from. A candidate class that decouples entirely passes neither side of that check. The selection burden is therefore comparative — the featured class must pass while competing assembly classes either fail a row or are classified as localized matter, radiation, reaction, or strong-field branches — and it remains open even after any single branch is retained.

Reading Discipline

Three rules keep this contract usable. First, requirements are not evidence: adding, sharpening, or reorganizing rows in this chapter changes no proof status anywhere. Second, claim levels travel with their owning chapters: a row stated here in working-theory voice may be a derivation, a closure target, or a comparison target at its source, and the source governs. Third, the ladder is ordered: any reported success should be located on the proof-burden ladder before it is celebrated, and any reported failure should be located on the first-failure ladder before it is generalized.

Base-Family Certificate Instantiation

This section instantiates the general contract for the base family, the **neutral braid** — the six-architrino, polarity-balanced case whose full definition follows in Noether Braid; the inventory facts used here (three electrinos, three positrinos, thirty ordered distinct source pairs) are all a reader needs in advance. The neutral braid claim is a theorem target, not a retained-branch result. A candidate branch B over a test window W is retained only if the required rows close on one ledger identity. The master certificate can be summarized as

$$\mathsf{R}_{\mathrm{NB}}(B,W)=(\mathsf{Inventory},\mathsf{Curves}^{\nu},\mathsf{Support},\mathsf{Root}^{\nu},\mathsf{Tail}^{\nu},\mathsf{Dynamics}^{\nu},\mathsf{Action}^{\nu}_{\Gamma},\mathsf{Noether}^{\nu},\mathsf{Framing}^{\nu},\mathsf{Event}^{\nu},\mathsf{Stability}^{\nu},\mathsf{Convergence},\mathsf{Status})$$

The corresponding retention predicate is

$$\mathrm{Retain}_{\mathrm{NB}}(B,W)\iff P_{\text{inventory}}\wedge P_{\text{curves}}\wedge P_{\text{support}}\wedge P_{\text{root}}\wedge P_{\text{tail}}\wedge P_{\text{dyn}}\wedge P_{\Gamma}\wedge P_{\text{Noether}}\wedge P_{\text{framing}}\wedge P_{\text{event}}\wedge P_{\text{stab}}\wedge P_{\text{conv}}$$

Every predicate in this conjunction must use the same source-pair policy, same-transmitter policy, memory depth, support descriptor, action convention, framing convention, event interval, and inventory ledger. If any row changes those conventions, the status is a ledger mismatch rather than a retention result.

The root row begins with all ordered distinct source pairs. With $I=\{1,\dots,6\}$,

$$\Pi_{\text{all}}=\{(i,j)\in I\times I:i\neq j\},\qquad|\Pi_{\text{all}}|=30$$

Same-transmitter rows (i,i) are governed by the declared same-transmitter policy and are deliberately excluded from Π_{all}; the ordered distinct-pair count is therefore $6\times5=30$. The 3 attractive and 2 repulsive transmitter-site counts for each receiver are inventory facts, not a compressed acceleration law. The acceleration contribution must still be assembled from the actual retained causal roots, delays, Jacobian floors, transmitter-side acceleration weights, and line-of-action vectors for these ordered pairs. A prescribed taxonomy member can reduce this ledger only after its reduction map proves how the compressed entries are inherited from the all-pairs ledger.

For Family C, let $I_C=\{1,\dots,12\}$. Its uncompressed ordered distinct-pair ledger is

$$\Pi^{C}_{\text{all}}=\{(i,j)\in I_C\times I_C:i\neq j\},\qquad|\Pi^{C}_{\text{all}}|=132.$$

C3 through C6 may expose two exact B1 or B1.3 component ledgers, but those component rows do not replace the 132-pair Family-C ledger unless a proved reduction map accounts for every cross-component pair. An associated Accessory Configuration remains a separate inventory and certificate input rather than part of these twelve defining worldlines.

The certificate should report the first blocking row as

$$\mathsf{F}_{\mathrm{NB}}(B,W)=\big(\text{first\_failed\_row},\text{ledger\_id},\text{margin},\text{blocking\_packet},\text{repair\_or\_rejection}\big)$$

Rows through convergence block branch retention. Case-reduction and observer-export rows classify downstream structure only after the required neutral rows close. Therefore a favorable Lorentz, photon, topology, mass-map, or shell-geometry diagnostic cannot rescue an open root, tail, dynamics, action, event, stability, or convergence row.

Reading Discipline

Reading discipline for future diagnostics on this chart, retained from earlier work at method level: a resolved causal-root ledger does not imply acceleration-balance closure; inventory attraction bias does not imply acceleration-balance closure; resolved positive-delay root rows do not imply acceleration-balance closure; and sampled phase or polarity-phase improvements do not imply retention. A negative result for one fixed-coordinate carrier hypothesis is not a rejection of the neutral braid, any A/B/C member, or the bounded-speed, controlled-self-hit, fold-layer, and medium-response programs. No measured residuals are carried in this chapter: results enter only when established, with instrument and claim level stated.

Braid Taxonomy

This chapter describes prescribed Noether braid geometries through explicit coordinates. The taxonomy has three levels: assembly composition, individual braid, and individual binary.

Each taxonomy member receives a neutral identifier consisting of a family letter and a member number, such as `A1`, `A2`, `A3`, or `B1`. A decimal suffix identifies a constrained variant of a member, such as `A1.1` or `B1.1`. The identifier carries no geometric meaning. The first three master tables together with the source record define the geometry; the Borg depiction renders that declared record. Family and member names are optional aliases.

This is a geometry-and-motion taxonomy. It does not establish that a prescribed configuration is generated, retained, or stable under the EOM solver.

Assembly Composition

Assembly composition describes how complete braid records are combined.

Coordinate	Meaning
Top-level braid count $N_{\mathcal{B}}$	Number of complete prescribed Noether braid records in the assembly. A Family-C record counts as one top-level braid even where C3 through C6 expose two exact component-braid rows.
Relative braid-center displacement	Position of each braid center relative to the assembly center when $N_{\mathcal{B}} > 1$.
Relative orientation	Orientation of each braid record relative to the assembly reference frame.
Relative phase	Timing offset between braid records.
Relative circulation	Whether the braid records advance with the same or opposite circulation sense.

An assembly containing two separate six-worldline braid records does not become Family C merely because it contains twelve worldlines in total. Family C is one shared twelve-worldline top-level record on the applicable common-axis chart. For a multi-braid assembly, record polarity conjugation, pro/anti orientation when defined, relative circulation, axis relation, and planarity as independent relations; no one relation is licensed by the others.

Individual Braid

A base, Family-A, or Family-B Noether braid consists of three neutral binaries. Family C consists of six neutral binaries in one twelve-worldline top-level record. Each binary contains one electrino and one positrino. Other polarity pairings are outside the present taxonomy.

The overarching translation characteristic is the speed of the complete assembly group. Let $\mathbf{X}_{\mathrm{grp}}(T)$ be the declared translation center of the prescribed assembly group. Its group velocity and group translation speed are

$$\mathbf{V}_{\mathrm{grp}}(T) = \frac{d\mathbf{X}_{\mathrm{grp}}}{dT}$$

and

$$s_{\mathrm{grp}}(T) = \|\mathbf{V}_{\mathrm{grp}}(T)\|$$

For one top-level braid record, including Family C, $\mathbf{X}_{\mathrm{grp}}$ is the declared center of that record. For an assembly containing several top-level braid records, it is the declared center of the complete assembly. The group translation speed is distinct from the internal orbital speeds of the constituent architrinos.

The braid-level record contains this overarching characteristic and the coordinate collections obtained from its three binaries:

Coordinate collection	Definition
Group translation speed s_{grp}	Translation speed of the complete top-level braid or multi-braid assembly group.
Binary midpoint data	The ordered midpoint vectors $(\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3)$. A member row may constrain their relation without redefining the individual midpoint coordinate.
Axis data	The ordered binary-axis unit vectors $(\hat{\mathbf{n}}_1, \hat{\mathbf{n}}_2, \hat{\mathbf{n}}_3)$. The vectors are recorded directly without assigning an axis-structure class.
Circulation data	The ordered circulation senses of the three binaries.

Many more braid geometries may be investigated. They are not enumerated here.

Individual Binary

For binary $a \in \{1, 2, 3\}$, let the endpoint positions in the Euclidean void be $\mathbf{X}_{a1}(T)$ and $\mathbf{X}_{a2}(T)$. Define the binary midpoint and half-separation vector by

$$\mathbf{c}_a(T) = \frac{\mathbf{X}_{a1}(T) + \mathbf{X}_{a2}(T)}{2}$$

and

$$\mathbf{d}_a(T) = \frac{\mathbf{X}_{a1}(T) - \mathbf{X}_{a2}(T)}{2}$$

Given an oriented binary-axis unit vector $\hat{\mathbf{n}}_a(T)$, choose the endpoint and axis orientations so that the axial coordinate is nonnegative, and define

$$h_a(T) = \mathbf{d}_a(T) \cdot \hat{\mathbf{n}}_a(T)$$

and

$$\rho_a(T) = \|\mathbf{d}_a(T) - h_a(T)\hat{\mathbf{n}}_a(T)\|$$

Here h_a is the **axial half-separation**, and ρ_a is the **transverse orbit radius**. The binary radius is the endpoint distance from the binary midpoint:

$$R_a(T) = \|\mathbf{d}_a(T)\|$$

The axial and transverse coordinates decompose that radius according to

$$R_a^2(T) = h_a^2(T) + \rho_a^2(T)$$

Frequency and phase belong to the individual binary. Every binary phase is specified relative to the same braid-level zero point.

The binary coordinate columns are:

Coordinate	Meaning
Radius R_a	Endpoint distance from the binary midpoint $\mathbf{c}_a$.
Frequency f_a	Repetition frequency of the prescribed binary motion.
Phase ϕ_a	Phase of binary a relative to the common braid-level zero point.

The coordinate limits have direct geometric meanings:

- $\rho_a = 0$: both endpoints remain on the binary axis.
- $h_a = 0$: both endpoints lie in the plane through $\mathbf{c}_a$ orthogonal to the binary axis.
- $h_a > 0$ and $\rho_a > 0$: the endpoints occupy separated transverse orbits around the binary axis.

If a display requires an angular coordinate, it may derive

$$\alpha_a(T) = \operatorname{atan2}(h_a(T), \rho_a(T))$$

This angle is not a primary taxonomy coordinate.

The taxonomy table uses fixed-coordinate prescribed time dependence as an idealized characteristic. Other possible time dependences, including breathing, precession, and other deformations, lie outside its present scope.

Family A: Noether Core

Family A is the original Noether core geometry. Its member distinctions and symmetry relationships are developed in Braid Family A. Let $\hat{\mathbf{n}}_a^{(0)}$ denote its three binary axes at the near-rest endpoint. These axes are mutually orthogonal:

$$\hat{\mathbf{n}}_a^{(0)} \cdot \hat{\mathbf{n}}_b^{(0)} = \delta_{ab}$$

The near-rest axes define the equal-component braid direction

$$\hat{\mathbf{u}}_A = \frac{\hat{\mathbf{n}}_1^{(0)} + \hat{\mathbf{n}}_2^{(0)} + \hat{\mathbf{n}}_3^{(0)}}{\sqrt{3}}$$

Family A translates along this direction:

$$\mathbf{V}_{\text{grp}}(T) = s_{\text{grp}}(T)\hat{\mathbf{u}}_A$$

Let $\lambda_A \in [0,1]$ denote the prescribed Family-A flattening coordinate. The near-rest endpoint is $\lambda_A = 0$. As λ_A increases, the three binary axes converge toward the translation direction. The flat endpoint is

$$\hat{\mathbf{n}}_1(1) = \hat{\mathbf{n}}_2(1) = \hat{\mathbf{n}}_3(1) = \hat{\mathbf{u}}_A$$

The combined binary envelope is nearly spherical at the near-rest endpoint in a weak-gradient deep-space environment. Increasing group translation speed or gravitational gradient increases λ_A, compresses the envelope along $\hat{\mathbf{u}}_A$, and makes the envelope increasingly oblate. The event-horizon response study and the photon-channel response study use the flat Family-A geometry at $\lambda_A = 1$ as prescribed input. These endpoint assignments are geometry-response charts; deriving either physical channel from an EOM-solver record remains open.

`A1` is the zero-axial-offset Family-A member. All three binary midpoints coincide with the braid center, and each binary has

$$\mathbf{c}_a(T) = \mathbf{X}_{\text{grp}}(T), \qquad h_a = 0, \qquad \rho_a = R_a.$$

Thus the electrino and positrino of binary a traverse the same geometric circle in the plane through the braid center orthogonal to $\hat{\mathbf{n}}_a$, while occupying antipodal points at every common time. The phrase “same plane” applies within each binary; the three Family-A binary planes remain distinct whenever their axes are distinct.

The A1 indices $a \in \{1,2,3\}$ are persistent record identities, not a sorting by radius, frequency, speed, or any derived dynamical role. Their radii satisfy

$$R_a > 0, \qquad a \in \{1,2,3\},$$

and may be assigned independently, including equal values. The three frequencies are also independently assignable. If an evolved branch later supplies a field-speed carrier, a boundary-leading path, or another distinguished role, that role is a diagnostic derived from the branch record and does not relabel the binaries.

`A2` is the fully symmetric Family-A member. Its three binaries have equal radii, equal axial half-separations, equal transverse orbit radii, equal frequencies, one circulation sense, and phases separated by 120°. Thus a 120° rotation about $\hat{\mathbf{u}}_A$ cyclically permutes the three binaries without selecting one of them.

`A3` is the general axial-decomposition Family-A member. Its three binary midpoints coincide with the braid center, while each persistent binary independently carries nonnegative h_a and ρ_a satisfying $R_a^2 = h_a^2 + \rho_a^2$. When $h_a > 0$ and $\rho_a > 0$, the two endpoint orbit centers are separated by $2h_a\hat{\mathbf{n}}_a$. A1 is the exact zero-axial-offset subset of A3:

$$A1.n = A3.n \cap \{h_1 = h_2 = h_3 = 0, \quad \mathbf{c}_1 = \mathbf{c}_2 = \mathbf{c}_3 = \mathbf{X}_{\text{grp}}\}$$

for each shared constrained-variant suffix $n \in \{1,2,3,4\}$. The unsuffixed A1 member is the corresponding zero-axial-offset subset of unsuffixed A3. A2 is selected by its cyclic symmetry constraints and occupies a symmetric locus within the A3 coordinate space; it is not renamed by this subset relation.

Family B: Coincident Binary Axes

Family B contains one-braid members whose three binary axes coincide. Its exact path geometry and coordinate boundaries are developed in Braid Family B. The B1 chart uses one common binary midpoint at the braid center,

$$\mathbf{c}_1(T) = \mathbf{c}_2(T) = \mathbf{c}_3(T) = \mathbf{X}_{\text{grp}}(T),$$

and one common oriented axis:

$$\hat{\mathbf{n}}_1 = \hat{\mathbf{n}}_2 = \hat{\mathbf{n}}_3 = \hat{\mathbf{n}}_B$$

`B1` is the fixed-coordinate common-frequency co-rotating member. Its binaries may have different radii, axial half-separations, transverse orbit radii, and phases, but share one midpoint, one axis, one frequency, and one circulation sense. The coincident-axis relation distinguishes Family B from Family A; the family identifier does not assert that either geometry is dynamically retained.

The three current Borg selections are `B1.1`, the interior reference with $h_a > 0$ and $\rho_a > 0$; `B1.2`, the high-axial interior selection with $h_a > \rho_a > 0$; and `B1.3`, the all-equatorial boundary with $h_a = 0$ and $\rho_a = R_a$. Each inherits every other B1 relation. Active B1 candidates additionally satisfy $\sum_a \rho_a^2 > 0$, equivalently nonzero total squared internal speed for the declared common frequency. The all-axial locus $\rho_a = 0$, $h_a = R_a$ remains part of the B1 coordinate boundary, but the former identifier `B1.4` is retained only as a deprecated historical null control.

Family A and Family B meet on a boundary. Every Family-A member reaches the coincident-axis relation at $\lambda_A = 1$; a common-frequency Family-A variant with one common circulation sense and coincident binary midpoints also occupies the B1 coordinate locus at that endpoint. The A2 face-opposite seed also admits a distinct body-diagonal rotating-channel chart on the cyclic-symmetric B1 sublocus described in B1 Hypotheses and Discrete Symmetry. This geometric coincidence does not identify the two families away from either overlap.

Family C: Coaxial Twelve-Architrino Geometry

Family C contains twelve architrino worldlines grouped into six neutral binaries on one common oriented axis. Its exact ordered path chart, binary-counterpart map, causal-delay relation, constrained component loci, and physical-mapping boundary are developed in Braid Family C.

The parent coordinates are the ordered axial positions ξ_m, spacing vector $\mathbf{d}_C$, total length L_C, radii ρ_m, angular frequencies ω_m, phases ϕ_m, circulation senses q_m, and fixed-point-free neutral-binary map π. Family C does not require its twelve worldlines to decompose into two B1 braids.

`C1` is the general co-rotating member: all twelve worldlines share one circulation sense. `C2` is the general counter-rotating member: worldlines 1 through 6 have one circulation sense and worldlines 7 through 12 have the opposite sense. Both retain the complete spacing, radius, frequency, phase, and binary-pairing coordinates.

`C3` and `C4` are the constrained loci in which the twelve worldlines decompose into two complete coaxial B1 components. C3 is co-rotating and C4 is counter-rotating. `C5` and `C6` further constrain those components to B1.3, so every binary in both components lies on the all-equatorial boundary $h_{ba} = 0$ and $\rho_{ba} = R_{ba}$. For C3 through C6, the component centers are separated along the common oriented axis by the positive coordinate d_C:

$$\hat{\mathbf{n}}_2 = \hat{\mathbf{n}}_1 = \hat{\mathbf{n}}_C, \qquad \Delta\mathbf{C} = d_C\hat{\mathbf{n}}_C, \qquad d_C > 0.$$

An optional six-architrino Accessory Configuration is separate declared inventory and does not change the C1 through C6 identifier. These members define prescribed geometry classes only; they do not assert a binding or retention mechanism.

Master Tables

The first three tables carry the geometry. The fourth table supplies optional names, source-record routing, Borg routing, and brief explanation. A constrained variant appears only in the tables whose values it changes. In every other table, it inherits the row of its parent member. Thus `A1.2` uses the `A1` assembly and braid rows together with the `A1.2` binary and navigation rows, while `A3.2` inherits from `A3`. `NA` means not applicable.

Assembly Composition Master Table

Member ID	Top-level braid count	Relative braid-center displacement	Relative orientation	Relative phase	Relative circulation
`A1`	1	NA	NA	NA	NA
`A2`	1	NA	NA	NA	NA
`A3`	1	NA	NA	NA	NA
`B1`	1	NA	NA	NA	NA
`C1`	1	NA	One common oriented axis	NA	Same across all twelve worldlines
`C2`	1	NA	One common oriented axis	Relative phase remains worldline-resolved	Opposite between ordered index subsets $\mathcal{I}_1$ and $\mathcal{I}_2$
`C3`	1, with two B1 components	$d_C\hat{\mathbf{n}}_C$, $d_C > 0$	Coaxial oriented axes	$\Delta\phi$	Same
`C4`	1, with two B1 components	$d_C\hat{\mathbf{n}}_C$, $d_C > 0$	Coaxial oriented axes	$\Delta\phi$	Opposite

Member ID	Top-level braid count	Relative braid-center displacement	Relative orientation	Relative phase	Relative circulation
C5	1, with two B1.3 components	$d_C\hat{\mathbf{n}}_C,\, d_C > 0$	Coaxial oriented axes	$\Delta\phi$	Same
C6	1, with two B1.3 components	$d_C\hat{\mathbf{n}}_C,\, d_C > 0$	Coaxial oriented axes	$\Delta\phi$	Opposite

Individual Braid Master Table

Member ID	Braid index	Component member	Group translation speed	Binary-midpoint relation	Axis relation	Distinguished direction	Common phase zero	Circulation data
A1	1	A1	Variable s_{grp}	$\mathbf{c}_1 = \mathbf{c}_2 = \mathbf{c}_3 = \mathbf{X}_{\mathrm{grp}}$	Orthogonal at $\lambda_A = 0$; coincident at $\lambda_A = 1$	Translation direction $\hat{\mathbf{u}}_A$	$T = 0$	Not yet specified
A2	1	A2	Variable s_{grp}	$\mathbf{c}_1 = \mathbf{c}_2 = \mathbf{c}_3 = \mathbf{X}_{\mathrm{grp}}$	Orthogonal at $\lambda_A = 0$; coincident at $\lambda_A = 1$	Translation direction $\hat{\mathbf{u}}_A$	$T = 0$	One common sense
A3	1	A3	Variable s_{grp}	$\mathbf{c}_1 = \mathbf{c}_2 = \mathbf{c}_3 = \mathbf{X}_{\mathrm{grp}}$	Orthogonal at $\lambda_A = 0$; coincident at $\lambda_A = 1$	Translation direction $\hat{\mathbf{u}}_A$	$T = 0$	Not yet specified
B1	1	B1	Variable s_{grp}	$\mathbf{c}_1 = \mathbf{c}_2 = \mathbf{c}_3 = \mathbf{X}_{\mathrm{grp}}$	$\hat{\mathbf{n}}_1 = \hat{\mathbf{n}}_2 = \hat{\mathbf{n}}_3 = \hat{\mathbf{n}}_B$	$\hat{\mathbf{n}}_B$	$T = 0$	One common sense

Individual Binary Master Table

Within A1 and A3, the symbols R_1, R_2, R_3 are independent positive coordinates attached to persistent binary indices. They do not encode a size order, and equality is permitted unless a constrained row says otherwise. A repeated symbol R or f declares equality across the corresponding rows. Unconstrained phases remain ϕ_1, ϕ_2, ϕ_3. A1 fixes $h_a = 0$ and $\rho_a = R_a$; A3 carries the general axial and transverse decomposition of R_a defined above. C3 through C6 inherit the individual-binary rows of their declared B1 or B1.3 components. C1 and C2 instead use the twelve-worldline coordinates and explicit counterpart map defined in Braid Family C.

Member ID	Braid index	Binary index	Radius	Axial half-separation	Transverse orbit radius	Frequency	Phase
A1	1	1	R_1	0	R_1	f_1	ϕ_1
A1	1	2	R_2	0	R_2	f_2	ϕ_2
A1	1	3	R_3	0	R_3	f_3	ϕ_3
A1.1	1	1	R_1	0	R_1	f	ϕ_1

Member ID	Braid index	Binary index	Radius	Axial half-separation	Transverse orbit radius	Frequency	Phase
A1.1	1	2	R_2	0	R_2	f	ϕ_2
A1.1	1	3	R_3	0	R_3	f	ϕ_3
A1.2	1	1	R	0	R	f	0
A1.2	1	2	R	0	R	f	$2\pi/3$
A1.2	1	3	R	0	R	f	$4\pi/3$
A1.3	1	1	R_1	0	R_1	$4f$	ϕ_1
A1.3	1	2	R_2	0	R_2	$2f$	ϕ_2
A1.3	1	3	R_3	0	R_3	f	ϕ_3
A1.4	1	1	R_1	0	R_1	$3f$	ϕ_1
A1.4	1	2	R_2	0	R_2	$2f$	ϕ_2
A1.4	1	3	R_3	0	R_3	f	ϕ_3
A2	1	1	R	h	ρ	f	0
A2	1	2	R	h	ρ	f	$2\pi/3$
A2	1	3	R	h	ρ	f	$4\pi/3$
A3	1	1	R_1	h_1	ρ_1	f_1	ϕ_1
A3	1	2	R_2	h_2	ρ_2	f_2	ϕ_2
A3	1	3	R_3	h_3	ρ_3	f_3	ϕ_3
A3.1	1	1	R_1	h_1	ρ_1	f	ϕ_1
A3.1	1	2	R_2	h_2	ρ_2	f	ϕ_2
A3.1	1	3	R_3	h_3	ρ_3	f	ϕ_3
A3.2	1	1	R	h_1	ρ_1	f	0
A3.2	1	2	R	h_2	ρ_2	f	$2\pi/3$
A3.2	1	3	R	h_3	ρ_3	f	$4\pi/3$
A3.3	1	1	R_1	h_1	ρ_1	$4f$	ϕ_1
A3.3	1	2	R_2	h_2	ρ_2	$2f$	ϕ_2
A3.3	1	3	R_3	h_3	ρ_3	f	ϕ_3
A3.4	1	1	R_1	h_1	ρ_1	$3f$	ϕ_1
A3.4	1	2	R_2	h_2	ρ_2	$2f$	ϕ_2
A3.4	1	3	R_3	h_3	ρ_3	f	ϕ_3
B1	1	1	R_1	h_1	ρ_1	f	ϕ_1
B1	1	2	R_2	h_2	ρ_2	f	ϕ_2
B1	1	3	R_3	h_3	ρ_3	f	ϕ_3
B1.1	1	1	R_1	$h_1 > 0$	$\rho_1 > 0$	f	ϕ_1
B1.1	1	2	R_2	$h_2 > 0$	$\rho_2 > 0$	f	ϕ_2
B1.1	1	3	R_3	$h_3 > 0$	$\rho_3 > 0$	f	ϕ_3
B1.2	1	1	R_1	$h_1 > \rho_1$	$\rho_1 > 0$	f	ϕ_1
B1.2	1	2	R_2	$h_2 > \rho_2$	$\rho_2 > 0$	f	ϕ_2
B1.2	1	3	R_3	$h_3 > \rho_3$	$\rho_3 > 0$	f	ϕ_3
B1.3	1	1	R_1	0	R_1	f	ϕ_1
B1.3	1	2	R_2	0	R_2	f	ϕ_2
B1.3	1	3	R_3	0	R_3	f	ϕ_3

The deprecated `B1.4` control is not an active master-table row. Its preserved boundary coordinates are $\rho_a = 0$ and $h_a = R_a$ for every binary, so its endpoint paths are the all-axial B1 limit and its internal speeds vanish.

Naming and Navigation Master Table

Family and member names are optional aliases. The Description column may aid navigation, but it does not define the geometry and must not introduce a characteristic absent from the first three master tables.

Every Family-A Borg depiction in this table selects the near-rest endpoint $\lambda_A = 0$. Its three source-defined binary axes are the mutually orthogonal x, y, and z axes, so the corresponding binary orbit planes are yz, xz, and xy. The wider taxonomy retains the prescribed interpolation through $0 < \lambda_A < 1$ and the coincident-axis endpoint at $\lambda_A = 1$.

Member ID	Family name	Member name	Geometry record	Borg depiction	Description
`A1`	Noether core	Coincident endpoint orbits	`family-a-a1-general-v1`	`A1 — coincident endpoint orbits`	Zero-axial-offset Family-A member whose two endpoint paths share one geometric circle within each binary.
`A1.1`	Noether core	Equal-frequency	`family-a-a1-1-equal-frequency-v1`	`A1.1 — equal frequency`	A1 constrained to one common binary frequency while retaining independently assignable radii.
`A1.2`	Noether core	Equal-frequency equal-radius	`family-a-a1-2-equal-frequency-equal-radius-v1`	`A1.2 — equal frequency, equal radius`	A1 constrained to equal radii, equal frequencies, and phases separated by $120°$.

C5	Coaxial twelve-architrino geometry	Co-rotating B1.3 pair	`family-c-c1-1-co-rotating-b1-3-pair-v1`	`C5 — co-rotating B1.3 pair`	C3 constrained to two all-equatorial B1.3 components.
C6	Coaxial twelve-architrino geometry	Counter-rotating B1.3 pair	`family-c-c2-1-counter-rotating-b1-3-pair-v1`	`C6 — counter-rotating B1.3 pair`	C4 constrained to two all-equatorial B1.3 components.

Braid Family A

Braid Family A

Family A contains prescribed one-braid geometries whose three binary axes are mutually orthogonal at the near-rest endpoint and converge toward the group-translation direction as the prescribed flattening coordinate increases. The canonical coordinates, response endpoints, and master-table rows are defined in Braid Taxonomy. This chapter explains how those coordinates distinguish A1, A2, A3, and their constrained loci.

Family A is a geometry-and-motion definition. It does not establish that an A1, A2, or A3 record is generated, retained, or stable under the EOM solver. The realization-independent retention burden is stated in Braid Recovery Requirements.

Shared Family-A Geometry

Every Family-A member is one complete Noether braid composed of three neutral binaries. Each binary contains one electrino and one positrino. The three binary midpoints coincide with the braid center. The binaries share a braid-level phase zero, while radius, axial half-separation, transverse orbit radius, frequency, phase, and circulation are binary coordinates.

At the near-rest endpoint, the three binary axes are mutually orthogonal. Their equal-component direction is the Family-A translation direction. The complete braid translates along that direction, and the translation speed is the braid's group translation speed rather than an internal architrino speed.

Every Family-A Borg catalog representative uses this near-rest endpoint: $\lambda_A = 0$, source axes along x, y, and z, and corresponding binary orbit planes yz, xz, and xy. This prescribed display selection does not remove the intermediate and flat response geometries from the wider Family-A taxonomy.

The prescribed flattening coordinate λ_A connects two endpoint geometries:

λ_A	Binary-axis relation	Envelope description
0	Three mutually orthogonal axes	Nearly spherical near-rest endpoint in the declared weak-gradient environment.
$0 < \lambda_A < 1$	Three axes converging toward the translation direction	Increasingly oblate intermediate geometry.
1	Three coincident axes along the translation direction	Flat Family-A response geometry used as prescribed input in event-horizon and photon-channel response studies.

This response is prescribed taxonomy. An EOM-solver derivation of the path through these geometries, including either physical endpoint assignment, remains open.

The coincident-axis endpoint is also a geometric boundary with Family B. A Family-A record does not become a Family-B record away from that boundary, and coincidence at one endpoint does not establish a shared dynamical branch.

A1

A1 is the zero-axial-offset Family-A member. Its indices $a \in \{1, 2, 3\}$ are persistent record identities. They are not assigned by sorting the radii, frequencies, speeds, or later dynamical roles. The radii are independently assignable positive coordinates, and equal values are permitted. The three frequencies are likewise independently assignable.

For every A1 binary,

$$\mathbf{c}_a(T) = \mathbf{X}_{\mathrm{grp}}(T), \qquad h_a = 0, \qquad \rho_a = R_a.$$

The two architrinos therefore remain antipodal while traversing the same geometric circle, whose center is the braid center. The three binary circles need not share one plane: at the near-rest endpoint their plane normals are the three mutually orthogonal Family-A axes.

A1 does not require the exact cyclic binary-permutation symmetry of A2. When its binary coordinates differ, a spatial rotation cannot map one binary onto another with different geometry. An integer frequency ratio can make the full prescribed figure repeat after a common period, but it does not by itself establish spatial equivalence.

A1 Constrained Variants

Each constrained variant inherits A1's persistent binary indices, common braid center, and zero axial half-separation unless its master-table row explicitly replaces another coordinate:

Member	Added constraint	What remains inherited
`A1.1`	One common frequency.	Independently assignable radii and phases; $h_a = 0$ and $\rho_a = R_a$.
`A1.2`	Equal radii, one common frequency, and phases 0, $2\pi/3$, and $4\pi/3$.	The shared zero-axial-offset relation remains fixed.
`A1.3`	Indexed frequency ratio $f_1 : f_2 : f_3 = 4 : 2 : 1$.	Independently assignable radii and unconstrained phases; the ratio does not order the radii.
`A1.4`	Indexed frequency ratio $f_1 : f_2 : f_3 = 3 : 2 : 1$.	Independently assignable radii and unconstrained phases; the ratio does not order the radii.

The exact radius, frequency, phase, axial-half-separation, and transverse-orbit-radius rows are carried only by the Individual Binary Master Table.

A2

A2 is the fully symmetric Family-A member. Its three binaries have equal radii, equal axial half-separations, equal transverse orbit radii, equal frequencies, one circulation sense, and phases separated by 120°. No binary is distinguished. A 120° rotation about the Family-A translation direction cyclically permutes the three binaries.

An exact near-rest reference fixture places the three binary axes on an orthonormal frame. At one common reference time, each positrino lies at distance R from the braid center along one positive frame axis and its electrino partner lies at the antipodal point. This is the face-opposite seed used by the invariant-channel analysis in A2 Symmetry and Return Response.

The fixture is one exact A2 representative, not the whole A2 coordinate space. At that reference instant it uses axial half-separation $h = R$ and transverse orbit radius $\rho = 0$. In the taxonomy motion about each binary's own fixed axis, that snapshot is static because $\rho = 0$; the body-diagonal rotating channel is a distinct prescribed motion of the same six positions. The A2 taxonomy permits any common pair (h, ρ) satisfying the binary-radius relation, provided all three binaries share that geometry and the other A2 constraints.

The member-specific symmetry lemma, reduced channels, two-ring geometry, axial polarity-dipole identity, momentum-screw alignment, and retention questions are developed in A2 Symmetry and Return Response. Those results constrain the fixture under their stated assumptions; they do not certify A2 retention.

A3

A3 is the general axial-decomposition Family-A member. It retains the common braid center and persistent binary identities of A1 while permitting each binary to carry its own nonnegative axial half-separation and transverse orbit radius:

$$R_a^2 = h_a^2 + \rho_a^2.$$

For endpoint sign $\sigma \in \{+1, -1\}$, the center of the endpoint's circular path is

$$\mathbf{O}_{a,\sigma}(T) = \mathbf{X}_{\mathrm{grp}}(T) + \sigma h_a \hat{\mathbf{n}}_a.$$

Thus $h_a > 0$ separates the two endpoint orbit centers by $2h_a\hat{\mathbf{n}}_a$, even though the endpoint positions remain antipodal about the binary midpoint at every common time. A3 permits $h_a = 0$, so A1 is its exact zero-axial-offset subset rather than a disjoint class.

A3 Constrained Variants

The A3 suffixes carry the same frequency, radius, and phase restrictions as the corresponding A1 suffixes, while retaining independently assignable axial/transverse decompositions:

Member	Added constraint	What remains inherited
`A3.1`	One common frequency.	Independently assignable radii, decompositions, and phases.
`A3.2`	Equal radii, one common frequency, and phases 0, $2\pi/3$, and $4\pi/3$.	The axial and transverse decompositions may differ among binaries.
`A3.3`	Indexed frequency ratio $f_1 : f_2 : f_3 = 4 : 2 : 1$.	Independently assignable radii, decompositions, and unconstrained phases.
`A3.4`	Indexed frequency ratio $f_1 : f_2 : f_3 = 3 : 2 : 1$.	Independently assignable radii, decompositions, and unconstrained phases.

For every shared suffix $n \in \{1, 2, 3, 4\}$,

$$A1.n = A3.n \cap \{h_1 = h_2 = h_3 = 0\}.$$

A1, A2, and A3 Relations

A1.2, A2, and A3.2 share equal radii, equal frequencies, and the same three phase values, but they are not identical members:

Coordinate or relation	`A1.2`	`A2`	`A3.2`
Axial half-separations	$h_1 = h_2 = h_3 = 0$	One common h	h_1, h_2, h_3 may differ
Transverse orbit radii	$\rho_1 = \rho_2 = \rho_3 = R$	One common ρ	ρ_1, ρ_2, ρ_3 may differ
Circulation	Inherited A1 value is not yet specified	One common sense	Inherited A3 value is not yet specified
Cyclic binary equivalence	Not required	Required	Not required

A1.2 is the $h = 0$ locus of A3.2. A2 occupies the cyclically symmetric locus of A3 and intersects A1 when its common geometry also has $h = 0$. These coordinate coincidences do not establish a physical transition.

Claim Boundary

The Family-A definitions are prescribed. They would be falsified as EOM-solver branch claims by a same-record evolution showing that the declared coordinate relations cannot be retained under the required causal-root, acceleration, action, and stability rows. Until such a record exists, Family A supplies exact display geometry and explicit closure targets, not a retained physical braid.

Braid A1 Dynamics and Interpretation

This specialist chapter carries the retention, phase-closure, cadence-retuning, scaling, strong-field, and downstream interpretation hypotheses specific to A1. The A1 coordinates and constrained variants are defined in Braid Family A; the realization-independent proof contract is defined in Braid Recovery Requirements.

Nothing in this chapter establishes an EOM-solver-retained A1 branch. Derived identities, conditional results, hypotheses, and observer-level mappings keep their stated claim grades.

Claim-Ownership Classification

The claims in this chapter have three distinct scopes: A1-specific hypotheses, family-general recovery requirements stated in A1 coordinates, and physical assignments that are not established for A1. The table classifies scope, not truth.

Claim unit	Classification	Consequence
Symmetry-distance diagnostic relative to A2	A1-specific hypothesis	The diagnostic depends on A1's departure from the A2 symmetry channel and does not generalize to every family.
Retention, causal-root closure, perturbation recovery, and same-record shielding tests	Family-general recovery requirements	A1 is one instantiation. The proof contract belongs to Braid Recovery Requirements, and the common analysis record belongs to Candidate Braid Analysis Methodology.
Integer phase return and root-ledger return	Family-general recovery requirement with an A1-specific coordinate form	Return is required for every periodic candidate; (k_1, k_2, k_3) and Λ_{A1} are A1 chart coordinates.

Claim unit	Classification	Consequence
Cadence-scale retuning map and rest-level scaling curve	A1-specific hypothesis	The maps depend on Λ_{A1} and cannot be assigned to another member without a separate derivation.
Fold-set action clicks	Family-general hypothesis	The machinery is owned by Braid Mathematics, not by A1.
Reduced closure label Λ_{A1} and its alignment restriction	A1-specific hypothesis	The label is available for A1 branch comparison only and does not establish a retained branch.
Dynamic exclusion-envelope export	Family-general export requirement with an A1 realization	The shared interface is owned by Braid Envelope Geometry.
Three-support-row shielding mapped to fermion generations	Unsupported A1 assignment	No retained branch, shielding extraction, or particle map currently establishes the assignment.
Family-A axis convergence under the prescribed response	A1-specific prescribed response and dynamical recovery target	The endpoint is part of the A1 chart; evolved convergence remains unproved.
Event-horizon, Planck-scale, and dipole-quiet identifications	Unsupported A1 assignments	These remain comparison hypotheses until A1-specific moment and strong-field records establish them. The A2 dipole theorem cannot be transferred to A1 by analogy.
A Noether braid as the structural candidate for fermion recovery	Family-general recovery requirement	Assigning A1, rather than another retained member, to a fermion class remains unsupported.

An unsupported A1 assignment is not part of the A1 definition and must not be consumed downstream as an A1 property. It remains an explicitly graded hypothesis awaiting derivation or rejection.

Retention and Interpretation

The A1 geometry, persistent binary indices, and constrained variants are defined in Braid Family A. The remaining material below concerns phase closure, retuning, dynamics, shielding, and downstream interpretations. It does not add coordinates to the A1 definition.

All equations use the persistent indices $a \in \{1,2,3\}$. The indices do not encode a radius order or preassign a field-speed carrier, self-hit channel, shielding rank, or envelope-leading path. Any such diagnostic must be extracted from the same retained branch record used by the equation in which it appears.

Symmetry-Distance Diagnostic

A2's exact threefold channel pins its kinematic angular momentum along the Family-A translation direction. A1 does not require the equal geometry and cyclic binary-permutation symmetry used by that theorem, so the same pinning result does not apply to a general A1 record. The resulting hypothesis is that nonzero precession may diagnose distance from the A2 symmetry channel, while decaying precession may diagnose relaxation toward it. This is an inferred diagnostic, not a proof that A1 precesses, that A1 relaxes toward A2, or that either member is retained. A retained evolution would falsify the diagnostic if its measured precession failed to track an independently defined symmetry-distance residual.

Retention and Shielding Hypotheses

A1 retention requires more than its prescribed binary coordinates. The three binary responses, inter-binary wake exchange, any branch-derived field-speed transfer, and the full envelope exposure must close into one persistent causal-return cycle. A time-averaged potential may be used as a comparison summary, but the proof burden is a same-record closure of the causal-root ledger, phase return, separator conditions, and perturbation response.

Far-field cancellation is a separate hypothesis. Rapid positive- and negative-polarity motion may suppress the exposed wake signature relative to the raw sum of the six constituent contributions, but quantitative shielding and any mass-map consequence remain closure targets. A same-record far-field calculation that does not show the required suppression would falsify that hypothesis without altering the A1 geometric definition.

Integer Phase-Closure States

An A1 record should be treated as a closed-cycle geometry before it is treated as a particle label. Over a stable return duration T_{ret} beginning at a chosen absolute-time origin T_0, each binary must return its phase together with the relevant causal-root ledger:

$$\Theta_a(T_0;T_{\mathrm{ret}}) = \int_{T_0}^{T_0+T_{\mathrm{ret}}} \omega_a(T')\,dT' + \Phi_a^{\mathrm{root}}(T_0;T_{\mathrm{ret}}) = 2\pi k_a, \qquad k_a \in \mathbb{Z}, \qquad a \in \{1,2,3\}$$

The integers k_a are winding counts over the closure period. They are not a claim that the layer frequencies are integer-valued at every instant. When ordinary layer frequency is used below, $\omega_a = 2\pi f_a$. The surrounding root ledger records which self-hit, partner-hit, and inter-layer branches made the closure admissible.

On the retuning hypothesis below, an accepted energy-level change is a one-h_{act} closed-cycle action transaction that moves the A1 record from one admissible integer-and-root ledger to another. The causal wake emitted by the retuned braid should therefore carry information about the braid's closure state. Higher-level atomic orbital configurations, when they are recovered, should appear as electron-assembly resonance envelopes in that structured nuclear and Noether sea wake environment, not as primitive labels pasted onto the braid.

The same closure-label machinery is the candidate carrier for branch-quantized Lorentz response. A moving A1 record should not be assigned a Lorentz factor independently of its internal ledger. Instead, a stable closure label should determine the all-binary retuning of radii, frequencies, characteristic speeds, and wake exchange; the full path-history envelope then projects the ruler factor seen by Physical Observers. In the homogeneous weak-field limit, the admitted labels must collapse to the observer-calibrated $\gamma_0(v_{\text{eff}}) = (1 - v_{\text{eff}}^2/c_0^2)^{-1/2}$ within the preferred-frame leakage bound.

Cadence-Scale Retuning Hypothesis

The single-braid version of the h_{act}-step claim is geometric rather than merely thermal. An accepted action transaction does not add energy to an undeformable object. It moves the A1 record from one admissible closure branch toward another, and the braid resolves that transaction by retuning its cadence-scale closure. The symbol h_{act} denotes the closed-cycle action unit in this chart; it is distinct from the finite-memory depth h_{mem} used in dynamics chapters, and its comparison with the observer-level Planck constant h remains part of action-scale closure.

The bookkeeping distinction is

$$h_{\text{act}} = \text{action per accepted cycle}, \qquad A_N = N h_{\text{act}}, \qquad E_N = A_N f_N$$

Here h_{act} is the fixed closed-cycle action unit, N is the integer number of accepted action units carried by the branch, A_N is the total branch action level, and f_N is a representative cadence extracted from the closed A1 branch. A one-h_{act} transaction changes the action ledger; a branch with many accepted units is scaled by $N h_{\text{act}}$. The accepted branch may answer through one or more of the cadence, binary radii, envelope scale, envelope ratio, orientation, strain, and inter-binary wake-exchange variables. The inter-binary ledgers $\mathcal{G}_{12}, \mathcal{G}_{13}, \mathcal{G}_{23}$ are defined in Reduced A1 Closure Label:

$$\Delta A_{\text{cyc}} = \pm h_{\text{act}} \quad \Rightarrow \quad (f_N,\ R_1, R_2, R_3,\ \lambda,\ \xi,\ \mathcal{G}_{12}, \mathcal{G}_{13}, \mathcal{G}_{23}) \longmapsto (f_N',\ R_1', R_2', R_3',\ \lambda',\ \xi',\ \mathcal{G}_{12}', \mathcal{G}_{13}', \mathcal{G}_{23}')$$

In the simplest fixed-speed layer estimate,

$$v_a \sim 2\pi R_a f_a, \qquad a \in \{1, 2, 3\}$$

If a branch keeps v_a approximately fixed while accepting the transaction, then

$$R_a f_a \approx \text{constant}, \qquad \Delta f_a > 0 \Rightarrow \Delta R_a < 0, \qquad \Delta f_a < 0 \Rightarrow \Delta R_a > 0$$

The proof target is the constrained map, not only this sign rule. On a fixed branch chart q, collect the logarithmic retuning variables into

$$\mathbf{y}_q = (\ln f_1, \ln f_2, \ln f_3,\ \ln R_1, \ln R_2, \ln R_3,\ \ln \lambda, \ln \xi)_q^T$$

Let $A_{\text{cyc},q}(\mathbf{y}, \mathcal{G})$ be the closed-cycle action ledger on that chart, and let

$$\mathcal{C}_q(\mathbf{y}, \mathcal{G}) = 0$$

collect the integer phase-closure, causal-root, separator, inter-layer wake-exchange, and stability conditions that define the branch. A first-order accepted retuning with action sign $s_{\text{act}} \in \{+1, -1\}$ must satisfy

$$DA_{\text{cyc},q}[\Delta \mathbf{y}] + \Delta A_{\text{wake}} = s_{\text{act}} h_{\text{act}}$$

together with the branch-preservation condition

$$D\mathcal{C}_q[\Delta \mathbf{y}] + \Delta \mathcal{C}_{\mathcal{G}} = 0$$

If $\Delta \mathcal{C}_{\mathcal{G}} = 0$, the retuning stays on the same causal-root ledger. If $\Delta \mathcal{C}_{\mathcal{G}} \neq 0$, the event is a branch transition and must be treated as a separator crossing or causal-locus reconnection rather than as smooth single-braid drift.

The local cadence-scale retuning map is therefore the closure target

$$\mathcal{R}_{\text{cyc}}^{(q,s_{\text{act}})} : (\Lambda_{A1}, \theta_{\text{env}}) \longmapsto (\Delta f_N, \Delta R_1, \Delta R_2, \Delta R_3, \Delta\lambda, \Delta\xi)$$

where Λ_{A1} is defined in Reduced A1 Closure Label, and θ_{env} records the local Noether sea state and neighboring-assembly conditions. The representative cadence increment is an extraction from the layer increments, for example

$$\Delta \ln f_N = w_1^{(q)} \Delta \ln f_1 + w_2^{(q)} \Delta \ln f_2 + w_3^{(q)} \Delta \ln f_3, \qquad w_1^{(q)} + w_2^{(q)} + w_3^{(q)} = 1$$

with the weights determined by the same branch and exposure record used for clock and medium coupling. The full A1 record need not put the entire transaction into a single binary. One binary may tighten while another expands, and the path-history envelope may change through λ or ξ, provided the total closure label remains admissible.

This is the local branchwise origin of the smoother Noether sea equilibrium-current language: individual retunings are discrete, while many asynchronous accepted retunings can coarse-grain into a continuous cadence-space current.

Action Clicks at the Field-Speed Hinge

The candidate physical implementation of the discrete action transaction — each accepted transaction realized as a controlled crossing of the causal-root fold set that changes the integer root count by one — is core-agnostic machinery and is developed at hypothesis level in Braid Mathematics. For this chapter's ledger the hypothesis-level consequences are that the closed-cycle action unit h_{act} is the action transacted in one crossing, that closure-label changes are tied to causal-root bifurcation, and that many asynchronous crossings coarse-grain into the smooth cadence-space current named above. No binary is assigned this role by the taxonomy, and no dynamical mechanism holding a branch at the field-speed locus is asserted.

Rest-Level Scaling Curve

The cadence-scale retuning map becomes more predictive when a homogeneous pool of group-velocity-zero Noether braids is assumed to occupy the same reduced closure label and the same integer rest level. In that case the pool is made of equal braids at one level N, while the scaling curve compares neighboring admissible rest levels along the same branch. The scaling variable is not h_{act} itself. The fixed quantity is the closed-cycle action unit h_{act}; the branch variable is the total action level

$$A_N = N h_{\text{act}}, \qquad N \in \mathbb{Z}_{>0}$$

For any declared binary channel $a \in \{1, 2, 3\}$, write its action allocation as

$$N_a = p_a^{(q)} N, \qquad I_a = N_a \hbar_{\text{act}} = p_a^{(q)} N \frac{h_{\text{act}}}{2\pi}$$

Here $p_a^{(q)}$ is the branch share carried by binary a and $\hbar_{\text{act}} \equiv h_{\text{act}}/(2\pi)$. With the reduced circular-action chart

$$I_a = \mu_a^{\text{rot}} R_a v_a$$

Here μ_a^{rot} is an effective rotational branch-response coefficient for this reduced chart. It is not a primitive mass assigned to architrinos; it is a bookkeeping response factor that must ultimately be extracted from the same branch record used by the mass-map program.

With this declaration, the action ledger determines the product

$$\boxed{R_a(N)\, v_a(N) = \frac{p_a^{(q)} N h_{\text{act}}}{2\pi \mu_a^{\text{rot}}}.}$$

This is the part fixed directly by the $N h_{\text{act}}$ action ledger. It says that a higher rest level must carry a larger radius-speed product in the selected channel, but it does not by itself decide whether the extra product appears as larger radius, higher speed, or both. The separate functions $R_a(N)$, $v_a(N)$, and

$$f_a(N) = \frac{v_a(N)}{2\pi R_a(N)}$$

therefore require one more branch-closure equation.

One possible closure is a branch-pinned speed, stated as a chart hypothesis only. No mechanism holding a branch at fixed speed is established. If the selected binary channel keeps

$$v_a = \beta_a c_f$$

with fixed β_a, then

$$\boxed{R_a(N) = \frac{p_a^{(q)} N h_{\mathrm{act}}}{2\pi \mu_a^{\mathrm{rot}} \beta_a c_f}, \qquad f_a(N) = \frac{\mu_a^{\mathrm{rot}} \beta_a^2 c_f^2}{p_a^{(q)} N h_{\mathrm{act}}}.}$$

This special branch gives

$$\boxed{R_a \propto N, \qquad v_a \propto N^0, \qquad f_a \propto N^{-1}.}$$

A different closure comes from a bare inverse-square radial balance. If the delayed root ledger reduces to

$$\frac{v_a^2}{R_a} = \frac{K_a}{4R_a^2} \mathcal{B}_a(\beta_a; \Lambda_{A1,a})$$

Here the factor $1/(4R_a^2)$ is the inverse-square factor for an opposite member at diameter $d = 2R_a$. The coefficient K_a is the reduced channel coupling combination, $\mathcal{B}_a(\beta_a; \Lambda_{A1,a})$ is the dimensionless delayed-root radial balance factor, and $\Lambda_{A1,a}$ is the selected channel sublabel inherited from the reduced A1 closure label. If $\mathcal{B}_a$ is approximately constant on the compared segment, then the same action product gives

$$\boxed{R_a \propto N^2, \qquad v_a \propto N^{-1}, \qquad f_a \propto N^{-3}.}$$

Thus the $N h_{\mathrm{act}}$ ledger alone does not canonize a single radius curve. It supplies the product law; the branch speed, delayed-root radial balance, tangential closure, and any Noether sea return terms decide the actual rest-level scaling.

If the selected binary channel instead carries a declared energy projection

$$E_a(N) = \zeta_a^{(q)} \mu_a^{\mathrm{rot}} v_a^2$$

then

$$\boxed{v_a(N) = \sqrt{\frac{E_a(N)}{\zeta_a^{(q)} \mu_a^{\mathrm{rot}}}}, \qquad R_a(N) = \frac{p_a^{(q)} N h_{\mathrm{act}} \sqrt{\zeta_a^{(q)}}}{2\pi \sqrt{\mu_a^{\mathrm{rot}} E_a(N)}}.}$$

This form is the safest way to use any external energy-level equation: insert the branch energy projection $E_a(N)$, then derive the corresponding channel radius and speed.

The same chart also gives a packing readout for the Noether sea, but the packing scale must be extracted from all six paths rather than from a preselected binary. In a nearly spherical exclusion-envelope approximation, let

$$R_{\mathrm{excl}} = \alpha_{\mathrm{env}}^{(q)} R_{\mathrm{env}}$$

where R_{env} is a branch-derived characteristic radius of the full path-history envelope and $\alpha_{\mathrm{env}}^{(q)}$ converts it into the selected exclusion-interface threshold. Equal exclusion-envelope center contact then occurs at

$$d_{\mathrm{nn}} = 2R_{\mathrm{excl}}$$

and the densest ordinary equal-sphere center density is

$$\rho^{\#}_{\mathrm{NS,max}} = \frac{1}{4\sqrt{2}R^3_{\mathrm{excl}}}$$

The density symbol functions as packing notation for this chart, distinct from the physical Noether sea density field $\rho_{\mathrm{NS}}(\mathbf{X},T)$; the $\#$ marks a center number density for the relevant Noether braid exclusion envelopes. Therefore the packing curve inherits the radius closure:

$$\rho^{\#}_{\mathrm{NS,max}}(N) \propto R_{\mathrm{env}}(N)^{-3}$$

If the branch independently proves that one selected channel a controls R_{env} with a fixed proportionality, then its fixed-speed estimate gives $\rho^{\#}_{\mathrm{NS,max}} \propto N^{-3}$, while its bare inverse-square estimate with approximately constant $\mathcal{B}_a$ gives $\rho^{\#}_{\mathrm{NS,max}} \propto N^{-6}$. Without that boundary-leading certificate, the single-channel exponents do not transfer to packing. These are branch diagnostics, not competing definitions of a Noether braid.

This packing formula is only the spherical leading estimate. At high relative velocity, high Noether sea delay, or high gravitational strain, the branch data cannot be kept constant:

$$p^{(q)}_a,\ \mu^{\mathrm{rot}}_a,\ \alpha^{(q)}_{\mathrm{env}},\ \mathcal{B}_a(\beta_a;\Lambda_{A1,a}) \longrightarrow p_a(q,\theta_{\mathrm{env}}),\ \mu^{\mathrm{rot}}_a(q,\theta_{\mathrm{env}}),\ \alpha_{\mathrm{env}}(q,\theta_{\mathrm{env}}),\ \mathcal{B}_a(\beta_a;\Lambda_{A1,a},\theta_{\mathrm{env}})$$

The scaling curve is therefore piecewise by branch. Once the branch supplies ξ and λ, the exclusion envelope must be treated as an oblate spheroidal envelope rather than a sphere, and the center-density calculation must inherit orientation, strain, and Noether sea delay data from the same branch label.

Reduced A1 Closure Label

For proof work, the integer phase-closure state should be packaged with the branch data that made the closure admissible. The reduced A1 closure label is a branch label, not a new ontological ingredient. The symbol Λ_{A1} denotes this reduced closure label:

$$\Lambda_{A1} = (k_1,k_2,k_3;\ \mathcal{G}_1,\mathcal{G}_2,\mathcal{G}_3;\ \mathcal{G}_{12},\mathcal{G}_{13},\mathcal{G}_{23};\ \chi_c)$$

Here k_1,k_2,k_3 are the binary winding counts over the chosen return period. The binary ledgers $\mathcal{G}_1,\mathcal{G}_2,\mathcal{G}_3$ record active self-hit and partner-hit branches, root multiplicities, winding or phase branch, emission-order data, and separator history. The inter-binary ledgers $\mathcal{G}_{12},\mathcal{G}_{13},\mathcal{G}_{23}$ record delayed exchange roots and phase-lock constraints between binary pairs. The branch label χ_c records braid chirality derived from the indexed path record, for example through Wr_c or a multi-component causal-writhe parity; it must not be inferred from a high/middle/low radius ordering.

The assembly counts are explicit aggregations of those ledgers:

$$N_s(\Lambda_{A1}) = \sum_{a=1}^{3} N_s(\mathcal{G}_a),$$

$$M_p(\Lambda_{A1}) = \sum_{a=1}^{3} M^{\mathrm{intra}}_p(\mathcal{G}_a) + \sum_{1\le a<b\le 3} M^{\mathrm{inter}}_p(\mathcal{G}_{ab}).$$

Here $\mathcal{G}_a$ carries the within-binary self and partner roots, while $\mathcal{G}_{ab}$ carries the directed cross-binary roots. Any compressed count must reproduce these transmitter-identity partitions.

This label is reduced because it omits the full architrino trajectories and retains only the closure data needed for branch comparison. It is useful only under a theorem-target burden: smooth branch-preserving deformations should keep Λ_{A1} fixed, while a change of label should be tied to a causal-root bifurcation, separator crossing, or causal-locus reconnection. The chirality entry χ_c is not yet proved by this definition; it names the entry that the later causal-writhe or ordered-frame proof must fill.

The quantum-number generalization begins at this level. Generation, spin, chirality, and later observer-level orbital labels should be read as downstream coarse-grainings or measurement labels derived from admissible A1 closure labels and their emitted causal-wake envelopes. They should not be imposed as primitive particle labels before the closure, wake-envelope, and apparatus-coupling maps have been derived.

For the horizon-interface entropy calculation, the counted labels must be restrictions of this same reduced closure label, not a second black-hole bookkeeping system. Define the branch-derived field-speed and self-hit index sets on a declared window W by

$$\mathcal{H}_q(W) = \left\{ a : \sup_{T\in W} |s_a(T) - c_f| \le \varepsilon_h c_f \right\}, \qquad \mathcal{S}_q(W) = \{a : \text{a retained same-transmitter root row exists on } W\}.$$

These sets preserve the binary indices and derive their roles from the retained record. The alignment-restricted label is the theorem-target restriction

$$\Lambda_{A1}^{\text{align}} = \Lambda_{A1}\Big|_{\substack{|\mathcal{H}_q(W)|\ge 2,\ |\mathcal{S}_q(W)|\ge 1\\ \text{coincident binary axes along } \hat{\mathbf{u}}_A\\ \text{precession ceases}}}$$

with the remaining admissible entries inherited from the binary ledgers, inter-binary ledgers, chirality entry, and emitted wake envelope. For a connected block U of alignment-area patches, the local label set to be counted has the schematic form

$$\mathcal{L}_U(\theta_{\text{env}}) = \left\{ \left(\Lambda_{A1,p}^{\text{align}}\right)_{p\in U} : \mathcal{G}_{\partial U},\ \mathcal{B}_{\partial\Omega}^{(\text{env})}(\theta_{\text{env}}; W),\ \text{conservation and interface compatibility hold} \right\} / \sim_{\text{env},\theta_{\text{env}},W}$$

Here $\mathcal{G}_{\partial U}$ records the causal-root and wake-exchange compatibility across the edge of the block. This expression does not yet derive the entropy coefficient. It identifies the native object whose block entropy density must be computed before $\log|\mathcal{L}_U|/|U| \to 1/4$ can be treated as more than a comparison target.

Geometry and Exclusion Envelope

The same A1 motion that may supply shielding is the geometric footprint a retained branch would sweep into a dynamic exclusion envelope. That envelope is not the braid definition itself; it is the candidate excluded-region readout of the A1 assembly. For the oblate spheroidal form, exclusion-envelope interpretation, and deformation channels, see Braid Envelope Geometry.

A1 Shielding and Fermion Generations

This section states an unsupported A1 assignment. No retained branch, computed shielding ledger, or particle-recovery map currently establishes that support-row count determines fermion generation. The hypothesis counts support; it does not rank the three A1 binaries by radius:

- **Isolated binary:** the most exposed shielding tier, corresponding to Generation III.
- **Two-support-row shielding tier:** one additional retained support row, corresponding to the Generation-II shielding tier.
- **A1:** a retained three-support-row braid, corresponding to the Generation-I shielding tier.

If an evolved family of records established this mapping, the generation ladder would become the visible signature of how many retained support rows participate in shielding. Until then, Particle Masses: Emergent Inertia in the Noether sea and the charged-lepton story beginning with Electron may consume it only as a recovery target, not as an A1 property.

Any attempt to pair this shielding ladder with accessory geometry must use a complete six-architrino Accessory Configuration. The six sites may lie inside, across, or outside the braid envelope, and their polarity and position records must be declared. Accessory Configuration geometry is not part of the A1 dynamics definition.

A1 Alignment and Planck-Scale Framing

Maximal curvature, same-transmitter-root access, field-speed occupancy, energy-transfer leverage, and external exposure are branch diagnostics, not A1 member assignments. A retained record may place these diagnostics on different binary indices, may place more than one diagnostic on one index, or may fail to supply a unique assignment. The sets $\mathcal{H}_q(W)$ and $\mathcal{S}_q(W)$ above record two of these distinctions without changing the binary identities.

The horizon-approach hypothesis for A1 is therefore permutation-neutral: as the assembly approaches its terminal-alignment target, the three binary axes converge to the Family-A translation direction, precession ceases, at least two branch-derived speed rows approach the field-speed locus, and at least one retained same-transmitter-root row remains available. Which indices satisfy those conditions, and how their frequencies, radii, and energy rows retune, must be measured on the evolved branch. This is a derivation target, not an evolved-trajectory result.

The canonical term for this whole-assembly transition is the **braid symmetry-breaking point**. It does not assign permanent roles to binaries 1, 2, or 3 and does not claim that their radii, frequencies, or energies become equal. Because $s_a = \omega_a \rho_a$, equal threshold speed does not by itself imply equal frequency, equal effective lever arm, equal radius, or equal energy.

The proposed local black-hole dual is an unsupported A1 assignment. It asks whether a retained A1 branch can make the horizon-interface, same-transmitter-root, and exterior-coupling diagnostics coexist while the binary axes align. Only a branch-derived strong-field record could establish that mapping; the prescribed endpoint does not.

Mapping hypothesis (unsupported): "Planck-scale" references may map to the **event-horizon alignment condition** (coincident A1 binary axes with branch-derived field-speed occupancy) only if an explicit derivation supplies that scale map; compare Singularity Resolution and Mapping the Planck Scale to A1 Geometry.

The alignment limit also has a proposed wake-signature reading, but the available theorem is member-specific. The axial polarity dipole identity proves the cancellation only for A2's symmetric two-ring geometry. A general A1 record does not inherit that identity. The A1 **dipole-quiet limit** is therefore a theorem target requiring an A1-specific cycle-resolved moment calculation. If that calculation leaves a nonzero leading polarity-signed moment at terminal alignment, the proposed identification with horizon darkness and the associated entropy interpretation fail.

The Foundation for Fermions

The Noether braid class supplies a family-general structural candidate for the fermion program. Different closure labels, shielding tiers, energy records, and surrounding axial/wake structures may map to Standard Model flavors and generations, but no current result selects A1 or establishes that mapping. It remains a derivation target until retained branch labels, shielding ledgers, and apparatus-coupling records have been recovered from the dynamics.

The collective motion, or **group velocity**, of a Noether braid assembly determines its emergent behavior. The way these assemblies interact and pack together can lead to different statistical properties. The geometry-facing version of that claim is developed in Fermi-Dirac and Bose-Einstein Statistics: volumetric Noether braid envelopes are the substrate candidate for fermionic exclusion, while strongly oblated coherent support is the candidate route to bosonic shared occupation.

A1 Dynamics

The A1 mechanism program — how a three-layer assembly could keep compatible branch records as one moving delayed system, with same-record closure across period, active-root ledger, deformation map, medium response, observer export, and event ledger — is an open obligation, not carried in this chapter. The realization-independent machinery lives with the shared mathematics in Braid Mathematics. Results enter this chapter only when established at their stated claim level.

For the strong-field continuation, see Black Holes and Horizon Chirality.

A2 Symmetry and Return Response

A2 is the fully symmetric Family-A member defined in Braid Family A. This specialist chapter owns the mathematics and retention analysis unique to its exact face-opposite reference fixture: the invariant symmetry channels, the two-ring projection, the axial polarity dipole, the momentum screw, the near-antipodality diagnostic, and the isolated and sea-embedded return-response questions.

The chapter does not redefine A2 and does not certify a retained branch. Its exact results constrain the declared A2 fixture under their stated hypotheses. The realization-independent retention contract remains in Braid Recovery Requirements, and the family-general speed split remains in Braid Mathematics.

Invariant Channels and Equivariant Reductions

The sharpest currently proved structure for A2 is a symmetry channel, not a retained branch. The face-opposite seed places the three electrinos opposite the three positrinos on the positive coordinate axes,

$$\epsilon_{+,x} = (R, 0, 0), \qquad \epsilon_{+,y} = (0, R, 0), \qquad \epsilon_{+,z} = (0, 0, R), \qquad \epsilon_{-,i} = -\epsilon_{+,i}$$

This seed lies on a common sphere, so it is the maximal-symmetry Family-A member: the A2 reference fixture defined in Braid Family A. Two finite symmetry groups act on the seed by simultaneous spatial transformation and site relabeling. For a coordinate-axis permutation $\rho \in S_3$, let M_ρ be the coordinate-permutation matrix and let ρ permute site labels within each polarity; let ι compose point inversion with polarity exchange. Both act on configurations by

$$(g \cdot \mathbf{X})_\ell(t) = M_g \, \mathbf{X}_{g^{-1}\ell}(t)$$

and because point inversion commutes with every permutation matrix, the groups are direct products: the zero-angular-momentum group $G_0 = S_3 \times \langle \iota \rangle$ of order twelve, and the body-diagonal rotating group $G_{\mathrm{rot}} = C_3 \times \langle \iota \rangle$ of order six, where $C_3 = \langle \varrho \rangle$ is the three-fold rotation about the body diagonal

$$\hat{\mathbf{n}} = \frac{(1,1,1)}{\sqrt{3}}$$

No physical process relabels an electrino as a positrino: every architrino is unique, with its own provenance and path history. The operations above are comparison maps between two possible configurations of the universe. If one configuration solves the delayed dynamics, its transformed twin solves it too. When the seed happens to be its own twin, the twins' shared trajectory is constrained, and that constraint is the entire content of the channel.

The Six-Point Symmetry Invariant Lemma

The channel statement is a derivation about the delayed dynamics, proved for the partner-wake master-equation kernel class. For receiver ℓ at reception time T_r, the retained acceleration law under proof is

$$\mathbf{A}_\ell[\mathbf{X}](T_r) = \sum_{\ell'} \sum_{T_t \in \mathcal{R}_{\ell\ell'}[\mathbf{X}](T_r)} \sigma_\ell \sigma_{\ell'} \, \kappa \, \frac{W(T_t)}{\left(d^2 + \varepsilon^2\right)^{3/2}} \, \mathbf{d}$$

where $\mathbf{d} = \mathbf{X}_\ell(T_r) - \mathbf{X}_{\ell'}(T_t)$ with $d = \|\mathbf{d}\|$, the causal roots T_t solve $d = c_f(T_r - T_t)$ within the retained history window, ε is the softening, κ the coupling, and the acceleration weight is $W = c_f/|D_t|$ on a sign-certified transmitter-side Jacobian floor. Receiver-side velocity remains in the signed root-playback record D_r/D_t but not in this instantaneous acceleration kernel.

Four explicit hypotheses carry the proof:

1. **Kernel equivariance.** The acceleration magnitude depends only on invariant scalars times the polarity product $\sigma_\ell \sigma_{\ell'}$, directed along $\hat{\mathbf{d}}$.
2. **Symmetric retained-root policy.** The retained-root set is determined by the root residual and declared invariant criteria only, with no ordering-dependent or label-dependent pruning.
3. **Well-posedness window.** On the window, pairwise separations keep a positive floor and all speeds stay below field speed by a fixed margin; then each directed pair has exactly one causal root, the Jacobian floor is automatic, and the method of steps yields a unique forward solution.
4. **Symmetric initial history.** The hold-window history is invariant under the acting group: the static seed is G_0-invariant, and the uniformly co-rotating prescribed seed about $\hat{\mathbf{n}}$ is G_{rot}-invariant. Transpositions reverse the rotation sense and are excluded from the rotating group; this is where ordered-braid chirality first enters the rotating channel.

Lemma. Under these hypotheses, the unique solution remains on the fixed-point set of the acting group for as long as the window lasts.

The proof has two moves. First, functional equivariance: the root residual is built from norms, so the retained root sets of transformed pairs correspond, every kernel scalar is invariant, and the polarity product is preserved — permutations fix each σ_ℓ, while ι flips both factors — so the acceleration functional transforms exactly as the configuration does. The ι case is precisely the charge-conjugate inversion oddness obligation: conjugating polarities and inverting space negates every acceleration. Second, uniqueness transfer: the transformed solution is again a solution with the same history, so uniqueness forces it to coincide with the original, which is exactly the statement that the solution stays on the fixed-point set.

The lemma converts the six-body problem into small closed reduced systems. On the zero-angular-momentum channel the fixed-point set is

$$\epsilon_{+,x} = (a,b,b), \qquad \epsilon_{+,y} = (b,a,b), \qquad \epsilon_{+,z} = (b,b,a), \qquad \epsilon_{-,i} = -\epsilon_{+,i}$$

a closed two-function state-dependent delay system in (a,b). On the body-diagonal rotating channel,

$$\epsilon_{+,y} = \varrho\, \epsilon_{+,x}, \qquad \epsilon_{+,z} = \varrho^2\, \epsilon_{+,x}, \qquad \epsilon_{-,i} = -\epsilon_{+,i}$$

a closed three-function reduced system in $\epsilon_{+,x}$ alone. Once the branch also carries group velocity along $\hat{\mathbf{n}}$, translation breaks ι while preserving C_3, and the reduction needs two representative worldlines, $\epsilon_{+,x}$ and $\epsilon_{-,x}$.

Exact corollaries follow on the channel: the dynamic center is identically zero and antipodal pairs are exact; all six sites share one radius and one speed, so the reduced-radius diagnostic is exact rather than an empirical average; the acceleration of $\epsilon_{+,x}$ has the template (A, B, B) forced by its stabilizer; and the kinematic angular momentum is exactly parallel to $\hat{\mathbf{n}}$ on the rotating channel.

The scope boundary is part of the result. Invariance of the channel does not prove stability transverse to it, and no statement in this section claims branch retention. The lemma is a derivation-closure result for the invariance and reduction obligations only, proved for the declared kernel class. Any solver kernel or runner that violates kernel equivariance or root-policy symmetry — an axis-fixed cap, asymmetric softening, or ordering-dependent pruning — voids the conclusion for that run, which makes the lemma an audit predicate on implementations. Applying the channel to any retained-history record still requires the same-record receiver-side, action, wake, event, support, and stability entries demanded by Braid Recovery Requirements.

Polarity Conjugation

Because the delayed acceleration kernel depends on polarity only through products $\sigma_i \sigma_j$, global polarity conjugation leaves every trajectory unchanged: an electrino-face-leading branch and a positrino-face-leading branch are exactly degenerate in isolation. The leading-octant sign can acquire physical meaning only through coupling to an environment that is not polarity-balanced, which is where ordered-braid chirality must obtain its content; the helicity sign of the momentum screw below is the candidate carrier of that chirality label. Translation along $\hat{\mathbf{n}}$, by contrast, produces a real asymmetry: with ι broken, the leading face meets fresh medium while the trailing face rides in the branch's own wake, and this fore-aft wake asymmetry is the native deformation channel developed further in A1 Dynamics.

A2 Two-Ring Geometry

Every site of the face-opposite A2 seed has the same height $\pm R/\sqrt{3}$ along $\hat{\mathbf{n}}$ and the same lever arm $R\sqrt{2/3}$ from the axis, because the body diagonal makes equal angles $\arccos(1/\sqrt{3})$ with the three coordinate axes. Viewed along $\hat{\mathbf{n}}$, the three electrinos form one triangular ring below the mid-plane and the three positrinos form a matching triangular ring above it. The two triangles are staggered by 60°, so their projections interleave into a hexagon.

The two-ring view also organizes the neutral braid's channel bookkeeping. Each site's two repulsive channels connect it to its own ring mates, and its three attractive channels connect it to the opposite ring. Intra-ring repulsion spaces each ring at 120°, while inter-ring attraction sets the ring separation. The same minimum-energy logic that arranges accessory charges around a dressed assembly therefore already organizes the core itself: two mutually repelling rings are bound face-to-face by cross-ring attraction. Each member of one ring couples attractively to all three members of the other, and the staggered rings give those connections a zigzag pattern. Under rotation the connections wind into helices about the axis, and the handedness of the winding is the chirality datum carried by the rotating channel. Equal lever arms give every site the same tangential speed under common-frequency co-rotation about $\hat{\mathbf{n}}$, and on the rotating channel the three opposite-polarity pairs hold an exact 120° phase separation at every instant, because the rotation by $2\pi/3$ about $\hat{\mathbf{n}}$ is one of the acting symmetries rather than an approximate phase convention.

Moments and the Axial Polarity Dipole

A **moment** here is a polarity-weighted sum over the configuration: the plain total $\sum_\ell \sigma_\ell$ is the net polarity inventory, the first moment $\sum_\ell \sigma_\ell \mathbf{X}_\ell$ is the dipole, and higher moments record signed shape at finer order. Moments matter because they are what a distant receiver can reconstruct from the superposed delayed potential, ranked by distance: the ℓ-th moment controls the contribution fading as $1/r^{\ell+1}$. For a polarity-neutral assembly the dipole is independent of the choice of origin, so the braid's dipole is a well-defined property of the branch rather than of a coordinate convention.

Since $\mathbb{I} + \varrho + \varrho^2 = 3\hat{\mathbf{n}}\hat{\mathbf{n}}^\top$ for the cyclic coordinate permutation ϱ, the polarity-signed dipole of the channel is exactly axial at all times, even under drift:

$$\sum_\ell \sigma_\ell \mathbf{X}_\ell = 3\,(\hat{\mathbf{n}} \cdot (\epsilon_{+,x} - \epsilon_{-,x}))\,\hat{\mathbf{n}}$$

The transverse dipole components cancel in balanced three-phase fashion. This cancellation is a statement about the braid's summed distant signature, not about the accelerations inside it: each architrino still receives the full delayed influence of all five partners through its own causal roots, and none of those per-receiver contributions vanish. What cancels is the collective polarity-signed moment that a distant receiver reconstructs from the superposed wakes. A branch that flattens toward the transverse plane therefore loses its leading polarity-signed moment entirely: the flattened fast configuration is quiet at dipole order, with its first surviving structure at higher moment order. This identity is the channel's native contribution to the energy-shielding story used by the Family-A chapters, and it links the terminal planar limit to wake quietness rather than to increased exposure.

Momentum Screw and Helicity

The same projector identity pins both kinematic momenta to the axis on the rotating channel:

$$\mathbf{P}_{\text{kin}} = 3\,\hat{\mathbf{n}} \cdot (\mathbf{v}_{+,x} + \mathbf{v}_{-,x})\,\hat{\mathbf{n}}, \qquad \mathbf{J}_{\text{kin}} \parallel \hat{\mathbf{n}}$$

The body-diagonal direction is therefore the central axis of the branch's momentum screw: the unique direction that carries both linear and angular kinematic momentum, with the transport state reduced to the two scalars $P_\parallel$ and $J_\parallel$. The displayed $\mathbf{P}_{\text{kin}} = \sum_i \mathbf{v}_i$ is an equal-weight linear diagnostic, not a primitive mass sum. For an isotropic momentum function, replace each velocity by $P(\|\mathbf{v}_i\|)\hat{\mathbf{v}}_i$; equal site speeds and the same projector symmetry preserve the axial direction conclusions. Their origin-independent combination $\mathbf{J} \cdot \mathbf{P}$ — helicity in normalized form, screw pitch in geometric form — is the natural combined label, since an origin shift changes $\mathbf{J}$ only by a term orthogonal to $\mathbf{P}$. In delayed dynamics the particle-only momenta are not separately conserved; the causal wakes carry momentum and angular momentum of their own, and conservation is a statement about the combined particle and wake ledger. On the channel, symmetry fixes the momentum directions exactly while the magnitudes exchange with the wake ledger.

For the translating rotating A2 channel, group velocity along $\hat{\mathbf{n}}$ is perpendicular to every site's tangential velocity. Its exact site-speed split is therefore an A2 realization of the family-general transverse internal-motion speed-budget lemma. A mechanism that pins the total site-speed budget remains an open branch hypothesis.

Retention and Return Response

The prescribed A2 geometry and its exact near-rest reference fixture do not establish retention. The following diagnostic and no-return result state what an A2 branch record must overcome.

Near-Antipodality Recovery Diagnostic

Exact antipodality belongs to the A2 reference fixture. A retained record under external disturbance need not preserve that ideal relation at every instant, so recovery is tested separately from the member definition. Let ι exchange the two opposite-polarity members of each binary, let $\mathbf{C}(T)$ be the declared braid-center curve, and let R be the common A2 binary radius. Define

$$\delta_{\text{anti},i}(T) = \frac{\left\|\mathbf{X}_i(T) + \mathbf{X}_{\iota(i)}(T) - 2\mathbf{C}(T)\right\|}{R}$$

A candidate recovery entry must declare tolerances and show

$$\sup_{T \in J} \delta_{\text{anti},i}(T) \le \varepsilon_{\text{anti}}, \qquad \delta_{\text{anti},i}(T + T_{\text{recov}}) \le \theta_{\text{recov}}\,\delta_{\text{anti},i}(T) + \varepsilon_{\text{drive}}, \qquad 0 \le \theta_{\text{recov}} < 1$$

for $T, T + T_{\text{recov}} \in J$. Here T_{recov} is the declared recovery time, θ_{recov} is the dimensionless recovery contraction factor, and $\varepsilon_{\text{drive}}$ is the driving residue. This is a certificate target, not an established A2 property.

Isolated Release and the Return-Response Question

Two claims about the face-opposite seed on the zero-angular-momentum channel must not be conflated. The symmetry claim is established: the seed stays exactly on the invariant channel, with the dynamic center at zero, all six radii equal, and antipodal partners exact — an equivariance theorem of the channel, independent of any trajectory. The retention claim is a separate question, and the isolated seed does not answer it in the affirmative: the channel carries no centrifugal support and the void supplies no restoring term, so nothing in the isolated construction makes it a self-maintaining branch. What the seed actually does once released is open, and is a target for direct evolution rather than a recorded result. Claim level: established equivariance theorem for the channel; the dynamical fate is open.

This pairing is informative rather than damaging. A2 was never expected to close as a bare partner-wake problem in the Euclidean void: the omitted ingredients include the outward floor from same-transmitter self-hit contributions, signed tangential exchange, retained wake-energy response, shielding, angular-momentum-bearing initial data, and local Noether sea response. Circular self-hit cannot supply centripetal support by itself. The void result therefore sharpens the retention question into a return-response question: which combination of internal and environmental terms changes the reduced-radius equation from escape to a second turning point, a stable support radius, or a bounded limit cycle while also closing the tangential ledger. The threefold rotating channel above supplies the first untested internal candidate, since the zero-angular-momentum release is a radial free-fall chart with no centrifugal support. The environmental candidate is the sea-embedding route stated next.

The question can be stated sharply rather than qualitatively, because the invariant channel carries a conditional no-return certificate. Two monitored conditions carry it: sub-field speed, meaning every worldline stays below the field speed c_f; and an opposite-polarity separation floor, meaning the closest opposite-polarity non-antipodal pair stays at least one reduced radius R apart. The floor holds automatically from the channel's own geometry, and the retained causal-root count reduces to exactly one root per directed pair, so sub-field speed is the only condition that must be watched forward in time. Under the two conditions the reduced-radius acceleration satisfies a signed inverse-square lower bound $\ddot{R} \geq -K/R^2$, with K built only from the branch's coupling, its declared speed and weight caps, and the polarity structure. Same-polarity partner terms cancel by an exact radial-sign argument, and the opposite-polarity terms are bounded by the floor. A short energy-integral argument then closes it: if the outward speed at a chosen certificate time clears the margin $\dot{R}^2 > 2K/R$, the reduced radius cannot turn back while the two conditions hold. This conditional statement is an established derivation on the channel, not a retained-branch claim. Whether any isolated branch actually clears the margin is an evolution question and is open.

The consequence sharpens the return-response question to a single named target. A return turn cannot be the first event — any return must be preceded by a violation of sub-field speed or the opposite-polarity floor — so once the margin is cleared on the isolated channel the reduced radius cannot turn back while the branch stays sub-field, and retention is possible only through a term that ends sub-field speed first, driving the internal speed to the field-speed hinge where the outward drive stops before the radius can turn. If the anti-damping indications of Braid Mathematics hold, any such transverse pumping feeds escape rather than return, and its only bearing on the certificate is that it pushes the speed toward c_f, the condition whose failure ends the window. The open target is therefore precise: exhibit an internal or environmental absorber that ends sub-field speed before the margin is crossed. The fold-geometry constraint on single-site absorbers is set out in Braid Mathematics; the environmental candidate is the sea-embedding route below.

The Sea-Embedding Route

The environmental route embeds the same A2 configuration at rest in a surrounding Noether sea of like assemblies. This does not define a new taxonomy member; it is the same configuration with like assemblies allowed to supply the environmental response needed for retention. In this reading, isolation is a limiting seed chart, and physical retention is local persistence inside an already populated medium.

The route inherits the return-response question directly: it asks whether the delayed response of a like-assembly population changes the reduced-radius equation from escape to a second turning point, a stable support radius, or a bounded limit cycle. Closing it requires an explicit like-assembly population record, a declared boundary condition, and a Noether sea response entry tied to the same target branch, under the same-record evidence discipline of Braid Recovery Requirements. Whether a static like-assembly environment can supply retention, and whether a dynamic, formation-history-driven Noether sea response can do what a static one cannot, are open questions; no environmental verdict is carried in this chapter.

Claim Boundary

The invariant-channel lemma, its exact channel corollaries, the two-ring geometry, the dipole identity, the momentum-screw alignment, and the conditional no-return bound retain their stated derivation or exact-kinematic grades. None establishes A2 branch retention. A same-record evolution that violates the lemma's hypotheses or its predicted fixed-point relations would falsify application of the theorem to that record; a retained A2 claim still requires the complete certificate defined in Braid Recovery Requirements.

A3.3 Doubling-Frequency Resonance Lock

This chapter owns the specialized A3.3 doubling-frequency $4{:}2{:}1$ lock study inside the broader Noether Braid Configuration Space. The persistent indices $a \in \{1, 2, 3\}$ identify the three A3 binaries, with $f_1 : f_2 : f_3 = 4 : 2 : 1$ in A3.3. The zero-axial-offset A1.3 member is the $h_1 = h_2 = h_3 = 0$ locus of the same frequency chart. The candidate is definitionally frequency-separated and tests that chart under explicit support, field-speed-carrier, phase-return, and stability assumptions. It does not order the radii, make doubling frequency the default Noether braid frequency, certify A3 dynamics from kinematics, or generalize to B1, whose iso-frequency common-axis structure has no doubling ladder to lock.

It should be read together with Binary Dynamics, A3.3, A1 Dynamics, and Mapping the Planck Scale, which provide the assembly scaffold, zero-offset subset, geometry, and scale-setting context for the lock relations derived here.

The level distinctions matter throughout. Ontologically, the three indexed binaries are assembly components built from architrino constituents. Dynamically, the reduced model replaces their full delayed causal-wake history by a finite-η branch chart. Effectively, low-order multipoles and potentials are comparison summaries of that branch behavior. As a derivation target, an integer lock is selected only after the phase-return degree/holonomy, cancellation score, and stability gap all favor the same branch.

The analysis keeps the field speed c_f explicit rather than setting it to one. Here r_a is the characteristic radius and $v_a = \|\mathbf{V}_a\|$ is the scalar tangential speed of one member of binary a around that binary's center. These analysis variables do not replace the exact endpoint-distance coordinate R_a in the taxonomy.

The general indexed state $\mathcal{T}_{3B}$, its S_3 relabeling action, and the iso-frequency and integer-ratio subfamilies are defined in Noether Braid Configuration Space. The doubling-frequency specialization adds the indexed relation $f_1 : f_2 : f_3 = 4 : 2 : 1$, the exact carrier identity $v_a = 2\pi f_a r_a$, integer phase-return data, and the finite-η selection and stability rows. It does not add a radius order or a permanent dynamical role assignment.

Status and Assumptions

The lock analysis is organized around one exact identity and four explicit assumptions. This separation prevents a kinematic formula from being mistaken for a dynamical selection principle.

Exact Kinematic Identity

For each binary carrier,

$$v_a = 2\pi f_a r_a = \beta_a c_f, \qquad 0 < \beta_a, \qquad c_f > 0$$

Equivalently,

$$f_a = \frac{v_a}{2\pi r_a}, \qquad r_a = \frac{v_a}{2\pi f_a}, \qquad v_a = 2\pi f_a r_a$$

Plain language: for any one binary carrier, if we know any two of frequency, tangential speed, and radius, then the third is fixed.

This identity is exact. It is not an assumption, and it does not select a lock by itself.
The logical spine is therefore:

1. **Kinematics:** $v_a = 2\pi f_a r_a$ relates speed, frequency, and radius without introducing topology.
2. **Integer closure:** Assumption 2 is the only place where the integer pair (m, n) enters; it turns frequency commensurability into return-map degree/holonomy data.
3. **Selection:** Assumption 4 and the finite-η return map decide whether one already-integer-labeled sector is dynamically preferred.

Everything before Assumption 2 is topology-free kinematics. Everything after Assumption 2 is selection among sectors that already carry integer phase-return data.

Assumption 1 (Candidate Caustic-Grazing Carrier)

For a reduced exterior or horizon-transition comparison chart, choose a candidate carrier index $h \in \{1, 2, 3\}$. The index h is an analysis parameter to be compared across all admissible choices, not an A3.3 taxonomy assignment. The candidate is not pinned exactly on an infinite-acceleration surface. It is modeled as a caustic-grazing carrier whose cycle-averaged value is the field speed:

$$v_h^{\mathrm{car}} = c_f, \qquad \beta_h^{\mathrm{car}} = 1$$

For compact notation, the algebra below writes $v_h = c_f$ and $\beta_h = 1$ for this carrier value.

The branch-level motion may have microscopic crossings

$$v_h(T) = c_f + \delta v_h(T), \qquad \langle \delta v_h \rangle_W = 0$$

over the declared window W. Each regularized crossing of the $J_h^t(\theta_h) = 0$ boundary is a caustic transit with finite impulse

$$\Delta \mathbf{V}_{h,j} = \int_{T_j^-}^{T_j^+} \mathbf{A}_h^{(\eta)}(T)\, dT, \qquad \|\Delta \mathbf{V}_{h,j}\| < \infty$$

rather than an infinite-acceleration constraint. These impulse events are candidate mechanical origins for the discrete causal-root ledger steps used in the energy bookkeeping.

This is the main regime assumption of the doubling-frequency-lock analysis. The speed c_f is the propagation speed of causal isochrons in the reduced dynamics, not an observer-level claim about an effective metric.
It is not a claim that every Noether braid regime has any fixed binary exactly at c_f. A promoted result must compare the three possible h assignments or prove from the retained record why only one is admissible.

Assumption 2 (Exact Integer Phase Closure)

Let the binary-3 reference period be $P_3 = \frac{1}{f_3}$. Assume that when binary 3 completes one full cycle, binaries 2 and 1 also land exactly at the beginning of their own cycles. Equivalently, there exist integers

$$m, n \in \mathbb{N}, \qquad 1 < m < n$$

such that

$$\theta_3(T + P_3) = \theta_3(T) + 2\pi$$

$$\theta_2(T + P_3) = \theta_2(T) + 2\pi m$$

$$\theta_1(T + P_3) = \theta_1(T) + 2\pi n$$

Therefore the indexed frequency triplet is $f_1 : f_2 : f_3 = n : m : 1$, with $f_2 = m f_3$ and $f_1 = n f_3$.

Plain language: after one binary-3 revolution, binaries 2 and 1 have completed whole numbers of revolutions as well, so the three-binary pattern closes exactly. Binary 3 is the phase reference because the A3.3 row assigns it the base frequency, not because it is geometrically outer.

This is the reduced constant-frequency carrier model. It is a branch-level closure assumption, not a statement that the assembly has only three degrees of freedom. In the full Noether braid closure problem, the simple phases $\theta_a(T) = q_a \omega_3 T + \phi_a$, with $(q_1, q_2, q_3) = (n, m, 1)$ and $\omega_3 = 2\pi f_3$, are replaced by integrated winding, causal-root, and frame-phase ledgers over the accepted branch chart.

Assumption 3 (Fixed Relative Phase Lock)

The lock is not just commensurate in frequency. It also carries fixed relative phase offsets over time. One convenient formulation is

$$\phi_{23}(T) \equiv \theta_2(T) - m\theta_3(T) = \phi_{23}^*$$

$$\phi_{13}(T) \equiv \theta_1(T) - n\theta_3(T) = \phi_{13}^*$$

with constants ϕ_{23}^*, ϕ_{13}^*.

Plain language: the binaries keep the same timing relationship cycle after cycle rather than drifting through one another.

Bundle Holonomy Reading

Assumptions 2 and 3 can be restated as a phase-bundle condition. Let the binary-3 phase be the base cycle and define the relative connection one-forms

$$\vartheta_{23} = d\theta_2 - m\, d\theta_3, \qquad \vartheta_{13} = d\theta_1 - n\, d\theta_3$$

Exact integer phase closure says the covering degrees over one binary-3 cycle are

$$\frac{1}{2\pi} \oint_{S_3^1} d\theta_2 = m, \qquad \frac{1}{2\pi} \oint_{S_3^1} d\theta_1 = n$$

or equivalently

$$\oint_{S_3^1} \vartheta_{23} = 0, \qquad \oint_{S_3^1} \vartheta_{13} = 0 \pmod{2\pi}$$

on the locked branch. Fixed relative phase then says these one-forms are flat on the retained return chart: their integrated values do not drift, and the constants ϕ^*_{23}, ϕ^*_{13} are the residual flat-connection data. The discrete and continuous pieces should be kept separate:

$$(m,n) = \text{covering degrees over } S^1_3, \qquad (\phi^*_{23}, \phi^*_{13}) = \text{flat-connection moduli}$$

Thus the lock is a flat relative-phase connection with integer holonomy, not a literal first Chern class over the binary-3 phase circle. In the language of Effective Lagrangian, the integers (m,n) are the phase-return degree data that make the reduced action-angle chart globally replayable rather than merely local.

The phase-bundle picture also requires genuine three-dimensional binary-plane independence. Use the canonical ordered-normal determinant D_{plane} defined in Noether Braid Configuration Space.

The reduced T^3 lock is nondegenerate only while $D_{\text{plane}} \neq 0$. Mutual orthogonality gives $|D_{\text{plane}}| = 1$, while horizon-alignment or coplanar degeneration drives $D_{\text{plane}} \to 0$ and collapses the three-circle bundle to a lower-dimensional projection. The determinant is therefore the natural order parameter for the loss of doubling-frequency precession at alignment.
For a promoted finite-η chart this is a conditioning floor,

$$|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0.$$

It is the phase-bundle analogue of the basis-conditioning and aperture floors in the frame-construction and detection chapters: $D_{\text{plane}} \to 0$ means the three plane normals no longer define a stable oriented frame. The codimension-one wall $D_{\text{plane}} = 0$ is also where the near-orthogonal Noether braid phase chart degenerates toward a coplanar cyclic sector, so crossing it is a sector-wall event rather than a harmless coordinate limit.

Assumption 4 (Bundle-Flatness and Cancellation Selection Principle)

Among the admissible binary-3-normalized integer locks $(1:m:n)$, the physically selected lock is assumed to be the one whose phase bundle admits the flattest replayable connection while minimizing exposed causal-wake leakage. The cycle-averaged cancellation of a low-order causal-wake multipole or effective potential signal is the effective diagnostic for that deeper bundle condition.

This is a selection principle, not yet a theorem. Its role is to explain why one exact integer lock might be preferred over nearby commensurate alternatives. The primary object is the branch bundle; the cancellation score is accepted only when it is computed from the same holonomy data, candidate-carrier impulse record, and finite-η return map.
The admissible class must be declared before minimization: positive radii, $1 < m < n$, a fixed finite-η branch chart, nonzero branch-transversality floors, and the speed bounds assigned to the exterior/horizon regime.

For a declared comparison chart, candidate binary h is the curvature carrier. Between caustic events the locked triple is modeled as flat phase transport. At its regularized caustics, the connection acquires concentrated curvature,

$$\Omega_{\text{phase}} = \sum_j \mathcal{F}_j\, \delta_\eta(\theta_h - \theta^*_{h,j}) \sum_{b \neq h} d\theta_h \wedge d\theta_b + \Omega_{\text{reg}}$$

where $\theta^*_{h,j}$ are the candidate-carrier caustic phases and $\mathcal{F}_j$ is proportional to the finite caustic impulse $\Delta \mathbf{V}_{h,j}$ and its wake-history increment on the retained branch. Any energy-routing fulcrum is therefore geometric and branch-derived: transfers may concentrate at the carrier caustic phases where the phase-bundle connection is not flat. This is the same ledger event class used by the self-hit echo bookkeeping.

A minimal test functional can be written before committing to a particular lock. Let $(q_1, q_2, q_3) = (n, m, 1)$, with phase variables $\theta_k(T) = q_k \omega_3 T + \phi_k$ and $\omega_3 = 2\pi f_3$. For a low-order truncation depth L, define

$$S_L(T) = \sum_{k \in \{1,2,3\}} \sum_{\ell=1}^{L} A_{k,\ell}(\beta_k, r_k, \eta, D_t, D_r, W^{\text{acc}}, J^t_k)\, e^{i\ell(q_k \omega_3 T + \phi_k)}$$

The coefficients $A_{k,\ell}$ are not free fit parameters. They must be extracted from the same finite-η transmitter-side acceleration-weight, branch-transversality, and causal-wake ledger used to test the candidate lock.
They therefore belong to the dynamics of the causal-wake branch chart, even when the resulting signal is later summarized as an effective potential.

For the caustic-grazing candidate carrier this extraction is not an ordinary smooth Fourier coefficient. A carrier harmonic must carry the caustic transversality weight of the window while keeping transmitter-side acceleration/action strength on the same retained record, schematically

$$A_{h,\ell} = \int_0^{2\pi} \frac{w^r_{h,\ell}(\theta_h)}{|J^t_h(\theta_h)| + \eta_J} e^{-i\ell\theta_h}\, d\theta_h$$

with η_J the declared Jacobian-floor regularization and $w^r_{h,\ell}$ the branch-derived numerator computed from the same retained D_t, D_r , and W^{acc} row for that harmonic channel. The J^t_h factor is a caustic-window transversality weight, not a substitute for transmitter-side acceleration weight. As η_J is lowered, the coefficient is dominated by neighborhoods of the caustic phases $\theta^*_{h,j}$, while the integrated impulse remains finite under the simple-caustic rule in Master Equation. Thus the selection question is not whether three generic Fourier amplitudes cancel, but whether the finite candidate-carrier impulse deposits the right spectral weight into the first common resonance block.

The cycle-averaged cancellation score over one binary-3 reference window starting at T_* is

$$C_L(m,n;\phi) = \frac{1}{P_3}\int_{T_*}^{T_*+P_3} |S_L(T')|^2\, dT' = \sum_\nu \left| \sum_{(k,\ell):\, \ell q_k = \nu} A_{k,\ell} e^{i\ell\phi_k} \right|^2$$

The doubling-frequency claim becomes a theorem target only if $(m,n) = (2,4)$ minimizes this score under the admissible branch equations and retains a positive stability gap.

Harmonic-overlap lemma. The score decomposes into resonance blocks labeled by ν. A phase choice can affect cancellation between two binaries only when their finite harmonic supports overlap:

$$\nu \in q_k\{1,\ldots,L\} \cap q_b\{1,\ldots,L\}$$

for distinct binary indices k and b. If a block has no overlap, its contribution to C_L is phase-independent and cannot select an integer lock. For the doubling-frequency candidate $(m,n) = (2,4)$, the first binary-3/binary-2 overlap is $\nu = 2$ via $(3, \ell = 2)$ and $(2, \ell = 1)$; the first all-binary overlap is

$$\nu = 4$$

via $(3, \ell = 4)$, $(2, \ell = 2)$, and $(1, \ell = 1)$. Thus this functional can select $1:2:4$ only if $L \geq 4$ and the $\nu = 4$ block has nontrivial branch-derived amplitudes. A complete cancellation of that all-binary block additionally requires the amplitude magnitudes to satisfy the polygon condition

$$\max(|A_{3,4}|, |A_{2,2}|, |A_{1,1}|) \leq \text{sum of the other two}$$

The lemma is only a harmonic support statement. It shows where cancellation is possible; it does not show that the branch-derived amplitudes or the return-map stability actually select the doubling-frequency lock.

The selection therefore has two independent requirements. The topological requirement is that the all-binary resonance block is nonempty; for the doubling-frequency candidate this is the $\nu = 4$ block. The dynamical requirement is that the branch-derived complex amplitudes in that block can close a polygon after the caustic-weighted carrier contribution is included. The first requirement belongs to the covering structure; the second belongs to the finite-η delayed dynamics and cannot be inferred from topology alone.

Topologically, the same $\nu = 4$ statement says the doubling-frequency lock is the first common cover of the three phase circles. The covering maps can be written

$$S^1_3 \xleftarrow{\times m} S^1_2 \xleftarrow{\times n/m} S^1_1$$

when m divides n. The doubling-frequency case $m = 2,\ n = 4$ is the minimal nontrivial self-similar cover because each indexed phase circle double-covers its reference neighbor. More generally, self-similar covers obey $n = m^2$; after $1{:}2{:}4$, the next such comparison family is $1{:}3{:}9$, not $1{:}2{:}3$ or $1{:}3{:}6$. This does not prove the doubling-frequency branch wins dynamically, but it explains why $1{:}2{:}4$ is the first topologically clean candidate before the amplitude calculation begins.

Equivalently, the resonance blocks are the isotypic components of the integer action generated by the lock, and $\nu = \mathrm{lcm}(1,2,4) = 4$ is the first common period of all three circles. The doubling-frequency tower is the unique minimal repeated cover

$$S^1 \xleftarrow{\times 2} S^1 \xleftarrow{\times 2} S^1$$

among non-identity integer towers. This is why the doubling-frequency family is also the natural candidate for a renormalization-style fixed point in the truncation analysis: repeated double covering is the simplest scale-similar phase organization.

Non-Assumptions

The doubling-frequency-lock analysis does **not** assume:

- common-speed closure $v_1 = v_2 = v_3$,
- any radius ordering or self-similar radius relation,
- or the specific frequency lock $1:2:4$ at the outset.

Those are possible special cases or later outcomes, not starting axioms here.
Only exact integer closure is studied here. Rational or self-similar locks can be compared only after clearing denominators or constructing a separate branch map.

Immediate Consequences

This section is pure algebra from the exact identity and the first two assumptions. It does not use the cancellation principle.

Let

$$(q_1, q_2, q_3) = (n, m, 1).$$

The exact identity gives every characteristic radius relative to the binary-3 reference radius:

$$r_a = \frac{\beta_a c_f}{2\pi q_a f_3}, \qquad \frac{r_a}{r_3} = \frac{\beta_a}{q_a \beta_3}, \qquad a \in \{1, 2, 3\}.$$

If the candidate carrier is binary h, Assumption 1 adds only $\beta_h = 1$. It does not order the other radii. Thus the frequency ratio and one field-speed condition still leave the remaining speed factors to be determined by the branch dynamics.

Proposition 1 (Exterior Integer Lock Formulas)

Under Assumptions 1-2,

$$f_1 : f_2 : f_3 = n : m : 1$$

and

$$r_1 : r_2 : r_3 = \frac{\beta_1}{n} : \frac{\beta_2}{m} : \beta_3.$$

Proof. The frequency ratio is exactly Assumption 2. The radius ratios follow from

$$r_a = \frac{\beta_a c_f}{2\pi f_a}$$

together with $(f_1, f_2, f_3) = (nf_3, mf_3, f_3)$. The carrier choice adds $\beta_h = 1$ only after h is declared. □

The geometry is controlled by integer phase closure plus a separately declared caustic-grazing carrier condition. The proposition makes no claim about which integer pair or carrier index is dynamically preferred.

Could $1{:}2{:}4$ Be a Solution?

If one later chooses the doubling-frequency integers

$$m = 2, \qquad n = 4$$

then

$$f_1 : f_2 : f_3 = 4 : 2 : 1$$

but the radius ratios become

$$r_1 : r_2 : r_3 = \frac{\beta_1}{4} : \frac{\beta_2}{2} : \beta_3.$$

So the doubling-frequency lock is a viable candidate pattern, but it does **not** by itself imply equal-speed geometry, and it does **not** by itself imply a self-similar radius law unless further assumptions are added.

What Exact Periodicity Gives, and What It Does Not

Exact periodicity naturally supports rational or integer commensurability, but it does not by itself choose the integers m, n.

What exact lock gives:

- the three indexed frequencies lie on a commensurate lattice,
- the three-binary configuration repeats after one binary-3 reference period,
- fixed relative phases become meaningful dynamical observables,
- the covering data (m, n) become phase-bundle winding data for the retained branch chart.

What exact lock does not give by itself:

- that the preferred lock is doubling-frequency,
- that the branch speeds are equal,
- that the radii are self-similar,
- or that cancellation is actually maximal for one specific integer pair (m, n).

The bundle-flatness and cancellation principle is the extra ingredient intended to select among the many admissible integer locks.

Interpreting the Cancellation Principle

The motivation for Assumption 4 is that a cycle-closing integer lock can support persistent superposition over repeated binary-3 reference periods only when the relative phase connection stays flat enough to replay. If the phase organization is favorable, the low-order causal-wake multipole or effective potential contribution can cancel more effectively over one full return cycle.

At the substrate level, the relevant quantity is exposed causal-wake leakage. At the effective level, the same organization may be reported as reduced low-order potential signal. At the inference level, the reduced model is allowed to select a lock only if the cancellation gap survives the declared truncation and stability tests.

In that sense, the selection principle is closer to a flat-bundle replay test than to a bare numerology of integer ratios. The intuition is that a physically preferred lock should minimize exposed wake leakage, phase-slip variance, and residual phase curvature subject to the delayed dynamics. If the bundle-flatness diagnostic and the cancellation score disagree, the cancellation score is only an effective summary and cannot by itself overrule a holonomy or return-map failure.

This does not yet prove which pair (m, n) wins. It states the criterion that the reduced model should test.

RG-Style Truncation Test

The cancellation functional uses a finite harmonic depth

$$L$$

That truncation must be certified rather than assumed. The useful analogy from renormalization-group reasoning is not that $\mathbb{AAA}$ inherits a field-theory RG flow, but that discarded modes must be shown irrelevant for the decision being made.

The branch geometry predicts which modes are most dangerous. Smooth noncarrier binaries should have rapidly decaying coefficients,

$$|A_{b,\ell}| \le Ce^{-c\ell}, \qquad b \ne h$$

on an analytic replayable chart. The candidate carrier instead has an algebraic pre-cutoff tail because its impulse is phase-localized:

$$|A_{h,\ell}| \lesssim C_\eta \, \ell^{-p_{\mathrm{fold}}}$$

with p_{fold} fixed by the caustic normal form and the regulator. Here S_L is the impulse-accumulated velocity-row signal obtained after integrating the regularized carrier impulse through the retained branch record; it is not the unintegrated acceleration or potential row. In a local fold coordinate $x = \theta_h - \theta^*_{h,j}$, a generic Whitney A_2 fold gives a velocity-row cusp $B_0 + B_1|x|^{1/2} + O(x)$, whose Fourier coefficients scale as $\ell^{-3/2}$. The corresponding unintegrated acceleration-row singularity would scale as $|x|^{-1/2}$ and would not supply the L_{eff}^{-2} tail budget used below. Thus the velocity-row normal form gives the pre-cutoff exponent

$$p_{\text{fold}} = \frac{3}{2}.$$

A cusp or higher catastrophe would change this exponent and therefore change the truncation budget. The finite-depth proof must therefore report the carrier-caustic spectral exponent or cutoff, not only assert that high harmonics are small. In the RG analogy, the smooth noncarrier harmonics are irrelevant tails, while the carrier caustic block is the marginal channel that can still affect selection beyond the first all-binary block.

For a candidate lock (m, n), define the tail score

$$T_L(m,n) \equiv \sum_{\nu > L_{\text{eff}}} \left| \sum_{(k,\ell):\, \ell q_k = \nu} A_{k,\ell} e^{i\ell\phi_k} \right|^2$$

where

$$L_{\text{eff}}$$

is the largest resonance block retained in the selection audit. The finite-depth proof must supply a bound

$$T_L(m,n) \le \varepsilon_L$$

uniformly over the admissible branch chart and then compare the winner gap

$$\Delta C_L \equiv \min_{(m,n)\neq(m_*,n_*)} \big(C_L(m,n) - C_L(m_*,n_*)\big)$$

against the truncation error. A lock is selected by the finite calculation only if

$$\Delta C_L > 2\varepsilon_L$$

For the generic A_2 fold exponent, the carrier tail dominates the smooth noncarrier tails:

$$|A_{h,\ell}|^2 = O(\ell^{-3}), \qquad \varepsilon_L = O(L_{\text{eff}}^{-2}).$$

Thus a practical finite-depth certificate must choose L_{eff} large enough that the bound implied by L_{eff}^{-2} is less than $\frac{1}{2}\Delta C_L$ on the same branch chart. This is a stopping rule for the selection calculation, not a new assumption about which lock wins.

This turns “higher harmonics are small” into a checkable theorem target tied to the same branch-derived amplitudes used in

$$C_L$$

Reduced-Theorem Target

The right theorem target is not “prove $1:2:4$ from kinematics alone.” The stronger target is a proof route that keeps kinematics, branch dynamics, phase-bundle topology, effective cancellation, and inference separate:

1. classify the admissible indexed integer locks $(n : m : 1)$ under exact delayed phase closure,
2. compute the corresponding radius relations for each candidate carrier choice h under $\beta_h = 1$,
3. require nondegenerate orbital-plane data $D_{\text{plane}} \neq 0$ so the retained phase bundle is genuinely three-dimensional,
4. define the phase-bundle curvature and caustic-weighted cancellation functional for the low-order causal-wake multipole or effective potential,
5. determine which integer lock minimizes residual curvature and exposed leakage in the exterior/horizon regime,
6. and verify the selected lock by a finite-η return map with a positive Floquet gap on the complement of the flat moduli.

Equivalently, for each candidate (m, n) one should construct a return map

$$P_{\eta,m,n} : \mathcal{S}_{m,n} \to \mathcal{S}_{m,n}$$

on the retained branch chart and require

$$\Delta_{m,n} = 1 - \max_{i \notin G} |\mu_i(P_{\eta,m,n})| > 0$$

off the neutral symmetry directions G.

Here $\mathcal{S}_{m,n}$ is a finite-η reduced phase-amplitude branch chart: it retains the binary phases, relative phase offsets, orbital-plane normals, radii, speeds, active branch data, branch-transversality floors, caustic-impulse rows, candidate-carrier index, and history variables needed to evaluate one binary-3-period return. The neutral directions G are not an arbitrary hand list. They are the tangent directions that preserve the same flat connection and branch identity:

$$G = T_{\text{global}} \oplus \mathfrak{so}(3)_{\text{rot}} \oplus T_{\text{flat}} \oplus G_{\text{rel}}$$

where T_{global} is the global time or phase shift, $\mathfrak{so}(3)_{\text{rot}}$ is the global spatial-rotation tangent space, $T_{\text{flat}} = \text{span}\{(\delta\phi_{23}, \delta\phi_{13})\}$ is the flat-connection moduli space, and G_{rel} contains any declared relabeling symmetry of the retained branch chart. A lock is dynamically stable only if the return map contracts on the complement of G and the flat-modulus directions remain genuinely neutral. If a flat-modulus direction becomes unstable, the frequency commensurability may remain while Assumption 3 fails through relative-phase drift.
The quotient rule is strict. A direction in T_{flat} is treated as a symmetry only when the holonomy-defect coordinate

$$\Theta(T) = (\phi_{23}(T) - \phi_{23}^*,\ \phi_{13}(T) - \phi_{13}^*)$$

has zero Floquet exponent on the retained return map. If Θ has a positive exponent, the same direction is a lock-breaking instability, not a quotient direction. This is the retained-branch version of the embedded-binary warning in Binary Dynamics: a reduced subsystem's apparent neutral direction cannot be removed unless it is neutral for the full retained branch chart.

If the minimizer turns out to be the binary-3-normalized lock $1{:}2{:}4$, equivalently $(m, n) = (2, 4)$, then the doubling-frequency hierarchy would be a derived selection result rather than a starting assumption.

In the invariant language of Noether Braid Topological Charge, the reduced theorem target is to find an admissible topological sector

$$[\mathfrak{B}]_{\text{freq}} = (N_s,\ M_p,\ c_1) = (N_s,\ M_p,\ (m, n))$$

with flat phase connection, positive Floquet gap off G, and $|D_{\text{plane}}|$ bounded away from zero outside the horizon-alignment locus. The doubling-frequency conjecture is the sharper claim that $(N_s, M_p, (2, 4))$ is the minimal-curvature such class in the exterior/horizon-transition regime.

Recurrence Diagnostic

The finite-η return-map test should also reject transient near-locks. For a sampled returned-branch trajectory, let $\boldsymbol{\psi}_i = (\theta_{3,i}, \phi_{23,i}, \phi_{13,i})$ be the returned phase row, $\mathbf{r}_i^{\text{bin}} = (r_{1,i}, r_{2,i}, r_{3,i})$ the binary-radius row, $\boldsymbol{\beta}_i = (\beta_{1,i}, \beta_{2,i}, \beta_{3,i})$ the speed-factor row, and $\mathcal{R}_i^{\text{rec}}$ the returned branch record containing active-root ledger data, candidate-carrier impulse rows, and retained causal-wake history variables. The sampled state is

$$z_i = (\boldsymbol{\psi}_i, \mathbf{r}_i^{\text{bin}}, \boldsymbol{\beta}_i, \mathcal{R}_i^{\text{rec}}, h_i, \hat{\mathbf{n}}_{1,i}, \hat{\mathbf{n}}_{2,i}, \hat{\mathbf{n}}_{3,i}) \in \mathcal{S}_{m,n}.$$

Define a recurrence matrix

$$Q_{ij}^{(\epsilon)} = \mathbf{1}\left[d_{\mathcal{S}}(z_i, z_j) < \epsilon\ \wedge\ \|\Theta_i - \Theta_j\| < \epsilon_\Theta\ \wedge\ |D_{\text{plane},i} - D_{\text{plane},j}| < \epsilon_D\right]$$

where $d_{\mathcal{S}}$ is the declared branch-chart distance after quotienting the neutral symmetries in G, while the holonomy-defect coordinate is not quotiented:

$$\Theta(T) = (\phi_{23}(T) - \phi_{23}^*,\ \phi_{13}(T) - \phi_{13}^*)$$

A candidate $1{:}2$ row, or a chained $1{:}2{:}4$ row, is recurrence-positive only if returned-section hits recur at the declared binary-3-period multiples, the recurrence period agrees with the winding and active-branch ledger, the relative-phase defect Θ recurs to zero, the plane determinant stays in the nondegenerate domain, the candidate-carrier assignment is stable under refinement or its transition is explicitly recorded, the recurrence structure persists under timestep, history-resolution, and η refinement, and nearby trials that fail the non-symmetry Floquet gap do not pass this recurrence check. This separates point recurrence from true phase-lock recurrence.

Ancillary Symmetry Check

The older $\mathbb{Z}_3$ dipole-cancellation identity belongs to a different assembly sector. It can still be kept as a planar symmetry test:

$$1 + e^{i2\pi/3} + e^{i4\pi/3} = 0$$

This is an in-plane cancellation for three equal phases separated by 120°. It is therefore naturally associated with coplanar, boson-like stealth arrangements rather than with the near-orthogonal rank-three bundle studied in this chapter. In compact form:

$$\mathbb{Z}_3 \text{ stealth} \longleftrightarrow \text{coplanar cyclic sector}$$

whereas

$$1{:}2{:}4 \text{ doubling-frequency cover} \longleftrightarrow \text{near-orthogonal } T^3 \text{ sector}$$

The two mechanisms can both reduce exposed causal-wake leakage, but they do it through different topology. Planar cyclic symmetry cancels inside one plane; the doubling-frequency Noether braid lock distributes the phase-bundle covering across three independent orbital planes. The $\mathbb{Z}_3$ identity should therefore not be used as evidence for or against the frequency-selection assumptions above.
The separating wall is the plane-degeneracy condition

$$D_{\text{plane}} = 0.$$

On one side, the near-orthogonal sector carries three independent phase circles and covering data. On the wall, the phase chart collapses into a coplanar cyclic configuration where cancellation is representation-theoretic inside one plane. Crossing this wall is therefore a change in cancellation topology, not a smooth deformation inside one sector. The reachable theorem target is that the doubling-frequency sector and the coplanar $\mathbb{Z}_3$ sector cannot be connected by a path that preserves both $|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0$ and a positive non-symmetry Floquet gap.

For a neighboring closure problem, see Horizon Chirality.

Braid Family B

Family B contains prescribed one-braid geometries whose three binary axes are the same oriented line. The canonical coordinates and master-table rows are defined in Braid Taxonomy. This chapter gives the exact B1 path geometry, its coordinate boundaries, and its intersection with Family A.

Family B is a geometry-and-motion definition. It does not establish that a B1 record is generated, retained, or stable under the EOM solver. The realization-independent retention burden is stated in Braid Recovery Requirements.

Shared Family-B Geometry

Every Family-B member is one complete Noether braid composed of three neutral binaries. The binaries share one oriented axis $\hat{\mathbf{n}}_B$. The source-defined B1 chart also gives them one common midpoint, the braid center $\mathbf{C}(T)$.

Choose transverse unit vectors $\hat{\mathbf{e}}_1$ and $\hat{\mathbf{e}}_2$ so that $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{n}}_B)$ is an orthonormal frame. For binary $a \in \{1, 2, 3\}$, define

$$\theta_a(T) = q\, 2\pi f T + \phi_a, \qquad q \in \{+1, -1\},$$

where f is the common frequency, ϕ_a is the binary phase relative to the braid-level zero point, and q is the common circulation sense. The binary half-separation vector is

$$\mathbf{d}_a(T) = h_a \hat{\mathbf{n}}_B + \rho_a \left[\cos\theta_a(T)\hat{\mathbf{e}}_1 + \sin\theta_a(T)\hat{\mathbf{e}}_2\right].$$

The two endpoint paths are

$$\mathbf{X}_{a1}(T) = \mathbf{C}(T) + \mathbf{d}_a(T), \qquad \mathbf{X}_{a2}(T) = \mathbf{C}(T) - \mathbf{d}_a(T).$$

These equations make the B1 restrictions explicit: the endpoints of each neutral binary remain antipodal about the common braid center; all three binaries use the same axis, frequency, and circulation sense; and the radii, axial half-separations, transverse orbit radii, and phases may differ by binary.

The radius decomposition $R_a^2 = h_a^2 + \rho_a^2$ is defined in the Individual Binary coordinate section. The internal speed of either endpoint of binary a is

$$s_a = 2\pi f \rho_a.$$

Thus internal speed is controlled by transverse orbit radius rather than by total binary radius alone. If a display derives the optional angle $\alpha_a = \operatorname{atan2}(h_a, \rho_a)$, the same relation is $s_a = 2\pi f R_a \cos\alpha_a$. The angle is not a primary taxonomy coordinate.

B1

B1 is the fixed-coordinate common-frequency co-rotating member of Family B. Its member-level constraints are:

Coordinate or relation	B1 value
Braid count	One
Binary midpoints	One common braid center $\mathbf{C}(T)$
Binary axes	$\hat{\mathbf{n}}_1 = \hat{\mathbf{n}}_2 = \hat{\mathbf{n}}_3 = \hat{\mathbf{n}}_B$
Frequency	One common f
Circulation	One common sense q
Radii	R_1, R_2, R_3 independently assignable
Axial half-separations	h_1, h_2, h_3 independently assignable subject to each radius decomposition
Transverse orbit radii	ρ_1, ρ_2, ρ_3 independently assignable subject to each radius decomposition
Phases	ϕ_1, ϕ_2, ϕ_3 independently assignable relative to the common zero point

Fixed-coordinate here means that the declared R_a, h_a, ρ_a, f, ϕ_a, frame, and circulation sense do not change during the prescribed record. The architrinos still move on their declared orbits. This is a prescribed-chart restriction, not evidence that the EOM solver retains the assembly.

B1 Catalog Members

The live Borg catalog assigns decimal member identifiers to three prescribed B1 coordinate selections. All three inherit the B1 common midpoint, coincident axis, common frequency, and common circulation relations:

Member ID	Coordinate selection
`B1.1`	Interior reference: $h_a > 0$ and $\rho_a > 0$ for every binary.
`B1.2`	High-axial interior: $h_a > \rho_a > 0$ for every binary.
`B1.3`	All-equatorial boundary: $h_a = 0$ and $\rho_a = R_a$ for every binary.

These identifiers distinguish the catalog records; they do not replace B1 as the parent member inherited by Family-C component braids.

An active B1 candidate must contain nonzero transverse internal motion. Define the transverse-motion magnitude

$$\mathcal{K}_\perp = \sum_{a=1}^{3} s_a^2 = (2\pi f)^2 \sum_{a=1}^{3} \rho_a^2$$

for the declared common frequency $f > 0$. Active-candidate eligibility requires

$$\mathcal{K}_\perp > 0$$

or, equivalently, $\sum_a \rho_a^2 > 0$. This is a taxonomy nondegeneracy condition: it requires at least one binary to have internal transverse motion. It is not a retention, stability, binding, energy, or physical-realization result.

Coordinate Boundaries

The equatorial and axial depictions are coordinate boundaries of B1, not separately identified braid families. Each binary can reach either boundary independently:

Boundary locus	Coordinate condition	Endpoint motion
Equatorial	$h_a = 0,\ \rho_a = R_a$	The endpoints traverse one circle in the plane through $\mathbf{C}(T)$ orthogonal to $\hat{\mathbf{n}}_B$.
Axial	$\rho_a = 0,\ h_a = R_a$	The endpoints remain on the common axis and have zero internal orbital speed.
Interior	$h_a > 0,\ \rho_a > 0$	The endpoints traverse separated transverse circles on opposite sides of the braid center.

The B1.3 all-equatorial display sets $h_a = 0$ for all three binaries. Mixed boundary records are also permitted by the B1 coordinates and remain active-candidate eligible when at least one ρ_a is nonzero.

At an axial locus, ϕ_a and f remain prescribed record labels but no longer change that binary's endpoint positions because its transverse orbit radius is zero. Two axial records that differ only in those labels therefore depict the same path geometry unless another retained record gives the labels an independent dynamical role.

Deprecated Axial-Limit Control

The former catalog identifier `B1.4` selected the all-axial limit

$$\rho_a = 0, \qquad h_a = R_a \qquad \text{for every } a \in \{1, 2, 3\}.$$

Its endpoint paths remain the exact B1 coordinate-boundary equations

$$\mathbf{X}_{a1}(T) = \mathbf{C}(T) + R_a \hat{\mathbf{n}}_B, \qquad \mathbf{X}_{a2}(T) = \mathbf{C}(T) - R_a \hat{\mathbf{n}}_B.$$

This limit has $\mathcal{K}_\perp = 0$: frequency, phase, and circulation labels do not create internal motion, and translation of $\mathbf{C}(T)$ only transports the static axial arrangement. The stable `B1.4` identifier and its prescribed source and record remain a deprecated axial-limit null control for historical reproducibility. It is not an active taxonomy member, a Borg catalog selection, a future sweep candidate, or a comparative-ranking participant.

Axial Translation

When the braid center translates along the common axis at constant group speed,

$$\mathbf{C}(T) = \mathbf{C}(0) + s_{\text{grp}} T \hat{\mathbf{n}}_B,$$

each non-axial endpoint follows an exact screw path: axial translation plus circular motion about the same axis. The axial and transverse velocity components are orthogonal, so the exact site-speed split is the channel kinematics developed in Braid Mathematics. A mechanism that fixes the total speed budget remains an open branch hypothesis.

Axial translation is a B1 specialization, not a Family-B requirement. A record whose group velocity is not parallel to $\hat{\mathbf{n}}_B$ retains the same internal B1 geometry but is not an axial screw path.

Boundary with Family A

Family A and Family B share a coordinate boundary. At $\lambda_A = 1$, the three Family-A axes coincide with the Family-A translation direction. A common-frequency Family-A record with one common circulation sense then satisfies the B1 axis, frequency, and circulation relations. It reaches the source-defined common-center B1 chart only if its three binary midpoints also coincide with the braid center.

The A2 face-opposite seed supplies a second exact overlap: common-frequency co-rotation about its body diagonal occupies the cyclic-symmetric A2/B1 sublocus, independently of $\lambda_A = 1$. These overlaps are coordinate-locus statements. They do not identify Family A with Family B away from the shared loci and do not establish a physical transition between them.

Claim Boundary

The B1 equations define prescribed paths exactly. They would be falsified as EOM-solver branch claims by a same-record evolution showing that the common-axis, common-frequency, common-center, or fixed-coordinate relations cannot be retained under the required causal-root, acceleration, action, and stability records. Until such evidence exists, B1 supplies an exact display geometry and explicit closure targets, not a retained physical braid.

Braid Family C

Family C contains prescribed twelve-architrino geometries whose twelve architrino worldlines are coaxial. The canonical assembly coordinates and master-table rows are defined in Braid Taxonomy. This chapter gives the exact common-axis path chart, the neutral-binary pairing contract, and the constrained members C1 through C6.

Family C is a geometry-and-motion definition. It does not establish that a Family-C record is generated, bound, retained, stable, or physically realized under the EOM solver. The realization-independent retention burden is stated in Braid Recovery Requirements.

Shared Family-C Coordinate Chart

Choose one oriented orthonormal frame

$$\mathcal{F}_C = (\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{n}}_C)$$

where $\hat{\mathbf{n}}_C$ is the common axis of all twelve architrino worldlines. Assign persistent indices

$$m \in \{1, \ldots, 12\}$$

and strictly ordered axial coordinates

$$\xi_1 < \xi_2 < \cdots < \xi_{12}.$$

The adjacent spacings and total train length are

$$d_m = \xi_{m+1} - \xi_m > 0, \qquad m \in \{1, \ldots, 11\}$$

and

$$L_C = \xi_{12} - \xi_1 = \sum_{m=1}^{11} d_m.$$

The spacing vector

$$\mathbf{d}_C = (d_1, \ldots, d_{11})$$

is a primary Family-C coordinate because it changes the exact causal delays between architrino worldlines. A common shift of every ξ_m is absorbed into the assembly center and does not create a thirteenth axial coordinate.

Let $\mathbf{X}_{\text{grp}}(T)$ be the prescribed assembly center. For uniform translation of that center at group speed s_{grp},

$$\mathbf{X}_{\text{grp}}(T) = \mathbf{C}_0 + s_{\text{grp}} T \hat{\mathbf{n}}_C.$$

Worldline m is

$$\mathbf{X}_m(T) = \mathbf{X}_{\text{grp}}(T) + \xi_m \hat{\mathbf{n}}_C + \rho_m \left[\cos\theta_m(T)\hat{\mathbf{e}}_1 + \sin\theta_m(T)\hat{\mathbf{e}}_2\right]$$

with

$$\theta_m(T) = q_m \omega_m T + \phi_m, \qquad q_m \in \{+1, -1\}.$$

The twelve radii $\rho_m > 0$, angular frequencies $\omega_m > 0$, phases ϕ_m, and circulation senses q_m are independently declared unless a member row constrains them. A complete-return record must declare a period $P_C > 0$ satisfying

$$\frac{\omega_m P_C}{2\pi} \in \mathbb{Z}$$

for every m.

Neutral-Binary Pairing

Every Family-C source record declares a fixed-point-free involution

$$\pi : \{1, \ldots, 12\} \to \{1, \ldots, 12\}$$

satisfying

$$\pi(\pi(m)) = m, \qquad \pi(m) \neq m.$$

The six unordered pairs $\{m, \pi(m)\}$ are the six neutral binaries. For each pair, the record declares opposite endpoint polarities and explicitly states the radius, frequency, phase, circulation, axial-midpoint, and axial-separation relations. The binary map is not inferred from axial adjacency, drawing color, or an optional Accessory Configuration.

The Family-C parent chart does not require the six binaries to divide into two complete B1 braids. A source may declare such a decomposition, but it is an additional constrained relation rather than the Family-C definition.

Optional Accessory Configuration

A Family-C assembly may also declare an Accessory Configuration containing six additional architrino worldlines. Those six sites are separate assembly inventory: their polarity and complete prescribed paths must be declared, and they are not counted among the twelve defining Family-C architrino worldlines.

Adding or removing an Accessory Configuration does not change the Family-C member identifier. It changes the declared assembly inventory and therefore changes the source record and its hash.

C1

C1 is the co-rotating Family-C member:

$$q_m = q_C, \qquad m \in \{1, \ldots, 12\}, \qquad q_C \in \{+1, -1\}.$$

C1 retains the full ordered-spacing, radius, frequency, phase, and binary-pairing coordinates. It does not require equal radii, equal spacings, equal frequencies, reflection symmetry, or decomposition into two B1 components.

C2

C2 is the counter-rotating Family-C member. The source record declares the two ordered index subsets

$$\mathcal{I}_1 = \{1, \ldots, 6\}, \qquad \mathcal{I}_2 = \{7, \ldots, 12\}$$

and imposes

$$q_m = q_C \quad \text{for } m \in \mathcal{I}_1, \qquad q_m = -q_C \quad \text{for } m \in \mathcal{I}_2.$$

The subsets define the circulation relation only. Neither subset is required to be a complete B1 braid, and binary counterparts may remain within one subset or cross between them when the source record declares the map exactly.

C3 and C4

C3 is the two-B1 constrained locus of C1. C4 is the two-B1 constrained locus of C2. In both members, the twelve worldlines can be partitioned into two complete B1 components indexed by $b \in \{1, 2\}$, with three neutral binaries $a \in \{1, 2, 3\}$ in each component.

Both component axes coincide with $\hat{\mathbf{n}}_C$, and their centers are separated only along that axis:

$$\mathbf{C}_1(T) = \mathbf{X}_{\text{grp}}(T) - \frac{d_C}{2}\hat{\mathbf{n}}_C, \qquad \mathbf{C}_2(T) = \mathbf{X}_{\text{grp}}(T) + \frac{d_C}{2}\hat{\mathbf{n}}_C, \qquad d_C > 0.$$

For each component, let $(R_{ba}, h_{ba}, \rho_{ba}, \phi_{ba})$ be its B1 binary coordinates, with

$$R_{ba}^2 = h_{ba}^2 + \rho_{ba}^2.$$

The half-separation vector is

$$\mathbf{s}_{ba}(T) = h_{ba}\hat{\mathbf{n}}_C + \rho_{ba}\left[\cos\theta_{ba}(T)\hat{\mathbf{e}}_1 + \sin\theta_{ba}(T)\hat{\mathbf{e}}_2\right]$$

and the endpoint worldlines are

$$\mathbf{X}_{ba+}(T) = \mathbf{C}_b(T) + \mathbf{s}_{ba}(T), \qquad \mathbf{X}_{ba-}(T) = \mathbf{C}_b(T) - \mathbf{s}_{ba}(T).$$

Each component separately inherits the complete B1 common-midpoint, common-axis, common-frequency, common-circulation, antipodality, and polarity-conjugacy relations. The source record declares the bijection between these twelve endpoint labels and the persistent Family-C indices m.

C3 imposes one common circulation sense across both components. C4 imposes opposite component circulation senses. Neither member requires the two components to have equal radii, equal frequencies, equal internal phases, or a phase lock.

C5 and C6

C5 is the all-equatorial two-B1.3 constrained locus of C3. C6 is the all-equatorial two-B1.3 constrained locus of C4. Both members impose

$$h_{ba} = 0, \qquad \rho_{ba} = R_{ba}, \qquad b \in \{1,2\}, \quad a \in \{1,2,3\}.$$

C5 retains the common-circulation relation. C6 retains the opposite-component-circulation relation. The axial center separation d_C, component frequencies, internal phases, and relative phase remain declared coordinates unless a source record constrains them.

Exact Causal-Delay Relation

For transmitter worldline a at time $T_r - u$ and receiver worldline b at reception time T_r, every retained positive causal delay solves

$$\left\|(\xi_b - \xi_a + s_{\mathrm{grp}}u)\,\hat{\mathbf{n}}_C + \mathbf{r}_b(T_r) - \mathbf{r}_a(T_r - u)\right\| = c_f u, \qquad u > 0$$

where

$$\mathbf{r}_m(T) = \rho_m\left[\cos\theta_m(T)\hat{\mathbf{e}}_1 + \sin\theta_m(T)\hat{\mathbf{e}}_2\right].$$

This equation is exact for the prescribed chart and generally transcendental because u appears inside the transmitter phase. Closed-form reduction is available only on separately demonstrated symmetric boundaries. Otherwise, prescribed-path analysis must enumerate every retained positive root without evolving any path.

Interface With Physical Hypotheses

Family C supplies a generic prescribed coordinate chart for twelve coaxial architrino worldlines. A particle or transport hypothesis occupies a constrained locus only after its extra polarity, phase, frequency, accessory, propagation, action, and angular-momentum relations are stated explicitly.

In particular, the photon-channel hypothesis is a **coaxial contra-rotating polarity-conjugate planar pair**. C2 supplies only a twelve-worldline counter-rotation chart. It does not by itself establish the photon-side planar decomposition, polarity conjugation, propagation-axis relation, null propagation, polarization, helicity, action target, binding, retention, or physical realization. Those obligations remain owned by Electroweak Bosons and its closure gates.

Claim Boundary

The Family-C equations are exact prescribed paths. A prescribed-path residual candidate is falsified when its declared causal-root, minimum-separation, speed, complete-cycle acceleration-balance, refinement, or independent-reconstruction requirements fail. Such a result remains analytical: it does not establish or refute stability, retention, binding, photon identity, quantization, or physical realization.

Noether Braid Configuration Space

This chapter gives the analysis space surrounding the canonical braid taxonomy: the evidence-level vocabulary and the rank-three angular-momentum-frame variables used to test a candidate record. It comes after the family map in Noether Braid, the prescribed coordinates in Braid Taxonomy, and the retention contract of Braid Recovery Requirements. The analyzed regions include Family A, the A3.3 $4{:}2{:}1$ lock and its A1.3 zero-axial-offset locus, iso-frequency candidates, and field-speed hinge-occupancy candidates. Within the rank-three sublocus, a branch candidate is a three-row state whose energies, phase offsets, angular-momentum rows, plane orientations, causal-root ledgers, frequencies, radii, speeds, and whole-branch group velocity must be solved together.

This is a search architecture and theorem target, not a completed classification theorem. The goal is to find which regions of the Noether braid configuration space support stable retained branches in a Noether sea populated by like assemblies, identify which branches remain candidate braids and which can be promoted to certified braids, and then use those branches as the entry point for assembly topological charge, energy differentials, shielding, and accessory-architrino capture.

The plain reading is that configuration space is the menu of possible branch records, not a list of already-existing particles. A candidate braid becomes important only when its rows return together under the delayed dynamics. Until then, labels such as `4:2:1`, iso-frequency, field-speed hinge, or rank-three are search coordinates.

This distinction prevents premature naming. A three-row branch is valuable because three independent angular-momentum rows can supply a full internal frame in Euclidean space. It is not valuable because three rows sound elegant. The solver still has to prove that the energies, phases, orientations, root ledgers, and group velocity belong to one retained record.

Document Role

This chapter owns the rank-three angular-momentum-frame search variables: unordered layer labels, angular-momentum two-form rows, the plane-frame determinant, group velocity, energy/frequency/speed/radius ledgers, role assignment, and permutation accounting. It is the place to ask whether a candidate branch supplies three retained angular-momentum rows with enough conditioning to form a volumetric internal frame.

It does not exhaust the full Noether braid class, certify A1 retention, or make $4{:}2{:}1$, iso-frequency, or field-speed-hinge assumptions the default. Those are specializations that must declare their member definition and same-record branch rows before any analysis label is attached.

Evidence-Level Terms

This chapter uses four evidence-level terms in a controlled way:

Term	Meaning in this chapter	What it does not claim by itself
branch	A candidate whole six-architrino Noether braid history over a declared finite memory window; this chapter's analysis space is the six-body base and Family-A/B case, while a twelve-worldline Family-C candidate carries the corresponding rows on its own declared ledger. The branch is the object whose inventory, paths, causal roots, wakes, energy/action rows, angular-momentum rows, phases, support data, response-center data, and Noether sea row are tested together.	A branch is not a single path, a single binary row, or a visual braid drawing. It is also not automatically stable or physical.
retained	Evidential status for a branch, row, or chart whose required data close on the same record under the declared tolerance, event/domain convention, and stability conditions.	`Retained` does not mean assumed, preferred, or merely still under discussion. If the same-record ledgers are missing, the object remains a candidate.
support	The geometric region, envelope, or comparison chart occupied by the branch data. A1 path support, a path-history-derived oblate spheroidal envelope, and an axial comparison chart describe different objects.	Support is not an acceleration law and not proof of retention. A support label says how the candidate is represented geometrically, not that the delayed dynamics preserve it.
record	The finite ledger attached to one branch over the declared memory window. It includes only data that can still affect the next delayed update or certificate: inventory, path history, causal-root rows, wake rows, energy/action rows, momentum and angular-momentum rows, phase and plane-orientation rows, support claims, response-center and group-velocity rows, and the local Noether sea row.	A record is not a narrative summary or a loose collection of diagnostics. A proof claim must say which rows close on the same record.

This chapter is the front door for classifying Noether braid configurations. It names the independent axes used to describe a candidate branch before any adjudication of retention. The taxonomy is therefore a configuration language, not a classification theorem.

A supplementary analysis record for a candidate branch $\mathfrak{B}$ can be written schematically as

$$\mathsf{Analysis}_{\mathfrak{B}} = (\mathsf{AngularMomentumFrame}, \mathsf{Handedness}, \mathsf{SpeedRegime}, \mathsf{HingeOccupancy})\,.$$

These entries are diagnostics that may be computed from a taxonomy member's record. They are not additional columns in the canonical taxonomy, and they do not by themselves prove that the delayed dynamics admit a stable branch. Retention and certification are evidence statuses, not configuration axes.

Family-B Example: B1

A reader who wants one concrete configuration to hold in mind while reading the axes below can use B1. Its three neutral binaries share one midpoint, one axis, one frequency, and one circulation sense. Binary a has internal speed $s_a = 2\pi f \rho_a$, so different transverse orbit radii produce different internal speeds even though all three binaries share f. The all-equatorial and all-axial depictions are coordinate boundaries of the same member. Active B1 candidate records require $\sum_a \rho_a^2 > 0$; the all-axial endpoint remains a coordinate boundary and deprecated null control rather than an active candidate.

The status discipline binds. B1 is a prescribed member, not a retained branch, and no family ranking is asserted. Its exact geometry does not establish physical formation, retention, or preference over another taxonomy member.

Supplementary Diagnostics

The canonical dimensions are defined only in Braid Taxonomy. This chapter adds analysis diagnostics that may be applied after a member is specified: angular-momentum-frame rank, frame handedness, speed regime, and field-speed-hinge occupancy. These diagnostics are intentionally outside the master taxonomy table until a later decision promotes one of them.

Base Inventory

The base inventory is the neutral six-architrino case described in Noether Braid. It contains three positive-polarity architrinos and three negative-polarity architrinos:

$$\#\{i : \sigma_i = +1\} = \#\{i : \sigma_i = -1\} = 3, \qquad \sum_i \sigma_i = 0.$$

This inventory says only that the candidate has the required polarity count and a shared causal-return ledger. It does not assume exact binary pairs, an A1 or B1 member, an orthogonal angular-momentum frame, or a protected topological class.

Angular-Momentum Frame

The angular-momentum-frame axis asks whether the retained branch emits enough angular-momentum rows to define a full internal 3D frame. The rows are ledger data extracted from the branch, not assumed circular orbits. The three-row or rank-three search region is developed below, but it remains only one region inside the broader Noether braid taxonomy rather than the definition of every Noether braid.

Frame value	Meaning	What it does not prove
not assigned	The branch has not yet supplied retained angular-momentum rows.	It does not reject the branch; it only leaves the frame axis open.
rank-three frame	The branch supplies three retained angular-momentum rows with nonzero frame determinant.	It does not by itself prove shell support, frequency lock, polarity placement, or certification.
planar lower-rank braid (PL)	The branch is lower-rank on this axis because the determinant defined in this section vanishes or because no retained three-row frame exists.	It is not automatically the planar reduced chart and not automatically a terminal A1 boundary.

For a rank-three frame, the branch record includes three angular-momentum two-form classes. Here class means a ledger-extracted angular-momentum two-form row up to the declared branch-window equivalence, not a de Rham cohomology class of the Euclidean void:

$$[\omega_J^{(a)}], \qquad a \in \{1,2,3\},$$

with derived plane normals $\hat{\mathbf{n}}_a$ when the Hodge-dual direction is nonzero. The frame is volumetric only when

$$D_{\text{plane}} = \det\begin{bmatrix}\hat{\mathbf{n}}_1 & \hat{\mathbf{n}}_2 & \hat{\mathbf{n}}_3\end{bmatrix} \neq 0.$$

A planar lower-rank braid (PL) may still be dynamically meaningful, but it is not a promoted rank-three Noether braid branch until the three-row frame condition and its conditioning floor are supplied on the same retained record.

The planar reduced chart is different. A reduced planar chart is a proof or simulation representation that places branch data into a common plane or near-plane so a restricted calculation can be performed. The canonical planar rank-three Noether braid reduced chart is the rank-three instance of this reduced chart usage. Such a chart may also represent a PL candidate, the terminal boundary of A1, or the photon-channel bridge described by the coaxial contra-rotating polarity-conjugate planar pair. The generic opposite-circulation composition coordinates for two complete B1 records are defined separately by C2; planarization and photon identity are additional constraints. A planar reduced chart should therefore be named as a chart, not used as a base-family name.

Angular-Momentum Handedness

Angular-momentum handedness records the orientation of the ordered rank-three frame when the frame exists. If the retained branch supplies ordered plane normals $\hat{\mathbf{n}}_1, \hat{\mathbf{n}}_2, \hat{\mathbf{n}}_3$, then the sign of D_{plane} gives the handedness of that ordered frame:

$$\operatorname{sgn}(D_{\text{plane}}) = \begin{cases} +1, & \text{positive-handed}, \\ -1, & \text{negative-handed}. \end{cases}$$

When $D_{\text{plane}} = 0$ or the branch has no retained three-row frame, handedness is not assigned as a rank-three property. It may still have planar chirality, circulation signs, or other lower-rank orientation diagnostics, but those are separate rows.

Speed, Hinge, And Frequency Families

The speed regime records how retained speed rows relate to the field speed c_f. Sub-field-speed rows satisfy speeds below the field-speed hinge; field-speed rows sit at the transition scale; super-field-speed rows enter regimes where delayed self-interaction can become available. These diagnostics remain attached to the persistent indices $a \in \{1, 2, 3\}$; a later branch may distinguish one or more indices without renaming them.

Field-speed hinge occupancy is a separate axis. It asks which row, if any, operates within a declared tolerance of c_f, and it must say which speed statistic is being tested: transverse carrier speed, orbital/circulation speed, or another branch-declared component. A hinge row is not automatically a self-hit row. It is the speed-regime condition at which the branch can transition from the partner-only regime toward a ledger with both partner-hit and self-hit access, provided the same-transmitter causal-root ledger and transversality rows also close.

Hinge value	Meaning
no hinge row	No retained row is declared within the c_f hinge tolerance.
single-hinge	One row is organized around the field-speed hinge.
multi-hinge	More than one row is organized around the field-speed hinge.
terminal hinge	The branch approaches a terminal-alignment regime, such as the braid symmetry-breaking point, where hinge occupancy and loss of volumetric slack must be tested together.

The frequency-ratio family records return or winding-frequency relations. The main examples are:

Frequency-ratio value	Meaning
iso-frequency `1:1:1`	Candidate family with common return rate across the three retained rows. The fixed-coordinate common-axis member is B1.
integer-ratio `3:2:1`	Candidate family with integer return rates but no repeated-doubling assumption.
doubling-frequency $4{:}2{:}1$	The A3.3 member with indexed ratio $f_1 : f_2 : f_3 = 4 : 2 : 1$, studied in A3.3 Doubling-Frequency Resonance Lock. A1.3 is its zero-axial-offset locus. The ratio does not imply a radius order.

Frequency-ratio labels are candidate-family labels until the phase-return degree, causal-root ledger, finite-memory gluing, and stability rows close on the same branch. Hinge labels require their own speed and causal-root rows; they are not frequency-ratio names.

Scope Of The Hypothesis

The three-row exact-binary hypothesis is a decomposition strategy, not an exhaustion theorem. There may be stable Noether braid configurations that do not admit a clean split into three persistent binary rows. The reason to study this decomposition first is that three independent angular-momentum directions are enough to span the orientation data of Euclidean three-space. In that sense, the three-row exact-binary decomposition is the minimal exact-binary architecture that can test whether a stable assembly carries a full three-dimensional internal frame.

This also means that the word `binary` names a retained angular-momentum row, not necessarily a perfectly circular two-body orbit at every instant. A certified row may have a conserved or slowly bounded angular-momentum ledger while the actual architrino paths on the retained support are quasiperiodic, braided, or chaotic. On such a row, f_a is a return or winding frequency, r_a is a characteristic lever arm, s_a is a speed row or speed statistic, and E_a is the retained branch-energy row. A circular carrier chart is the cleanest comparison case, not the only admissible path geometry.

In geometric language, the three rows are derived from three retained angular-momentum two-form classes on the branch, not from three assumed circular sub-orbits. The brackets do not mean de Rham cohomology classes of $\mathbb{R}^3$; they mean the declared equivalence of branch-window angular-momentum bivectors that preserve the same retained ledger row. Write these classes schematically as

$$[\omega_J^{(a)}], \qquad a \in \{1,2,3\}.$$

The plane normal $\hat{\mathbf{n}}_a$ is the Euclidean Hodge-dual direction extracted from that class,

$$\hat{\mathbf{n}}_a = \frac{\star[\omega_J^{(a)}]}{\|\star[\omega_J^{(a)}]\|},$$

whenever the numerator is nonzero. The Hodge dual is applied to a representative after the branch ledger row is declared; a refinement that changes the dual direction is a different retained row, not the same class. Thus axis language means a ledger direction derived from the retained branch record. It is not an assumption that constituent paths are axial, circular, or disjoint.

Why Three Retained Rows

The reason to begin with three retained rows is geometric. Euclidean space has three independent spatial directions, and a stable three-dimensional assembly needs enough internal direction data to define an orientation frame rather than only a planar cycle. A single binary row supplies one orbital plane and one plane normal. Two rows can define a relative angle, but they do not by themselves supply a full nondegenerate three-axis frame. Three retained rows can, when their plane normals are independent, define a local three-dimensional frame.

Use the ordered plane normals and canonical determinant defined in Angular-Momentum Frame. The branch is genuinely three-dimensional only when $D_{\text{plane}} \neq 0$. Near $|D_{\text{plane}}| = 1$, the three planes are close to mutually orthogonal. Near $D_{\text{plane}} = 0$, the rank-three frame degenerates toward a coplanar or lower-dimensional support. This determinant is therefore a natural order parameter for the transition between a volumetric Noether braid branch and a planar or horizon-aligned branch.

For promotion work this becomes a nondegeneracy floor:

$$|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0.$$

It is the frame-bundle analogue of the Jacobian and separatrix floors used elsewhere: the map from three retained plane normals to an oriented internal frame loses conditioning when this determinant approaches zero. The wall $D_{\text{plane}} = 0$ is therefore the coplanar or horizon-aligned stratum where the frame ceases to be rank three. In current sector language, this is the boundary between a volumetric near-orthogonal sector and a planar cyclic sector; the solver must determine which side a retained branch actually occupies.

This is a statement about a derived orientation frame, not a claim that the constituent architrino paths are axial. The actual six paths may be braided, quasiperiodic, chaotic, shell-supported, or otherwise noncircular while still emitting retained angular-momentum rows from which principal directions can be extracted. Axis language in this chapter therefore means a ledger or envelope direction derived from the branch record, not a primitive path pattern.

The claim is not that every stable assembly must have three exact binary rows. The broader Noether braid class permits six-body branches before exact binary grouping is certified. The three-row exact-binary search inside that class is the minimal exact-binary architecture that can test full three-dimensional frame closure.

Equivalently, the three-row exact-binary locus is a sublocus of the six-body Noether braid configuration class:

$$\mathcal{T}_{3B}^{\text{locus}} \subset \mathcal{N}_{6\text{-body}}.$$

A six-body branch belongs to this sublocus only when its retained angular-momentum record admits three independent rows, or equivalently a rank-three frame extraction with $D_{\text{plane}} \neq 0$. A planar, oblate, or lower-rank Noether braid may still be stable, but it is not a promoted rank-three Noether braid branch until the three-row frame condition is met.

General Branch State

Use the persistent binary indices $a \in \{1, 2, 3\}$. These labels are bookkeeping identities only. They do not imply an ordering of frequency, radius, energy, speed, phase, plane orientation, or root-ledger complexity, and they are not replaced when two coordinate values cross. The minimal branch record for this sublocus is

$$\mathcal{T}_{3B} = \{(f_a,\, r_a,\, E_a,\, s_a,\, \phi_a,\, \hat{\mathbf{n}}_a,\, \mathcal{L}_a)\}_{a=1}^{3}\,.$$

Here f_a is the layer frequency or return rate, r_a is the characteristic radius or retained lever arm, E_a is the retained branch-energy row, $s_a = \|\mathbf{V}_a\|$ is the scalar tangential speed or speed statistic, ϕ_a is the phase origin or offset, $\hat{\mathbf{n}}_a$ is the orbital-plane normal, and $\mathcal{L}_a$ is the active causal-root ledger data for that layer. On a circular carrier chart,

$$s_a = 2\pi f_a r_a.$$

This identity is kinematic only. It does not select the frequencies, radii, speeds, energies, phase offsets, plane orientations, or causal-root ledgers.

The practical search should treat the branch energy row E_a, angular-momentum row, phase data, and causal-root ledger $\mathcal{L}_a$ as primary retained data. The radius and speed are then constrained by the selected carrier chart, conservation laws, and the branch's energy closure. In simple circular rows, fixed f_a and E_a may determine an admissible r_a and s_a after the kinetic, binding, and wake-energy terms are specified. In noncircular rows, the same energy may correspond to a bounded family of paths with the same return frequency but different local speed profile. Thus energy is central, but it is not by itself a complete coordinate on the Noether braid configuration space.

Branch Group Velocity

The internal plane data do not encode group velocity. The plane normals $\hat{\mathbf{n}}_a$ describe the assembly's internal angular-momentum frame. The group velocity is the drift of the retained branch envelope or response center through the local Noether sea:

$$\mathbf{V}_{\mathrm{grp}} = \frac{d\mathbf{X}_{\mathrm{resp}}}{dT} \quad \text{relative to the declared Noether sea record.}$$

The full branch record should therefore be read as

$$B_{3B} = (\mathcal{T}_{3B},\, \mathbf{X}_{\mathrm{resp}},\, \mathbf{V}_{\mathrm{grp}},\, \mathbf{P}_{\mathfrak{B}},\, \mathbf{J}_{\mathfrak{B}},\, \theta_{\mathrm{sea}})\,,$$

where $\mathbf{P}_{\mathfrak{B}}$ and $\mathbf{J}_{\mathfrak{B}}$ are the branch-total momentum and angular-momentum ledgers, and θ_{sea} is the local Noether sea response record used to compare moving branches.

This distinction matters for the equivalence-principle and Lorentz-closure programs. In a validated low-energy regime, uniform group velocity should not become an observable composition-dependent force merely because two assemblies carry different internal plane orientations. That is an effective recovery target: the moving branch must retune its clock, ruler, and signal rows so that preferred-frame leakage stays below the declared bounds. It is not a reason to omit $\mathbf{V}_{\mathrm{grp}}$ from the dynamics. The correct statement is that $\mathbf{V}_{\mathrm{grp}}$ is a separate branch-transport variable whose observable leakage must be suppressed by common-channel closure.

This variable is unambiguous only when the response-center theorem target closes on the same branch. The exposed-energy response center, inertial response center, and wake-momentum boundary ledger must agree up to the declared response residual $\mathcal{R}_{\mathrm{resp}}$. If they do not, the phrase "group velocity of the branch" can point to different moment maps, and the candidate is not ready for certified-braid promotion. Thus $\mathbf{V}_{\mathrm{grp}}$ is part of the retained record, but its use as a single transport velocity is conditional on center-of-response closure.

Candidate And Certified Braids

A **candidate braid** is a proposed Noether braid branch or branch family whose certificate rows have not all closed. A **certified braid** is a theorem-target status for a Noether braid branch, not a new primitive substance. A branch is certified only when its full retained record returns to itself under the delayed dynamics, up to declared symmetries, and its required stability, alignment, and observer-export rows close on the same record.

The retained record is not an arbitrary internal diary and it is not an arbitrary collection of architrinos. It is the finite branch chart for one Noether braid: the six-body polarity-neutral inventory of three positive-polarity and three negative-polarity architrinos, together with the path-history rows, causal-root ledger, wake-tail rows, energy/action rows, momentum and angular-momentum rows, phase data, plane-orientation data, response-center data, group-velocity row, and Noether sea record that can still affect the next delayed update of that same six-body branch. A path-history segment belongs to the retained record only while it can still enter a self-hit, partner-hit, wake-tail, boundary, or branch-return row on the declared memory window.

Let $P^{(\mathbf{V})}_{T_{\rm ret}}$ be the finite-memory return map over one branch return duration $T_{\rm ret}$, including translation by the branch group velocity $\mathbf{V}_{\rm grp}$. Let $\mathcal{G}_{\rm sym}$ contain only declared neutral symmetries such as global phase shift, global spatial rotation, translation of the response center, and permitted S_3 layer relabeling. A rank-three Noether braid branch B_{3B} is a candidate for certified-braid promotion when there exists $g \in \mathcal{G}_{\rm sym}$ such that

$$\mathcal{R}_{\rm cert} = d_{\mathfrak{B}} \left(P^{(\mathbf{V})}_{T_{\rm ret}}(B_{3B}),\, g \cdot B_{3B} \right) \le \epsilon_{\rm cert},$$

on the same retained branch chart $\mathfrak{B}$, with the non-symmetry return directions carrying a positive stability margin. The metric $d_{\mathfrak{B}}$ must compare the same branch rows: causal-root ledger, energy/action ledger, angular-momentum rows, phase data, plane-orientation data, response-center motion, group velocity, Noether sea record, and assembly topological charge.

This residual-and-Floquet requirement is the braid instance of the absolute-time clock certificate, not an imported spacetime premise; see Absolute Time Defense.

The quotient group $\mathcal{G}_{\rm sym}$ is not a convenience list. It must be the neutral group of the retained return map: directions removed from the stability test have zero Floquet exponent because they are declared symmetries of the full branch chart. A direction that is neutral in an isolated sub-row but unstable in the enclosing rank-three Noether braid chart is not quotiented. In that sense, the certified-braid certificate is the branch-symplectic promotion test evaluated on the retained branch chart: the finite-memory return map must recur modulo true neutral symmetries while contracting or bounding every non-symmetry direction, and an action-derived reduced Hamiltonian promotion must also report the return-map symplectic residual $\mathcal{R}_\Omega$ defined under the Master Equation closure interface.

The branch-intrinsic conserved record must also export Lorentz-compatible observer rows before certification. In the homogeneous moving-branch regime, the same retained record must recover the ruler and clock deformation laws,

$$\xi = \frac{R_\parallel}{R_\perp} \to \frac{1}{\gamma}, \qquad \frac{d\tau}{dt_{\rm eff}} \to \frac{1}{\gamma},$$

with preferred-frame leakage bounded by the declared $\epsilon_{\rm LV}$ or two-way anisotropy diagnostic. The observer components are produced through a derived moving-assembly map,

$$C_{\rm obs} = \Lambda_{\rm eff} \left(\mathbf{V}_{\rm grp}, \theta_{\rm sea} \right) C_{\rm branch} + O(\epsilon_{\rm LV}),$$

when Lorentz closure applies. Here $C_{\rm branch}$ is the branch-intrinsic component vector being exported, such as an energy-momentum, angular-momentum, clock, or ruler row, and $C_{\rm obs}$ is the corresponding effective observer-chart component vector. The map $\Lambda_{\rm eff}$ is the effective export map, not the reduced A1 closure label Λ_{A1}. The export may dress those components, but it does not replace the branch record itself. Topological rows such as assembly topological charge remain branch-intrinsic invariants unless the branch crosses a fold, reconnection, or other declared surgery event.

Momentum And Principal-Direction Decomposition

A candidate for certified-braid promotion should also say how its three retained rows align with the conserved momentum ledgers. A branch whose retained record returns but whose axes do not align with branch-total momentum and angular momentum remains a return-map candidate, not a promoted certified braid. The branch-total momentum and angular momentum should be computed on the same finite window as the return map:

$$\mathbf{P}_{\mathfrak{B}} = \mathbf{P}_{\rm mech} + \mathbf{P}_{\rm wake}, \qquad \mathbf{J}_{\mathfrak{B}} = \mathbf{J}_{\rm mech} + \mathbf{J}_{\rm wake}.$$

The mechanical and wake terms must use the same endpoint convention as the retained branch chart; otherwise the axis comparison is only a visualization.

When $\|\mathbf{P}_{\mathfrak{B}}\| > 0$, the unit vector

$$\hat{\mathbf{e}}_P = \frac{\mathbf{P}_{\mathfrak{B}}}{\|\mathbf{P}_{\mathfrak{B}}\|}$$

is the transport axis. When $\|\mathbf{J}_{\mathfrak{B}}\| > 0$, the unit vector

$$\hat{\mathbf{e}}_J = \frac{\mathbf{J}_{\mathfrak{B}}}{\|\mathbf{J}_{\mathfrak{B}}\|}$$

is the branch's total angular-momentum axis. The three retained plane normals $\hat{\mathbf{n}}_a$ should then be read as a principal-direction decomposition of $\mathbf{J}_{\mathfrak{B}}$, not as arbitrary visual decoration and not as a claim that the paths themselves lie on axes. A simple diagnostic is the angular-momentum closure vector

$$\mathcal{R}_{J-\text{axis}} = \left\| \hat{\mathbf{e}}_J - \frac{\sum_{a=1}^{3} w_a \hat{\mathbf{n}}_a}{\left\|\sum_{a=1}^{3} w_a \hat{\mathbf{n}}_a\right\|} \right\|,$$

where the weights w_a are declared branch-action, branch-angular-momentum, or energy-row weights and the weighted normal sum is required to be nonzero. This is not yet a theorem: it is the axis-alignment row a solver must populate before claiming that the three retained rows faithfully decompose the assembly's conserved angular momentum.

The stronger faithful-decomposition test is spectral. Build the symmetric branch angular-momentum frame tensor

$$\mathsf{J}_{\mathfrak{B}}^{ij} = \sum_{a=1}^{3} J_a \, \hat{n}_a^i \hat{n}_a^j,$$

with J_a supplied by the retained branch-angular-momentum or action row. A promoted rank-three Noether braid branch should show that this tensor has three nonzero eigenvalues and that its eigenframe agrees with the retained normal frame up to the allowed S_3 relabeling and sign conventions. This is an orthogonality-sensitive test: when the normals are not mutually orthogonal, the eigenvectors of $\mathsf{J}_{\mathfrak{B}}^{ij}$ need not coincide with $\{\hat{\mathbf{n}}_a\}$ even if the retained weights are nonzero. If two J_a are equal within tolerance, the certificate must use an eigenvalue-gap condition or a subspace-match criterion rather than a unique eigenvector match. If diagonalizing $\mathsf{J}_{\mathfrak{B}}^{ij}$ produces a different frame, then $\mathcal{R}_{J-\text{axis}}$ is not a mere visualization error: the three retained rows are not a faithful decomposition of the conserved angular-momentum ledger.

The retained angular-momentum decomposition does not select one coarse envelope family. In a rest branch, $\mathbf{P}_{\mathfrak{B}} = \mathbf{0}$, so the internal angular-momentum axes and plane determinant describe the retained three-dimensional support, while the swept constituent paths separately determine whether the envelope is fusiform, oblate spheroidal, or another certified form. In a moving branch, $\hat{\mathbf{e}}_P$ marks the drift direction relative to the Noether sea, and Lorentz closure asks whether the family-declared envelope deforms with a longitudinal-to-transverse ratio

$$\xi = \frac{R_\parallel}{R_\perp}, \qquad R_\parallel \text{ measured along } \hat{\mathbf{e}}_P,$$

while the same internal angular-momentum ledger remains retained. Thus the retained rows decompose internal angular momentum into principal directions, while group velocity and total momentum select the moving-envelope axis. They do not convert the B1 common-axis internal geometry into a Family-A oblate response; B1's member-declared rest envelope and its moving-envelope projection are separate records in Braid Envelope Geometry.

Unordered Layer Semantics

The search must not assume that one binary is high-frequency, low-frequency, high-energy, low-energy, fast, slow, boundary-leading, field-speed-carrying, or otherwise geometrically privileged before the retained branch supplies that diagnostic. The raw search domain is therefore the indexed but unsorted product

$$\tilde{\mathcal{C}}_{3B} = \{(\mathcal{T}_1, \mathcal{T}_2, \mathcal{T}_3) : \mathcal{T}_a = (f_a, r_a, E_a, s_a, \phi_a, \hat{\mathbf{n}}_a, \mathcal{L}_a)\}\,.$$

The symmetric group S_3 acts on this space by permuting the three support-row records:

$$\pi \cdot (\mathcal{T}_1, \mathcal{T}_2, \mathcal{T}_3) = (\mathcal{T}_{\pi^{-1}(1)}, \mathcal{T}_{\pi^{-1}(2)}, \mathcal{T}_{\pi^{-1}(3)}), \qquad \pi \in S_3.$$

Two rows may therefore be the same physical candidate up to a relabeling even when they appear as distinct solver outputs.

The default search policy is to keep $\tilde{\mathcal{C}}_{3B}$ unquotiented. Repeated S_3-related solutions are useful confirmation that the solver is finding a symmetric sector rather than a one-off artifact. An analysis tool may later isolate one representative sector by computing a permutation-invariant key,

$$\mathrm{key}(B) = \mathrm{sort}_{a=1}^{3} \mathrm{fingerprint}(\mathcal{T}_a),$$

but that quotient is an analysis summary, not the search domain. No branch is rejected merely because a symmetric relabeling has already appeared.

When branch counts, continuation-family cardinalities, or basin weights are reported, the quotient must be applied explicitly. If a physical branch has stabilizer subgroup $\mathrm{Stab}_{S_3}(B)$, then its orbit size in the unquotiented cover is

$$\frac{|S_3|}{|\,\mathrm{Stab}_{S_3}(B)|}.$$

The unquotiented solver rows are useful evidence, but they are not independent physical branches. Any comparison to the finite-continuation family $\mathfrak{S}_{\Omega,W}^{\mathrm{ME},\eta}$, the regularized Master Equation continuation set over window W and mollifier η, or to basin measures must reduce by the same S_3 orbit accounting rather than overcounting six label copies as six distinct certified braids.

The general configuration ratios are

$$f_1 : f_2 : f_3, \qquad r_1 : r_2 : r_3, \qquad E_1 : E_2 : E_3, \qquad s_1 : s_2 : s_3.$$

These ratios are reported in the current layer labels. They are not sorted ratios and they carry no inequality unless a retained branch later assigns a role order.

The branch-search problem is to find retained stable states

$$\mathcal{T}_{3B} \in \tilde{\mathcal{C}}_{3B}$$

over this full variable set, then compare their energy differentials

$$\Delta E_{ab} = E_a - E_b$$

and ledger decompositions on the same retained row set. The doubling-frequency, iso-frequency, and broader integer-ratio families are subfamilies of $\tilde{\mathcal{C}}_{3B}$, not definitions of it. Field-speed hinge occupancy is a separate speed-regime axis on the same branch rows, not a frequency-ratio family.

Super-Field-Speed Carrier Rows

The general search naturally includes carrier speeds above the causal wake propagation speed. Since

$$s_a = 2\pi f_a r_a,$$

fixing one row of the search does not fix the others. Even an iso-frequency family

$$f_1 = f_2 = f_3$$

can have different radii, energies, speeds, phases, and active root ledgers:

$$r_1 : r_2 : r_3 \neq 1 : 1 : 1, \qquad s_1 : s_2 : s_3 \neq 1 : 1 : 1.$$

If one retained lever arm is large enough at the common frequency, then that layer has $s_a > c_f$.

This is not a signal-speed claim. The primitive causal wake still propagates at c_f. A row with $s_a > c_f$ is a carrier-trajectory row in the retained branch chart. Its importance is dynamical: it changes the causal-root inventory. Super-field-speed carrier motion can create additional self-hit and partner-hit roots, acceleration-Jacobian sign changes, and move the branch into the fold and caustic regimes that feed the causal-root ledger. The possibility of one or more super-field-speed layers is therefore a reason to scan the full Noether braid configuration space rather than preselecting a single speed hierarchy.

In a certified row, the important event is not speed alone but the appearance of same-transmitter causal roots with the required transversality floors; a certified row that contributes acceleration or action additionally carries the same-record transmitter-side acceleration weight, while the signed-root topology below is fixed by root existence and the causal-root Jacobian sign. Still, $s_a > c_f$ is the natural warning gate for the layer's self-hit signed-root complex:

$$C_+^{(a)} \oplus C_-^{(a)}.$$

This is the layerwise specialization of the signed causal-root complex: simple same-transmitter roots are split by the sign of their causal-root Jacobian before the layer contributes to assembly topological charge.
A branch with one super-field-speed layer can carry a different assembly topological charge structure from a branch with two or three such layers, because the self-hit ledgers and signed degrees are layer-dependent. This is another reason the search must preserve the full unordered speed tuple $s_1 : s_2 : s_3$ rather than collapsing immediately to a preferred hierarchy.

Family B realizes this decoupling directly. In B1, each binary has internal speed $s_a = 2\pi f \rho_a$, so the speed tuple is independent of the total-radius values when the transverse orbit radii are chosen independently. The equatorial and axial cases are coordinate boundaries of B1. Its harmonic-matching hypothesis and discrete-symmetry derivations are stated in B1 Hypotheses and Discrete Symmetry. No family ordering is asserted.

A terminology boundary applies throughout this section: the field-speed value $s_a = c_f$ is a **coordinate locus** of the configuration space — the boundary where the same-transmitter root inventory changes — and nothing here asserts that any dynamical mechanism holds a layer at that locus. Occupancy of the locus is a chart label, not an attractor claim.

Stability In A Sea Of Like Assemblies

An isolated Noether braid return map is not enough for Noether braid promotion. A retained branch must also remain stable when embedded in a Noether sea containing like assemblies. The relevant stability question is not only whether one branch closes, but whether a population of similar branches can coexist without destroying the retained ledgers.

For a candidate branch B over a window W, write the stability target schematically as

$$\mathrm{Stable}_{3B}(B; W, \mathcal{N}_{\mathrm{sea}}) \Longleftrightarrow P_{\mathrm{root}} \wedge P_{\mathrm{phase}} \wedge P_{\mathrm{energy}} \wedge P_{\mathrm{return}} \wedge P_{\mathrm{sea}}.$$

Here P_{root} requires persistent causal-root ledgers with positive root floors except at declared caustic transits, P_{phase} requires bounded phase-offset drift, P_{energy} requires a closed branch-energy row, P_{return} requires a Floquet, Conley, or comparable return certificate, and P_{sea} requires the same branch to remain coherent under the background Noether sea response generated by like assemblies. This last predicate is the bridge from an isolated branch search to a stable medium of assemblies.

The result of this search should be an atlas of stable regions in $\tilde{\mathcal{C}}_{3B}$, not a single preferred row. Patterns may include doubling-frequency locks, iso-frequency families, integer-ratio families such as `3:2:1`, field-speed hinge-occupancy regimes, planar degenerations, and mixed regimes where one or more layers run above c_f while the whole assembly remains a retained delayed branch. If a stable region is S_3-symmetric, the atlas may also report the corresponding quotient-sector representative, but the unquotiented evidence should remain available.

Toward A Periodic Table Of The Noether Braid

The phrase "periodic table of the Noether braid" names the classification program, not an already completed table. The proposed atlas should classify retained branches by:

1. The compact assembly topological charge $[\mathfrak{B}]_{\mathrm{top}} = (N_s, M_p, c_1)$ and its signed-degree refinement, where N_s counts active self-hit roots, M_p counts active partner-hit roots, and c_1 is the phase-return degree slot defined in Noether Braid Topological Charge.
2. The frequency, radius, energy, and speed ratios of $\mathcal{T}_{3B}$.
3. The plane-orientation determinant D_{plane} and handedness data.
4. The energy differentials ΔE_{ab} and their wake-history decomposition.
5. The response of the branch to a sea of like assemblies.
6. The capture or exclusion behavior of additional architrinos near the branch.

The classification is topological only where the entries are invariant under branch-preserving deformation. It is dynamical where the entries depend on energy balance, phase locking, sea response, and return-map stability. A promoted table must therefore carry both topological labels and dynamical margins.

Accessory Configuration Capture

After a stable braid has been retained, the next search level asks whether an **Accessory Configuration** can couple to that braid without destroying the braid ledger. An Accessory Configuration is exactly six additional architrinos, each with a declared electrino or positrino polarity, that are associated with the braid but are not members of its neutral six-architrino core. Their positions may be inside, across, or outside the braid envelope. The name does not prescribe an axial, polar, planar, or surrounding placement.

For a braid branch B, define the admissible configuration set in the six-site phase-position-history space by

$$\mathcal{C}_{\mathrm{acc}}(B) = \left\{ (\mathbf{X}_p, \mathbf{V}_p, \tau_p, \phi_p)_{p=1}^{6} : \mathrm{Retain}_{\mathrm{acc}}\left[B; (\mathbf{X}_p, \mathbf{V}_p, \tau_p, \phi_p)_{p=1}^{6}\right] = 1 \right\}.$$

The retention predicate must use the same causal-root, action, energy, and return-map conventions as the braid branch. It must preserve the braid ledger while giving all six accessory architrinos bounded delayed-return rows, finite energy exchange, and bounded phase drift. Six visually plausible positions are not an Accessory Configuration branch certificate.

Topologically, admissible capture preserves the braid's assembly topological charge while augmenting the complete assembly record with a six-site accessory ledger. If the core values of N_s, M_p, c_1, signed degree, or phase-return data change, the event is not capture in this sense; it is a braid reconfiguration through a fold, reconnection, or branch surgery.

The architectural question is therefore

$$B \longrightarrow \left(\mathcal{C}_{\mathrm{acc}}(B), (\tau_p)_{p=1}^{6}, \text{placement record}, \Delta E_{\mathrm{acc}}\right).$$

An axial six-site organization is one possible derived Accessory Configuration, not its definition. The retained calculation must decide the polarity assignment, placement, and path geometry.

Frame Orthogonality And Framing Anisotropy

The configuration-space program also supplies a compact theorem target for anisotropy leakage. A faithful rank-three Noether braid branch has two related order parameters: the frame determinant D_{plane} and the trace-free framing quadrupole Q_A used by Absolute Timespace. Let w_a be normalized spectral weights supplied by the retained action, energy, or angular-momentum tensor row, with $\sum_a w_a = 1$. The finite retained-frame representative of the foundation average is

$$Q_A^{ij} = \sum_{a=1}^{3} w_a \left(\hat{n}_a^i \hat{n}_a^j - \frac{1}{3} h^{ij} \right)$$

Writing $\lambda_a = w_a - \frac{1}{3}$ separates this into two channels:

$$Q_A^{ij} = \frac{1}{3} \left(\sum_{a=1}^{3} \hat{n}_a^i \hat{n}_a^j - h^{ij} \right) + \sum_{a=1}^{3} \lambda_a \left(\hat{n}_a^i \hat{n}_a^j - \frac{1}{3} h^{ij} \right), \qquad \sum_a \lambda_a = 0$$

where the first term measures non-orthogonal-frame leakage and the second term measures spectral-weight anisotropy. The weights are branch data, not parameters chosen after the fact.

The reachable theorem target is therefore two-part:

$$|D_{\mathrm{plane}}| \to 1 \quad \Longrightarrow \quad \left\| \frac{1}{3} \left(\sum_{a=1}^{3} \hat{n}_a^i \hat{n}_a^j - h^{ij} \right) \right\| \to 0, \qquad |D_{\mathrm{plane}}| \to 1 \quad \text{and} \quad \max_a |\lambda_a| \to 0 \quad \Longrightarrow \quad \|Q_A\| \to 0$$

while degeneration toward $D_{\mathrm{plane}} = 0$ may produce large framing anisotropy even with nearly equal weights. Orthogonality suppresses the non-orthogonal-frame contribution; near-degenerate retained spectral weights, shielding, or averaging must separately suppress the weight-anisotropy contribution. If both parts are proved for a retained branch class, the same geometric row would suppress Lorentz period anisotropy, clock-orientation leakage, Hughes-Drever-type inertial anisotropy, and scalar-mass anisotropy. Both parts remain theorem targets; no measured family comparison currently bears on them.

Relation To The Doubling-frequency Chapter

A3.3 Doubling-Frequency Resonance Lock studies one restricted member inside this broader configuration space. It asks whether the indexed A3 frequency triplet, especially the A3.3 relation $f_1 : f_2 : f_3 = 4 : 2 : 1$, can close as an integer phase-bundle lock with a stable return map and controlled caustic behavior. The A1.3 chart inherits the same frequency relation on the zero-axial-offset locus.

The doubling-frequency chapter should therefore be read as a specialized search row:

$$\mathcal{C}_{\mathrm{dbl}} \subset \tilde{\mathcal{C}}_{3B}.$$

Iso-frequency, unequal-radius candidates occupy a different row:

$$\mathcal{C}_{f=f=f} = \{B \in \tilde{\mathcal{C}}_{3B} : f_1 = f_2 = f_3\}.$$

Both rows are legitimate until the retained-branch certificates decide which, if either, survives. The general Noether braid search keeps the mathematics wide enough for the solver to discover stable configurations rather than forcing every stable Noether braid into a preselected frequency pattern.

B1 Hypotheses and Discrete Symmetry

This chapter owns the B1 harmonic-matching hypothesis, discrete-symmetry derivations, and open retention burden. The prescribed common-center, common-axis path geometry and its equatorial, axial, and axial-translation loci are defined in Braid Family B.

The status discipline of the braid stack binds throughout. B1 is a prescribed member, not a retained branch. The kernel-covariance results below are derivations within their declared scope; physical formation, self-support, retention, selection, and observer-level symmetry recovery remain open. The retained-branch certificate target of Braid Recovery Requirements governs those claims.

The Harmonic-Matching Hypothesis

The fixed-coordinate co-rotation hypothesis is motivated by a structural argument; the argument does not select the B1 antipodal geometry, and its quantitative force is untested. A circular orbit's kinematic requirement is a single-harmonic rotating vector, so only the time-constant part of the received causal wake in the co-rotating frame can supply it. Common-frequency co-rotation puts all wake power into exactly that part. Any relative binary motion — frequency locks between binaries, counter-rotation, or speed modulation — moves wake power into oscillating harmonics that circular kinematics cannot absorb, and the lowest-mode orbit deformations add kinematic harmonics faster than they match wake harmonics.

Causal delay is what would make this principle decisive rather than a soft preference. During one antipodal wake transit at near-field speed the pair rotates through roughly a third of a turn, so static-binding intuition — including the naive Kepler-third-law scaling for frequency-separated binaries — does not transfer to the delayed dynamics. Claim level: analytic structural argument; the comparative strength of common-frequency co-rotation against the other taxonomy members is not established.

The fixed-coordinate prescription has a second, exact consequence: every pairwise alignment scalar between sites is time-constant, so any alignment condition arranged once in the geometry holds around the entire cycle, sustained by the co-rotation itself rather than by a separate phase-locking mechanism.

Cyclic-Symmetric A2/B1 Overlap

The face-opposite A2 seed has a second exact chart on the body-diagonal axis $\hat{\mathbf{n}} = (1,1,1)/\sqrt{3}$. Every site has axial height magnitude

$$h = \frac{R}{\sqrt{3}}$$

and transverse radius

$$\rho = R\sqrt{\frac{2}{3}}, \qquad \frac{h}{\rho} = \frac{1}{\sqrt{2}}.$$

The three equal-radius path pairs share that axis, a common angular frequency and circulation sense, and phases separated by 120°. Under common-frequency co-rotation about $\hat{\mathbf{n}}$ they therefore occupy a cyclic-symmetric B1 sublocus. The same prescribed worldlines admit an A2 rotating-channel chart and a B1 chart; the labels describe coordinate structures and do not duplicate the physical inventory.

This overlap is independent of the Family-A $\lambda_A = 1$ boundary. It also does not certify retention. The scoped anti-damping results derive axial no-balance for a polarity-segregated interior fixed-coordinate two-ring chart, so that chart cannot be an equilibrium under those assumptions. The all-equatorial boundary remains the only fixed-coordinate B1-family locus not excluded by that axial argument, but it still requires the full retained-branch certificate.

Discrete-Symmetry Structure

Claim level: **analytical (derivation grade) for the declared kernel's discrete-symmetry covariance; derivation target for physical formation, branch retention, and weak-sector parity and CP recovery.** This section distinguishes what the interaction law fixes from what the imposed fixed-channel geometry and any later effective transaction operator would still have to establish.

The law's evenness. The pairwise causal-wake law is even under polarity conjugation C (every electrino $\leftrightarrow$ positrino: only the polarity product $\sigma_a\sigma_b$ enters, invariant under a global sign flip of every polarity) and even under parity P (the acceleration is radial along the delayed line of action, $\propto \hat{\mathbf{r}}/r^2$, with no primitive handedness). Two exact degeneracies follow at once, as theorems about the law rather than observations about a solution: the C-image of any closed configuration — the polarity-conjugate braid, the same geometry with every polarity reversed — is a degenerate solution, and the P-image — the mirror geometry with rotation sense reflected — is a degenerate enantiomer. Polarity conjugation does not change the pro/anti ordered orientation because it does not move a worldline.

The chiral invariant. A prescribed B1 member is chiral when its axial polarity dipole $\mathbf{p}$ (polar, reversed by both C and P) is locked to its spin $\mathbf{S}$ (axial, invariant under both C and P), with the binary phase offsets supplying the third locked structure. Their product is a pseudoscalar,

$$\chi = \operatorname{sign}(\mathbf{p} \cdot \mathbf{S}),$$

the declared chiral invariant of that prescribed member. Its transformation law is forced by the vector characters above:

operation	$\mathbf{p}$	$\mathbf{S}$	χ
C (polarity conjugation)	$-\mathbf{p}$	$+\mathbf{S}$	$-\chi$
P (parity)	$-\mathbf{p}$	$+\mathbf{S}$	$-\chi$
CP	$+\mathbf{p}$	$+\mathbf{S}$	$+\chi$

So C and P each reverse χ, while CP preserves it. For the declared polarity-product radial kernel, the C-, P-, and CP-transforms of any solution are degenerate transformed solutions. This is an exact covariance of the declared kernel; it does not establish formation into an ι-fixed history, branch retention, or CP conservation in weak reaction channels. Claim level: derivation grade for the declared kernel.

The pro/anti ordered orientation is a separate sign. Let o_{PA} denote the deformation-stable orientation extracted from the indexed B1 path or angular-momentum-frame record. It is not a high/middle/low radius order. Because C leaves worldlines fixed, o_{PA} is C-even; because P mirrors the orientation, it is P-odd. The polarity-assignment sign on this chart is therefore

$$c_{\mathrm{pol}} \equiv \chi o_{\mathrm{PA}}, \qquad \chi = o_{\mathrm{PA}} c_{\mathrm{pol}}.$$

Thus C reverses c_{pol} at fixed o_{PA}, while P reverses o_{PA} at fixed c_{pol}. With left/right defined by the sign of χ, C maps a left braid to a right polarity-conjugate braid on the same pro/anti orientation; CP maps it to a left polarity-conjugate braid on the mirrored orientation. This is exact covariance of the declared kernel plus definition-level sign bookkeeping. It does not establish formation, branch retention, or CP conservation in weak reaction channels.

Any axial polarity-orientation selection must be C-covariant. If a dynamical mechanism selects a preferred drift orientation relative to the axial polarity dipole — one polarity-leading side — the kernel evenness forces the selection to lock to χ rather than to an absolute polarity: a braid and its C-image would lead with opposite polarities, and the two configurations would be exactly degenerate under the kernel covariance. Whether any such selection mechanism exists is an open question; none is asserted here.

The crossing order is the observable face of o_{PA}, not of χ alone. An observer stationed on the incoming drift axis, watching the three binary paths cross a reference meridian as the braid rotates, records a fixed cyclic order — $1{:}2{:}3$ or $1{:}3{:}2$ — whose sign is o_{PA}; the two orders are the P-image enantiomers. Polarity conjugation leaves that sequence unchanged while reversing χ. For a prescribed common-frequency co-rotating chart this order is a structural invariant, and its invariance is also a representability marker: a genuine closed braid preserves the order, whereas a differential- or counter-rotating configuration lets the binaries lap and the order scramble.

Which channels could read the glove. Effective channels that do not resolve the internal lock are candidates to inherit the declared kernel's parity covariance. A weak-flavored transaction channel that reorganizes the internal lock is a candidate route by which a maximal B1 lock could produce maximal parity selectivity, but no weak-transaction operator has yet been derived from a retained branch record. The primitive kernel remains CP-covariant; reproducing the measured nonzero CP asymmetries therefore requires a separate CP-odd effective event or branch residual. Candidate sources include Noether sea polarity/chirality texture and interference between transaction paths at different drift-dependent internal angles, but these are hypotheses rather than established next-order terms. The combined CPT benchmark is carried in Angular Momentum and Spin.

The B1 construction therefore supplies a conditional discrete-symmetry scaffold, not yet a recovery of the observed pattern. A retained chiral branch and a derived weak-transaction operator must still produce the observed handedness selectivity, while a separate CP-odd event or branch residual must reproduce the measured kaon and B-system asymmetries. Neither recovery has been established. Claim level: derivation target for weak parity and CP recovery; the primitive-kernel covariance is exact within its declared scope.

Candidate Status and Open Burden

B1 is a prescribed member. Everything beyond its exact geometry and the declared kernel-covariance structure is open: whether any realization satisfies the master equation, whether a satisfying realization persists under evolution, whether persistence requires an environment, and how B1 compares with the other taxonomy members. Those questions are governed by the retention contract of Braid Recovery Requirements. Results enter this chapter only when established, with instrument and claim level stated.

Braid Mathematics

Six architrinos interacting through delayed causal wakes form a hard dynamical problem: the state is an entire path history, the per-hit accelerations arrive along causal roots that must be solved for, and no general closed-form solution exists. This chapter collects what can nevertheless be established exactly — by symmetry, geometry, and kinematics — before any support-band structure is chosen and before any branch is claimed to persist. The machinery here is core-agnostic: every braid realization in the Noether Braid family consumes it, and none of it asserts branch retention.

The results divide by strength, and the division is stated with each result. Exact derivations include the transverse speed-budget lemmas and the constant-lag reduction of the rotating-wave ansatz. Scoped negative results include the anti-damping family, which rejects specific fixed-coordinate charts without rejecting the braid program. Candidate mechanisms at hypothesis level include the action-click picture at the causal-root fold set and the Accessory Configuration moment analysis. Theorem targets include the eigen-braid spectrum system. Claim levels travel with their statements throughout. The A2-specific invariant channels, two-ring geometry, dipole identity, momentum-screw alignment, and return-response analysis live in A2 Symmetry and Return Response.

Document Role

This chapter owns the shared mathematical machinery of the braid family: the substrate levels and speed hierarchy with the transverse speed-budget lemmas, the spiral-helical motion picture and mass thesis, the hinge equation sketch, the bounded-weight inverse-square escape lemma, the acceleration-gradient comparison, the scoped anti-damping negative results, the eigen-braid spectrum framing, the action-click mechanism, and the Accessory Configuration moment analysis. The neutral six-body base lives in Noether Braid; prescribed coordinates and definitions live in Braid Taxonomy, Braid Family A, and Braid Family B. The realization-independent proof obligations live in Braid Recovery Requirements. Realization chapters state which of this machinery their configurations inherit and what fixture-specific evidence they add.

Substrate and Effective Levels

Braid dynamics uses four levels of description:

Level	Meaning
Substrate ontology	Euclidean void, absolute substrate time T, architrinos, causal wakes, and causal-root branch structure.
Assembly dynamics	Noether braids, their coupled binary layers, self-hit multiplicity, shielding, phase closure, and root-ledger transitions.

Level	Meaning
Observer-inference exports	Rest mass, photon propagation, reconstructed kinematics, geodesics, and horizon behavior as later reconstructed by assembly-built observers.
Inference and closure status	Mathematical closures that remain to be derived before effective claims can be treated as proved rather than reconstructed.

The distinction matters because the Euclidean void is not being curved at the substrate level. Curvature, geodesic motion, lapse, and horizon language enter only as observer-level bookkeeping reconstructed downstream from Noether sea state variables and assembly response.

Speed Hierarchy

Several speed symbols must remain separated:

Symbol or phrase	Meaning
c_f	Primitive wake propagation speed in the substrate.
$c_{\text{eff}}(\mathbf{X}, T)$	Noether sea dressed assembly-channel propagation speed used only after a downstream observer-channel map has been declared.
$c_\gamma(\mathbf{X}, T)$	Local photon-channel speed; equality with $c_{\text{eff}}(\mathbf{X}, T)$ is a photon-channel closure target for the working observer-level photon branch, not a definition.
Locally measured light speed	The operational speed reconstructed downstream from assembly periods, rulers, and photon synchronization.

The primitive speed c_f is used for wake-intersection and self-hit geometry. The effective speed c_{eff} belongs to Noether sea dressed closure and observer-level comparisons. These are not interchangeable. Any diagnostic that moves from primitive wake geometry to observer-level periods, rulers, or photons must declare its dressing map outside the primitive branch calculation.

Transverse Causal Budget Lemma

When a retained moving branch is exported to a clock, ruler, or photon-synchronization channel, the branch must declare the channel speed used by that export. The primitive branch chart solves causal roots with c_f. A dressed clock/ruler comparison uses $c_\star = c_{\text{eff}}(\mathbf{X}, T)$ after the Noether sea dressing map has been declared, while a photon synchronization comparison uses its declared photon-channel speed $c_\gamma(\mathbf{X}, T)$. The weak homogeneous measured limit may identify the declared channel speed with c_0 only after the clock, ruler, and photon rows collapse to one observer-accessible speed within the preferred-frame leakage budget.

For a branch whose response center drifts through the local Noether sea with material drift $\mathbf{w}$, the transverse budget is

$$c_\star^2 = \|\mathbf{w}\|^2 + c_\perp^2, \qquad \beta_\star = \frac{\|\mathbf{w}\|}{c_\star}, \qquad \gamma_\star = \frac{1}{\sqrt{1-\beta_\star^2}}$$

Thus an observer-export clock or ruler row must extract

$$\frac{c_\perp}{c_\star} = \frac{1}{\gamma_\star}$$

from the same retained branch record, not append it as an independent Lorentz factor. The lemma fails as a citation target if a calculation solves primitive roots with c_f and then reports an observer-level clock, ruler, or photon speed without the declared dressing map, or if the clock, ruler, and photon rows are sourced from different branch ledgers.

Transverse Internal-Motion Speed-Budget Lemma

Let one site's native velocity be decomposed into group translation and internal motion,

$$\mathbf{V}_i = \mathbf{V}_{\text{grp}} + \mathbf{v}_i^{\text{int}}$$

The exact native speed identity is

$$\|\mathbf{V}_i\|^2 = \|\mathbf{V}_{\text{grp}}\|^2 + \|\mathbf{v}_i^{\text{int}}\|^2 + 2\mathbf{V}_{\text{grp}} \cdot \mathbf{v}_i^{\text{int}}$$

If the internal motion is transverse to the group translation at every instant, then the cross term vanishes and the site speed is the exact quadrature

$$\|\mathbf{V}_i\|^2 = u^2 + v_{\mathrm{int},i}^2, \qquad u = \|\mathbf{V}_{\mathrm{grp}}\|, \qquad v_{\mathrm{int},i} = \|\mathbf{v}_i^{\mathrm{int}}\|$$

If a branch additionally pins the total site speed to $\|\mathbf{V}_i\| = \beta_{\mathrm{pin}} c_f$, the available internal speed is forced to

$$v_{\mathrm{int},i}(u) = \sqrt{\beta_{\mathrm{pin}}^2 c_f^2 - u^2}$$

The quadrature is exact kinematics under the transverse-motion hypothesis. The pinning of β_{pin} is a separate branch hypothesis, not an established retention mechanism. The A2 body-diagonal rotating channel and the B1 axial screw chart are two realizations of the transverse geometry; neither realization makes fixed total site speed automatic. A record with $\mathbf{V}_{\mathrm{grp}} \cdot \mathbf{v}_i^{\mathrm{int}} \neq 0$ falsifies use of the quadrature for that site and must retain the cross term, which generally makes the maximum speed phase dependent.

The same pinned-speed hypothesis appears in the retained A1 scaling material of A1 Dynamics: a branch that holds an indexed internal speed fixed while accepting action transactions is forced onto the $R_a f_a \approx \mathrm{constant}$ product law. The shared lemma shows how the hypothesis would also constrain transport; it does not establish that A1, A2, or B1 satisfies the pinning condition.

Spiral-Helical Motion Picture

A resting Noether braid is a phase-locked structure of coupled binary layers. When the braid moves with center-of-mass velocity $\mathbf{V}_{\mathrm{cm}}$, the rest-state circular or near-circular binary motions are drawn into braided spiral-helical cable patterns through the Euclidean void.

The spiral-helical picture is not decorative. A causal wake sent between partners, or between the layers, must now reach a receiver that has moved during the wake's travel time. The internal phase geometry must therefore retune its pitch, radius, tilt, and timing to preserve the same closure ledger. In dynamics language, bulk velocity is encoded as internal geometry.

This is the common mechanical basis for three later downstream readouts:

- branch-period stretch, because each completed internal cycle requires a different causal path in absolute time;
- longitudinal ruler contraction, because inter-assembly spacing must retune for forward and backward exchange;
- inertial response, because acceleration forces the internal causal ledger to re-close under a changing kinematic bias.

Mass Thesis as a Dynamics Target

The conservative mass thesis is that rest mass is not primitive architrino substance. It is the externally measurable response of shielded, phase-locked internal causal history.

In roadmap form, the target relation is

$$m_0(A) c_{\mathrm{eff}}^2 \sim \zeta(A) E_{\mathrm{internal}}(A)$$

where $E_{\mathrm{internal}}(A)$ is the closed internal causal-history energy ledger of assembly A, and $\zeta(A)$ is the shielding or leakage factor that controls how much of that ledger couples to external probes. This is not yet a derived mass formula. It becomes a theorem only after the shielding factor, the internal energy ledger, and the first-order momentum-skew response are derived from the closed braid dynamics.

Hinge Equation Sketch

Equation of motion near the hinge ($v \approx c_f$) For each architrino i interacting with its partner j:

$$\frac{d^2\mathbf{X}_i}{dT^2}(T) = \mathbf{a}_{i,j}(T; \{T_{p,k}\}) + \mathbf{a}_{i,i}^{\mathrm{active}}(T; \{T_{s,m}\}) + \mathbf{a}_{\mathrm{ext}}(T)$$

with delay constraints (causal roots):

$$\|\mathbf{X}_j(T_{p,k}) - \mathbf{X}_i(T)\| = c_f\,(T - T_{p,k}), \quad \|\mathbf{X}_i(T_{s,m}) - \mathbf{X}_i(T)\| = c_f\,(T - T_{s,m})$$

where $\mathbf{a}_{i,i}^{\mathrm{active}}$ is a shorthand for the sum over retained self-hit roots in $\mathcal{C}_{ii}(T)$, not an instantaneous switch $H(s-1)$. Self-hit remains path-history dependent: roots emitted during an earlier super-field-speed interval can stay active after the current speed has changed.
The second constraint is the native small-scale bridge-like causal structure in this sketch: the receiver at $\mathbf{X}_i(T)$ is linked to an earlier point on the same worldline by its own causal wake. The connectedness is path-history closure in the causal-root ledger,

not a tunnel in the Euclidean void. Any connected-geometry translation belongs only after coarse-graining into an effective horizon-interface or metric description.

and $s = \|\mathbf{V}\|/c_f$. For symmetric, non-translating circular geometry, the delay angles satisfy

$$\delta_p = 2s\cos(\delta_p/2), \qquad \delta_s = 2s\sin(\delta_s/2)$$

with no self-hit solution for $s \le 1$ and a small-root branch $\tilde{\delta}_s \to 0^+$ for $s > 1$. The radial/tangential split then reads

$$\ddot{r} - r\dot{\theta}^2 = A_{\text{rad}}(\delta_p, \delta_s), \qquad r\ddot{\theta} + 2\dot{r}\dot{\theta} = T(\delta_p, \delta_s)$$

The symmetry breaking at the hinge is geometric: as $\tilde{\delta}_s \to 0^+$ the self-hit radial factor scales like $1/\sin(\tilde{\delta}_s/2)$, turning on a large outward term while the state remains continuous.

The working guess that the self-hit regime may change the effective action-step scale from ΔL_c to $2\Delta L_c$ is a theorem burden for the broader causal-closure program. This chapter keeps only the local hinge geometry needed to state the dynamical branch condition.

Bounded-Weight Inverse-Square Escape Lemma

Let $R(T) > 0$ be a declared outward scalar coordinate on an interval where $\dot{R} > 0$, and suppose the complete projected acceleration satisfies

$$\ddot{R} \ge -\frac{K}{R^2}$$

for a constant $K > 0$. Then

$$\mathcal{E}_R = \frac{1}{2}\dot{R}^2 - \frac{K}{R}$$

is nondecreasing, because

$$\frac{d\mathcal{E}_R}{dT} = \dot{R}\left(\ddot{R} + \frac{K}{R^2}\right) \ge 0.$$

If at some T_*,

$$\dot{R}(T_*)^2 > \frac{2K}{R(T_*)},$$

then $\mathcal{E}_R(T_*) > 0$ and $\dot{R}$ cannot later reach zero while the hypotheses remain valid. This is an escape certificate for that scalar chart, not a family-general no-binding theorem.

A braid application must derive R and the bound K from the actual retained acceleration ledger. A speed cap, separation floor, acceleration-weight cap, and polarity inventory can supply such a bound only when their projection covers every retained root contribution on the same interval. Failure of any bound suspends the certificate. The A2 isolated-release channel is one conditional application route; see A2 Symmetry and Return Response.

Acceleration-Gradient Branch Comparison

The local dynamics burden behind later equivalence-principle recovery is a substrate comparison, not an observer postulate. A uniformly accelerated assembly and a stationary assembly placed in a matched Noether sea gradient should output compatible delay-geometry records on the same kind of branch packet (the scan packet defined with A1 diagnostics in A1 Dynamics):

$$\mathcal{D}^{\text{accel}}_{A1}(W) \sim \mathcal{D}^{\text{grad}}_{A1}(W)$$

with the comparison made from phase-closure residuals, anisotropy ratios, branch-period records, stability thresholds, and cycle-averaged causal-work or phase-slip variance.

The ambient Noether sea must participate in this comparison. Deforming the assembly alone is not enough, because the gradient-driven case changes the Noether sea response record while the accelerated case changes how the same retained causal-root ledger is transported through absolute time. The downstream observer-inference question is whether those exported packets recover the usual local equivalence behavior. This chapter only asks whether the substrate packets match before that translation.

Scoped Anti-Damping Results

A recurring obstruction shapes the whole retention program: in chart after chart, the delayed kernel does net positive work on the assembly's current motion. The wake pushes forward rather than braking — anti-damping — so a persistent braid cannot close as a static acceleration balance; it must supply an exchange or export channel for the pumped action. The evidence family consists of scoped negative results, each valid only under its own chart, kernel, and conventions:

1. **Circular partner-wake binary.** On the uniform circular benchmark, the retained circular row has an inward radial component and a forward tangential work row; the combination accelerates the orbiting motion and prevents a partner-only constant-speed circle. Any sub-field-speed contraction claim must beat this row through non-circular geometry, wake-flux export, recoil, or a later multi-root ledger. The detailed statement lives in Binary Dynamics.
2. **Collinear self-hit reading.** Along a true collinear history, the same-transmitter term is naturally read as an anti-damping or positive-work contribution on the physically relevant post-crossing outbound branch: self-interaction tends to reinforce the current radial motion rather than furnish a centrifugal-style barrier. The open question is therefore whether partner attraction can recapture the motion despite that self-drive.
3. **Fixed-coordinate octahedral chart.** The fixed-coordinate zero-offset octahedral carrier at fixed speed is conjectured to carry a nonzero tangential residual rejecting the narrow fixed-speed branch chart; this conjecture is unverified, and the reading discipline for that chart is recorded in Braid Recovery Requirements.
4. **Zero-angular-momentum channel invariance.** The face-opposite seed placed on the zero-angular-momentum channel stays exactly on that channel: the dynamic center holds at zero, all six radii stay equal, and antipodal partners stay exact. This is the invariant-channel theorem, not a statement of the seed's dynamical fate, which is open; the fixture record lives in the A2 isolated-release analysis.
5. **Fixed-coordinate single-frequency rotating-wave family.** The fixed-coordinate single-frequency A2 rotating wave fails twice, independently. Axially: same-ring contributions have exactly zero axial component, while every opposite-ring contribution pulls the two rings together, and a sum of strictly one-signed terms cannot vanish — so this rotating wave has no axial equilibrium at any two-ring aspect and any sub-field rim speed, and the tested single-frequency family, if it existed, would be forced planar. This axial no-balance statement is a derivation. Tangentially: on the planar hexagon, the conjectured behavior is a strictly positive tangential residual growing with rim speed while the radial residual stays inward — the delayed kernel pumping the rotation rather than braking it. That tangential conjecture is unverified; the axial derivation stands on its own.

The reading discipline matters as much as the results. Each entry is scoped to the chart and assumptions that produced it; the agreement across charts is qualitative consilience, and no ledger quantity may be consumed across charts. None of these results rejects the neutral braid, A1, A2, B1, and C-family, bounded-speed, controlled self-hit, fold-layer, or medium-response programs.

The constructive consequence is a sharpened search. The scoped negative results direct the live search away from the tested fixed-coordinate single-frequency charts. They do not prove that every retained branch must deform. Candidate alternatives exchange pumped tangential action with another internal channel — radial breathing against rotation or the two-frequency class whose closed figures are the integer phase-closure states — absorb it through same-transmitter contributions at the field-speed hinge, or export it to a Noether sea environment. A fixed-coordinate ansatz cannot represent wake exhaust by construction, so a retained branch must have somewhere to put any pumped action, with escaped boundary flux recorded by wake escapement. The spectrum hunt below therefore emphasizes relative periodic orbits while leaving any untested relative-equilibrium branch to its own acceptance record.

The Eigen-Braid Spectrum

If persistent braids exist, the family should have a spectrum: a discrete set of admissible internal configurations, the way a bounded resonator has modes. The natural first ansatz is the rotating wave — a relative equilibrium of the delayed dynamics on the body-diagonal channel,

$$\mathbf{X}_\ell(t) = \mathrm{Rot}(\hat{\mathbf{n}}, \omega t)\,\mathbf{X}_\ell(0) + u\,\hat{\mathbf{n}}\,t$$

with angular rate ω and axial drift u. On the channel the free data reduce to the representative worldlines of the equivariant reduction, and the natural branch coordinate is the screw pitch, equivalently the pair (u, ω) with the channel radius.

A constant-lag reduction makes the ansatz tractable, and it is a derivation. On the rotating-wave ansatz, every directed-pair causal delay is constant in time: splitting any initial separation into axial and transverse parts relative to $\hat{\mathbf{n}}$, the rotation acts only on the transverse part and the drift only on the axial part, so the separation norm between reception time T_r and transmitter emission time $T_r - \tau$ depends on τ alone. Each directed pair's root residual

$$F_{ij}(\tau) = \|\mathbf{\Delta}_\perp(\tau)\|^2 + \left(\Delta_\parallel + u\tau\right)^2 - c_f^2\tau^2$$

is a fixed transcendental function of the lag τ, and causal roots are its zeros: constant phase lags. The same argument covers same-transmitter root records. The consequence is structural: on this ansatz the state-dependent delay system collapses to a finite algebraic problem, and the infinite-dimensional history disappears from the unknowns.

The spectrum system is then a theorem target. An admissible rotating-wave row is a solution of a finite residual system: for each representative receiver, the kinematic identity that the kernel sum over all constant-lag roots equals the ansatz acceleration; the root equations $F_{ij}(\tau_r) = 0$ for every retained lag in the declared root-topology class; and the admissibility inequalities — sub-field speed or declared hinge occupancy, positive Jacobian floors, transmitter-side acceleration-weight floors, noncollision margins. Solutions form the **eigen-braid spectrum**: for fixed drift and fixed root-topology class, a solution set $\{(\omega_k, R_k)\}$ indexed by root topology and winding data. Discreteness is a target rather than an assumption — the residuals are real-analytic away from caustics and collisions, so solution sets are generically isolated, and a degenerate continuum would itself be a reportable structure.

A second interface target rides on the spectrum. Each row carries a definite screw pitch and helicity sign, and the interface hypothesis is that admissible rows at fixed root topology form a discrete pitch ladder whose transitions are root-topology transitions — the click picture below — so that action quantization is inherited from integer root counts rather than imposed.

The current status keeps the target honest. The axial no-balance derivation above forces the tested fixed-coordinate single-frequency family planar, and the anti-damping indications (where they hold) disfavor it further, so the live spectrum question is posed for relative periodic orbits — breathing against rotation with periodic rather than constant delays — and for hinge-occupying and sea-embedded rows. A found row would still be a relative equilibrium or relative periodic orbit only; transverse stability, action and wake balance, and the same-record rows of Braid Recovery Requirements all remain between a spectrum row and a retained branch.

Action Clicks at the Fold Set

The material in this section is a candidate mechanism at hypothesis level: it proposes how the discrete action transaction of the cadence-scale retuning hypothesis is physically implemented, and none of it is yet supported by a retained branch record.

Start with an everyday machine. A mechanical watch does not spend energy continuously; an escapement lets the stored energy advance the mechanism one discrete click at a time, and the click count is an integer because a gear tooth is either engaged or it is not. The proposal here is that the field-speed hinge is the braid's escapement.

Three properties make the field speed special for the hinge row, and none of them is arbitrary. First, c_f is the boundary of self-interaction: delayed same-transmitter causal roots exist only for a strand that has exceeded field speed somewhere on its recent path, so crossing the edge is not a matter of degree — it opens a class of causal roots that simply do not exist below it. Second, the transmitter-side factor of the transmitter-side acceleration weight W^{acc} approaches its caustic as a source's normal speed approaches c_f, so the edge is where wake delivery is most sharply concentrated. Third, for a given support radius, the stored kinematic angular momentum of a row grows with its tangential speed and saturates at the sub-field edge, so the hinge is the configuration that stores the most angular momentum per unit radius without opening the self-interaction ledger. The hinge row sits at the marginal point of all three properties at once.

The click itself is then a root-topology event, and it already has a canonical mathematical home: the causal-root fold set Σ_{ij} defined in Architrino, where the root residual and its emission-time derivative vanish together. An accepted transaction momentarily carries the hinge row across the edge, one same-transmitter causal root opens or closes — a controlled crossing of the fold set rather than a pathology — and the branch re-locks below the edge with its integer ledger changed by one. Quantization on this reading is not imposed on the dynamics; it is inherited from the fact that a causal root either exists or does not, so the count of active roots is an integer and every admissible transaction changes it by a whole step. The closed-cycle action unit h_{act} is the action transacted in one such click, and the statement that closure-label changes are tied to causal-root bifurcation becomes the click's formal description. The hinge acts as the assembly's double-entry accountant: each click posts one entry to the internal integer ledger and a matching entry to the outgoing wake, so the books balance event by event rather than continuously. A wake entry remains on the books whether or not it is ever received; in a populated Noether sea essentially every entry is eventually redeemed by some receiver, and the unredeemed remainder is regulated by the medium's convergence requirement rather than lost.

The click is also an instance of the codimension-one transition pattern stated in Emergence of Structure: an integer branch label changes only when the retained chart crosses a singular stratum, and self-hit onset is named there as exactly such a fold. The hinge click is that fold crossed deliberately and repeatedly, under control, as the branch's transaction mechanism.

The statistical layer is where familiar physics should emerge. A single braid is a discrete clicking system: its energy record changes in whole steps at particular instants, and the timing of a given click depends sensitively on the phase of the internal cycle when the transaction arrives, which makes individual click outcomes practically unpredictable even though the substrate dynamics is deterministic. Click-outcome weights therefore belong to the declared-measure basin formalism of Emergence of Structure: a click probability is a basin volume under a declared preparation measure, and any Born-rule contact inherits that chapter's measure discipline rather than adding a probability postulate. A population of braids clicks asynchronously, and the coarse-grained result is a smooth cadence-space current — the same relationship as between molecular collisions and smooth gas pressure. On this reading, the smoothness of observed energy exchange is a law-of-large-numbers statement about click ensembles, and the discreteness that quantum measurements keep finding at the bottom is the escapement showing through. The same picture supplies a destabilization boundary: a transaction rate slow compared with the internal cadence lets the braid re-lock between clicks (an adiabatic exchange), while forcing faster than the cadence — a sharp transverse re-pointing of the branch axis, or an abrupt longitudinal deceleration — outruns the re-locking and breaks the phase lock instead of advancing it, releasing structure rather than storing action. Whether this adiabatic-to-diabatic boundary reproduces observed radiative and decay thresholds is an open, falsifiable target: in solver records, clicks should appear as integer transitions in the active root count of the hinge row, and the declared hinge tolerance is the click window.

Fold Geometry of the Click: Coincidence Versus Finite Chord

Whether a hinge click can supply a clean, chart-defined transacted amount depends on where on the fold set the crossing is born, and the two singular loci of the point-transceiver ontology separate the cases. Architrino distinguishes the coincidence stratum $\{r_{ij} = 0\}$ — a spatial point-kernel problem that requires a declared spatial regularization — from the caustic stratum $\{\partial_{T_t} F_{ij} = 0\}$ — a causal-root fold that requires a fold-resolution chart. A click carries a chart-defined magnitude only when its crossing sits on the second locus while staying clear of the first.

A same-transmitter (self-hit) crossing on a smooth strand is born on the coincidence stratum. As the causal lag $\Delta \to 0$ the separation is $\|\mathbf{X}(T) - \mathbf{X}(T-\Delta)\| = |\mathbf{v}|\,\Delta + O(\Delta^2)$, so the same-transmitter root nucleates exactly at the field-speed crossing with a vanishing chord, $r_{ij} \to 0$ as the root opens. On the symmetric one-band channel this onset is a cusp rather than a generic fold, and the transacted amount is not fixed by the fold chart; it is set by the declared spatial regularization scale ϵ_c. Identifying the physical value of ϵ_c with a conditional minimum-circular-binary or near-field two-body scale is a separate hypothesis, not part of the substrate regularization definition. This is a scoped negative for any single-site absorber picture: the symmetric single-site self-hit cannot supply a chart-defined transacted amount, because its magnitude is a property of ϵ_c rather than of the branch geometry. Same-transmitter rows remain in the ontology; they simply do not fix a clean click on their own.

A cross-hit crossing between two distinct strands can instead be born at finite chord. When the transmitter-side alignment $\mathbf{v}_j \cdot \hat{\mathbf{r}}_{ij} = c_f$ holds at finite separation, the crossing sits on the caustic stratum with $r_{ij} \neq 0$: a generic (Whitney A_2) fold of nonzero curvature whose transacted impulse is finite and independent of the short-distance regularization. This is the surviving route to a chart-clean click magnitude, and it is a theorem target rather than a result. It is contingent on a hinge geometry that sustains the alignment $\mathbf{v}_j \cdot \hat{\mathbf{r}}_{ij} = c_f$ across a click window — the same dynamic-alignment and formation-history condition that gates the A2 return-response question. Whether a braid's own formation and recycling dynamics hold that alignment long enough to transact is the open question on which the clean click magnitude, and with it the whole hinge-absorber route, depends.

Accessory Configuration

An **Accessory Configuration** is a declared set of six architrinos associated with a Noether braid but not included in the braid's neutral six-architrino core. Each accessory site has its own declared electrino or positrino polarity. The six positions may lie inside the braid's effective envelope, cross that envelope, or lie outside it; the term does not assume an axial layer, a surrounding shell, or any other placement geometry.

Let the accessory sites be indexed by $p \in \{1, \ldots, 6\}$, with polarity signs $\tau_p \in \{+1, -1\}$ and positions relative to the braid group center

$$\mathbf{r}_p(T) = \mathbf{X}_p^{\mathrm{acc}}(T) - \mathbf{X}_{\mathrm{grp}}(T).$$

The first configuration data are the net accessory polarity and polarity-signed spatial moments,

$$Q_{\mathrm{acc}} = \sum_{p=1}^{6} \tau_p, \qquad \mathbf{p}_{\mathrm{acc}} = \sum_{p=1}^{6} \tau_p \mathbf{r}_p,$$

with higher moments built from the same six signed positions. These moments are derived readouts of a specified Accessory Configuration. They do not determine the six trajectories, prove confinement, or establish a retained assembly.

At hypothesis level, configurations whose low-order polarity-signed moments cancel may expose less structure to distant receivers than configurations with the same net accessory polarity but larger surviving moments. The net polarity Q_{acc} cannot be hidden by rearranging the six sites. Any additional quietness ordering must be computed from the actual six-site polarity assignment, positions, path histories, and braid coupling. It cannot be inferred from an equal-polarity point arrangement or from a four-site or two-site substitute.

The required dynamical test is a same-record calculation: the braid core must remain retained while all six accessory trajectories acquire bounded causal-return ledgers, and the computed far-field wake must be compared with the moment ordering. The moment hypothesis fails if the first surviving moment does not track independently computed exposed-wake or mass-response records.

Candidate Braid Analysis Methodology

This chapter defines an analytical method for prescribed braid records. Its purpose is controlled comparison: every candidate is evaluated with the same causal-wake formula, probe set, retained-history rule, return window, and scoring rules before one geometry is said to cancel or expose more wake than another.

A prescribed record supplies known transmitter paths from which the delayed roots, wake superposition, virtual-probe response, cancellation, angular structure, and spectra can be evaluated at any event $(T, \mathbf{X})$. The method concerns only those analytical consequences of the declared paths. It does not assess assembly stability, environmental support, or any unprescribed motion.

The phrase **absolute observer position** means a coordinate probe at an event $(T, \mathbf{X})$ in absolute time and the Euclidean void. It does not introduce a Physical Observer or an effective spacetime frame. The native coordinates are

$$(T, \mathbf{X}) = (T, X^1, X^2, X^3).$$

Analysis Record

Every published candidate analysis must identify one source record. At minimum that record carries:

- the paths $\mathbf{X}_j(T)$, velocities $\mathbf{V}_j(T)$, polarities q_j, and persistent identities of all architrinos;
- the family/member identifier and complete taxonomy-coordinate row;
- the prescribed-geometry engine and chart version;
- the retained history interval, analysis window, return duration T_{ret}, and absolute-time origin T_0;
- the field speed c_f, coupling convention, root policy, self-hit policy, and any mollifier or cutoff;
- the spatial probe set, enclosing surfaces, temporal sampling rule, and numerical tolerances; and
- the source hash, engine identity, parameter vector, sampling seed, and generated result hash.

Write the scored result as $\mathbf{G}[S; P]$, where S is the complete source record and P is the complete analysis protocol. The protocol includes the probe set, history depth, root policy, surface geometry, normalization, tolerances, and sampling rule.

Any source change $S \to S'$ invalidates the prior score by default. A score may be retained only when a dependency review demonstrates that the changed field cannot enter that measure. In particular:

- a path, radius, frequency, phase, group-translation, polarity, or retained-history change requires new roots and recomputation of every downstream wake measure;
- a probe, boundary, root-policy, normalization, or tolerance change defines a new protocol P' and requires every compared candidate to be evaluated under P';

- an added environmental response defines a different analysis outside the scope of this method; and
- a metadata-only correction may preserve numerical measures only when the source identity and dependency review are recorded with the correction.

Comparing $\mathbf{G}[S;P]$ directly with $\mathbf{G}[S';P']$ is uncontrolled unless the difference is explicitly presented as a sensitivity study. The dependency review must state which measures were invalidated, which were recomputed, and why any retained measure is invariant.

Superimposed Causal-Wake Map

The $\mathbb{AAA}$-native wake equation used here is not an imported wave-equation partial differential equation. It constructs the superimposed causal-wake map from the same delayed causal isochrons used by the Master Equation. The equation is the construction rule. For one declared source record and analysis protocol, its evaluated scalar is the wake map; the map's spatial or temporal structure is its wake pattern, and a frequency or angular-mode decomposition is its wake spectrum. An assembly's wake is shorthand for the superposition of its constituent architrino wakes, not emission by the assembly as a single transmitter.

For source j, emission time $T_t < T$, and coordinate probe $\mathbf{X}$, define

$$\mathbf{r}_j(T,\mathbf{X};T_t) = \mathbf{X} - \mathbf{X}_j(T_t), \qquad r_j = \|\mathbf{r}_j\|, \qquad \hat{\mathbf{r}}_j = \frac{\mathbf{r}_j}{r_j},$$

and the causal constraint

$$g_j(T,\mathbf{X};T_t) = r_j(T,\mathbf{X};T_t) - c_f(T - T_t).$$

The active emission-time roots are

$$\mathcal{C}_j(T,\mathbf{X}) = \{T_t < T : g_j(T,\mathbf{X};T_t) = 0\}.$$

The source-normalized signed wake equation is

$$\boxed{\mathcal{W}(T,\mathbf{X}) = \sum_j q_j \int_{T_{\min}}^{T} \frac{\delta(g_j(T,\mathbf{X};T_t))}{4\pi r_j^2(T,\mathbf{X};T_t)}\, dT_t}$$

for the declared retained-history start $T_{\min}$. For fixed source record S and protocol P, the resulting scalar $\mathcal{W}(T,\mathbf{X})$ is the causal-wake map. It records signed causal-wake exposure under the declared source normalization. It is not by itself energy, potential, or acceleration.

For simple roots, define the transmitter-side factor

$$D_{t,j} = c_f - \hat{\mathbf{r}}_j \cdot \mathbf{V}_j(T_t).$$

The delta integral collapses to

$$\boxed{\mathcal{W}(T,\mathbf{X}) = \sum_j \sum_{T_t \in \mathcal{C}_j(T,\mathbf{X})} \frac{q_j}{4\pi r_j^2 |D_{t,j}|}}$$

when $|D_{t,j}| > 0$ on every retained root. A root with $D_{t,j} = 0$ is a caustic-like chart boundary and must be routed through the declared fold or regularization treatment rather than silently clipped.

Total path speed above c_f does not by itself invalidate this reduction. It removes the global shortcut that proves g_j strictly increasing from a whole-path speed bound, but the event can still contain finitely many transverse roots with either sign of $D_{t,j}$. The event-specific root policy therefore partitions the retained emission-time interval and, on each partition, uses declared bounds on speed, acceleration, distance, and the derivative

$$\frac{\partial g_j}{\partial T_t} = D_{t,j} = c_f - \hat{\mathbf{r}}_j \cdot \mathbf{V}_j(T_t)$$

to certify one of two dispositions:

1. the residual interval excludes zero, so the partition is root-free; or

2. the derivative interval excludes zero, so the partition is monotonic and any endpoint sign change isolates exactly one simple root.

Every isolated root is retained, including a descending branch with $D_{t,j} < 0$. The root ordinal is assigned in increasing emission-time order for that transmitter. The event is complete only when every retained partition has one of the two certified dispositions. If the subdivision depth or candidate-interval limit is reached while a possible root or fold remains, the event is **drawn but not evaluated**: it receives no score, and the unresolved interval, reason code, transmitter identity, and exact rerun instruction must remain in the campaign table. This fail-closed disposition is distinct from a measured gate rejection.

The unsigned companion ledger

$$\mathcal{W}_{\text{abs}}(T, \mathbf{X}) = \sum_{j} \sum_{T_t \in \mathcal{C}_j(T, \mathbf{X})} \frac{|q_j|}{4\pi r_j^2 |D_{t,j}|}$$

separates weak net exposure caused by cancellation from weak exposure caused by small individual contributions. The pointwise signed-cancellation ratio

$$\chi_{\mathcal{W}}(T, \mathbf{X}) = \frac{|\mathcal{W}(T, \mathbf{X})|}{\mathcal{W}_{\text{abs}}(T, \mathbf{X}) + \varepsilon_{\mathcal{W}}}$$

lies near zero when the signed contributions cancel and near one when they reinforce, subject to the declared denominator floor $\varepsilon_{\mathcal{W}} > 0$.

Explicit Prescribed-Orbit Reduction

For a circular prescribed endpoint with fixed orbit center $\mathbf{C}_j$, orthonormal plane vectors $\mathbf{u}_j$ and $\mathbf{v}_j$, radius R_j, angular frequency ω_j, and phase ϕ_j, write

$$\mathbf{X}_j(T_t) = \mathbf{C}_j + R_j \left[\mathbf{u}_j \cos(\omega_j T_t + \phi_j) + \mathbf{v}_j \sin(\omega_j T_t + \phi_j) \right].$$

At an arbitrary event $(T, \mathbf{X})$, define

$$\mathbf{d}_j = \mathbf{X} - \mathbf{C}_j, \qquad A_j = \mathbf{d}_j \cdot \mathbf{u}_j, \qquad B_j = \mathbf{d}_j \cdot \mathbf{v}_j,$$

$$H_j = \sqrt{A_j^2 + B_j^2}, \qquad \delta_j = \operatorname{atan2}(B_j, A_j).$$

The causal-root condition then reduces exactly to the scalar equation

$$\boxed{c_f^2 (T - T_t)^2 = \|\mathbf{d}_j\|^2 + R_j^2 - 2 R_j H_j \cos(\omega_j T_t + \phi_j - \delta_j)}$$

for each transmitter j. Thus the full spatial problem does not require evolving the source: at each requested $(T, \mathbf{X})$, solve this one-dimensional delayed-time equation over the retained history, substitute all certified roots into $\mathcal{W}$ or $\mathbf{A}_p$, and sum the six endpoint contributions. A translating orbit is handled by placing the declared center path $\mathbf{C}_j(T_t)$ directly in the original causal equation; the fixed-center reduction above applies in a co-translating coordinate chart only when that chart and its conversion back to absolute coordinates are stated.

This reduction supports complete time traces, spatial slices, enclosing-surface maps, angular decompositions, and spectra for prescribed circular records. More general prescribed paths use the same root equation $g_j = 0$ without the circular trigonometric reduction.

Virtual-Probe Response

The scalar wake map does not encode the polarity or direction of a receiving architrino. For a stationary virtual probe with declared charge q_p at $\mathbf{X}$, the acceleration-first response is

$$\boxed{\mathbf{A}_p(T, \mathbf{X}; q_p) = \sum_{j} \sum_{T_t \in \mathcal{C}_j(T, \mathbf{X})} \kappa \operatorname{sign}(q_j q_p) |q_j q_p| \frac{c_f}{|D_{t,j}|} \frac{\hat{\mathbf{r}}_j}{r_j^2}}$$

under the canonical simple-root acceleration convention of the Master Equation. The stationary probe is a comparison instrument, not an added source in the braid record. Positive- and negative-polarity probe responses must be reported separately when their distinction matters.

For a moving diagnostic probe $\mathbf{X}_p(T)$, the same arriving-hit strength applies at its current position. Its velocity changes root playback through

$$m_{p\leftarrow j} = \frac{D_{r,j}}{D_{t,j}}, \qquad D_{r,j} = c_f - \hat{\mathbf{r}}_j \cdot \mathbf{V}_p(T),$$

but $D_{r,j}$ does not multiply the instantaneous acceleration.

Wakes Experienced Inside the Braid

At receiver architrino i, set $\mathbf{X} = \mathbf{X}_i(T)$ and exclude i from the transmitter sum to obtain the wake received from the other architrinos:

$$\boxed{\mathbf{A}_i^{\text{others}}(T) = \sum_{j\neq i} \sum_{T_t \in \mathcal{C}_{i\leftarrow j}(T)} \mathbf{A}_{i\leftarrow j}(T; T_t)}$$

Self-hit acceleration, when active, is recorded separately as $\mathbf{A}_i^{\text{self}}(T)$. This separation prevents a geometry with strong self-hit support from being mistaken for one stabilized by inter-architrino exchange.

Over the complete orbital or return cycle,

$$T_0 \le T < T_0 + T_{\text{ret}},$$

the internal report must retain each pairwise contribution, the net vector, its components in the declared braid frame, root identities, D_t margins, and root-playback derivatives. Cycle averages must not replace peak values or root-transition events.

Because the paths are known, their required kinematic acceleration is also known analytically. Define the prescribed-path equation mismatch

$$\boxed{\mathbf{R}_i^{\text{path}}(T) = \frac{d^2\mathbf{X}_i}{dT^2} - \left(\mathbf{A}_i^{\text{others}}(T) + \mathbf{A}_i^{\text{self}}(T)\right)}$$

under the declared self-hit convention. This is a pointwise comparison between the acceleration required by the prescribed path and the acceleration supplied by the analytical causal-hit sum. Its peak, RMS, mean vector, phase dependence, and per-binary decomposition are legitimate prescribed-record measures. If the self-hit term or another accepted acceleration contribution is unavailable, the result must be labeled a partial mismatch rather than a complete Master Equation residual. A small mismatch measures compatibility of the declared chart with the evaluated acceleration contributions; it does not establish stability.

When the declared isolated acceleration inventory is certified complete, summing these rows gives a stronger falsification-only reduction. Define

$$\mathbf{S}_A(T) = \sum_i \mathbf{A}_i(T)$$

for the evaluated canonical-kernel acceleration supplied to every declared architrino. If the prescribed kinematics satisfy

$$\sum_i \frac{d^2\mathbf{X}_i}{dT^2} = 0$$

pointwise, as occurs for antipodal prescribed pairs about inertially moving centers, then any exact solution on that prescribed history must satisfy

$$\boxed{\mathbf{S}_A(T) = 0}$$

at every evaluation time. This follows directly by summing the individual equations of motion; it introduces no force, mass, momentum, return-map, or stability assumption.

Plainly: the prescribed pair accelerations cancel before the interaction law is evaluated, so the complete evaluated acceleration sum must also cancel at each instant if that exact history solves the equations.

A value of $\|\mathbf{S}_A(T)\|$ beyond the declared numerical tolerance and convergence allowance falsifies only that exact isolated prescribed history under the certified inventory. A zero value is recorded only as not falsified by this screen. It does not establish a branch, a taxonomy member, stability, retention, or physical realization. If the same-worldline contribution, root inventory, or another contribution inside the declared isolated system is not certified complete, the screen is inapplicable rather than partial.

The summed row can hide equal-and-opposite member errors. Therefore a certified complete inventory also carries the stronger pointwise member screen

$$E_\infty(W) = \max_{\substack{i \\ T\in W}} \left\| \mathbf{R}_i^{\mathrm{path}}(T) \right\|, \qquad E_2(W) = \left[\frac{1}{N|G_W|} \sum_i \sum_{T\in G_W} \left\| \mathbf{R}_i^{\mathrm{path}}(T) \right\|^2 \right]^{1/2},$$

where G_W is the declared time grid in window W. Any sampled member residual above the adjudication threshold falsifies that exact isolated prescribed history even when $\sum_i \mathbf{R}_i^{\mathrm{path}} = 0$. A sampled near-zero is only a search diagnostic and must survive time-grid refinement and independent causal-root residual checks.

Plainly: two wrong accelerations can cancel in the total. Checking every architrino separately prevents that cancellation from hiding a bad prescribed record.

For a declared cycle split into first and second halves, $W_P = W_{1/2}^{(1)} \cup W_{1/2}^{(2)}$, the same-grid reductions obey

$$E_\infty(W_P) = \max\left\{ E_\infty(W_{1/2}^{(1)}), E_\infty(W_{1/2}^{(2)}) \right\},$$

and

$$E_2(W_P)^2 = \frac{|G_1| E_2(W_{1/2}^{(1)})^2 + |G_2| E_2(W_{1/2}^{(2)})^2}{|G_1| + |G_2|}.$$

Thus one half-cycle is useful only as a staged early rejector. Candidate search minimizes the refined full-cycle E_∞ first and refined full-cycle E_2 second, while retaining both half-cycle peaks and their imbalance as diagnostics. One favorable half cannot support positive selection; both halves are required, and the window split changes no return-symmetry or taxonomy contract.

Plainly: the full-cycle worst error is exactly the worse half's worst error. Testing one half can save work when it already fails, but passing one half says nothing about the other half.

Probe Geometry

A candidate should be tested on the same nested probe geometry:

1. the braid center and each binary midpoint;
2. each architrino path and declared binary axis;
3. a three-dimensional interior grid covering the path-history envelope;
4. one or more enclosing surfaces S_R outside that envelope;
5. a far-field directional grid with enough angular resolution to separate isotropic and anisotropic leakage; and
6. adaptive samples near small-$|D_t|$ roots, close approaches, envelope extrema, and rapid phase changes.

The enclosing radius R must be large enough to test the intended far-field approximation and varied to show whether the extracted angular coefficients have settled. A single favorable direction cannot establish external wake cancellation.

Objective Measures

Every measure in this chapter is a deterministic analytical consequence of a prescribed source record. Root finding, quadrature, and sampling may be performed numerically, but they evaluate the declared formulas rather than evolving the source.

Prescribed-Record Analytical Measures

Measure	Definition or required record	What it tests
Prescribed-period closure	Position, velocity, and phase differences between T_0 and $T_0 + T_{\mathrm{ret}}$	Whether the declared formulas and chosen return period are internally consistent

Measure	Definition or required record	What it tests
Minimum separation	$d_{\min} = \min_{T,i\neq j} \lVert \mathbf{X}_i(T) - \mathbf{X}_j(T) \rVert$	Whether the prescribed chart contains a collision, an undeclared coincidence, or a near-singular pair geometry
Root-transversality margin	$\min \lvert D_{t,j} \rvert$ over all retained probe and internal roots	Distance from an unresolved causal-root fold
Root-topology ledger	Root counts, identities, births, deaths, and reconnections versus T	Whether averaged curves hide causal-branch changes
Internal prescribed-path response	Per-endpoint peak, RMS, and cycle integral of $\mathbf{A}_i^{\text{others}}$ evaluated on the prescribed paths	The acceleration that the other prescribed paths would deliver, not whether those paths persist
Prescribed-path equation mismatch	Peak, RMS, mean, phase-resolved, and per-binary rows of $\mathbf{R}_i^{\text{path}}$; when its hypotheses hold, the falsification-only pointwise sum $\mathbf{S}_A(T)$	Pointwise compatibility between the prescribed kinematics and the evaluated acceleration contributions, without promoting a non-falsifying sum to a branch claim
External signed exposure	$\mathcal{W}$ on S_R through the complete cycle	Net polarity-signed wake exposure
External raw exposure	$\mathcal{W}_{\text{abs}}$ on S_R through the complete cycle	Wake strength before signed cancellation
Complete-cycle signed normal wake flux	$F_{\text{signed}}(R)$ from the outward-normal projection of the signed causal-wake contributions	The global signed crossing total, which vanishes for a polarity-neutral assembly and is therefore not a cancellation score
Complete-cycle raw normal wake flux	$F_{\text{raw}}(R)$ with transmitter and root identities retained before absolute aggregation	The emitted wake measure crossing S_R before polarity cancellation; its source-normalized reference is $T_{\text{ret}} \sum_j \lvert q_j \rvert$
Complete-cycle residual normal wake flux	$F_{\text{res}}(R)$ from the absolute locally superposed signed normal flux	How much local signed wake survives cancellation over the complete cycle
Complete-cycle normal wake-flux cancellation	$\eta_{\mathcal{W},\text{flux}}(R) = F_{\text{res}}(R)/F_{\text{raw}}(R)$	Linear wake cancellation under the declared enclosing-surface convention, not energy or work
Frequency-resolved normal wake-flux cancellation	$\eta_{\mathcal{W},\text{flux}}^{(\ell mn)}(R)$ from transmitter-root-tagged complex coefficients	Which temporal harmonics and angular modes survive phase-sensitive signed superposition at each enclosing radius
Resonance-block cancellation score	$C_L(m,n;\phi)$ with certified tail bound ε_L for a declared lock	Whether the leading score gap over every alternative exceeds $2\varepsilon_L$ under the A3.3 cancellation certificate
Directional response	$\mathbf{A}_p$ for both probe polarities on S_R	Vector exposure and polarity dependence
Angular ledger	Cycle-resolved isotropic and higher angular coefficients	Which external angular channels survive cancellation
Anisotropy	Non-isotropic far-field ledger relative to the naive constituent ledger	Whether a scalar cancellation summary is adequate
Spatial response gradient	$\nabla_{\mathbf{X}} \mathbf{A}_p$ away from source paths and causal-root folds	How differently nearby absolute-coordinate probes respond
Temporal variation	$\partial_T \mathcal{W}$ and $\partial_T \mathbf{A}_p$ on continuous root branches	Peak rate of change and phase localization of wake features
Radial scaling	The same angular and exposure rows evaluated over a declared sequence of enclosing radii R	Whether a claimed far-field regime and its power-law scaling have been reached
Symmetry residual	Difference between a measure and its transform under each declared chart symmetry	Which prescribed symmetries survive in the causal-wake field
Spectral ledger	Fourier coefficients over T_{ret} for selected internal and external rows	Harmonic content, sidebands, and phase locking
Source-parameter sensitivity	Recomputed measures under declared changes of radius, frequency, phase, orientation, and translation	How dependent the analytical result is on the prescribed coordinates
Numerical convergence	Change under tighter root and quadrature tolerances for the same S and P	Whether the analytical result has been evaluated accurately

Minimum separation is a validity diagnostic, not a claim that architrinos are hard objects. A zero separation may make the $1/r^2$ response singular or expose an undeclared coincidence in the chart. A small separation warns that a reported score may be dominated by a near-singular pair. It should normally be a gate or an annotation, not a reward to maximize.

The term **return residual** is replaced here by **prescribed-period closure residual**. It checks only that the declared orbital path formulas return to the same position relative to the declared common translating center, and to the same velocity and phase, after T_{ret}. The absolute displacement of a translating source is recorded separately as $\mathbf{V}_{\text{grp}} T_{\text{ret}}$ and is subtracted before computing the orbital position residual. Closure is often zero by construction and is an integrity check on the chart and selected period, not a stability measure. Root and wake ledgers may also be checked for periodicity, but their endpoint differences remain analytical consistency diagnostics.

Spatial and temporal derivatives must be evaluated branch by branch. At a causal-root birth, death, or fold, the discontinuity or singular behavior is itself the reported event; a derivative must not be fabricated by differencing across it.

Two additional diagnostics are useful but must not be mislabeled as energy. Define the cycle-and-surface external-exposure norm

$$\mathcal{L}_{\mathrm{ext}}(R)=\frac{1}{T_{\mathrm{ret}}}\int_{T_0}^{T_0+T_{\mathrm{ret}}}\int_{S_R}\|\mathbf{A}_p(T,\mathbf{X})\|^2\,dA\,dT$$

and the corresponding uncancelled norm $\mathcal{L}_{\mathrm{raw}}(R)$ formed by replacing the net vector with the sum of constituent response magnitudes before squaring. Then

$$\eta_{\mathrm{ext}}(R)=\frac{\mathcal{L}_{\mathrm{ext}}(R)}{\mathcal{L}_{\mathrm{raw}}(R)+\varepsilon_L}$$

is a geometry-response exposure fraction. It measures external cancellation under a declared probe and surface convention. It is analytically computable from a prescribed record and is not the apparent-energy fraction.

Complete-Cycle Normal Causal-Wake Flux

The causal-wake map also supports a linear complete-cycle surface diagnostic. It is distinct from the acceleration-squared exposure fraction and from every energy construction. A plain surface integral of $\mathcal{W}$ is insufficient because it omits the direction in which each causal wake crosses the surface.

For a retained simple root emitted by transmitter j, define its outward-normal wake-flux density on S_R by

$$f_{j,T_t}(T,\mathbf{X})=\frac{q_j c_f}{4\pi r_j^2|D_{t,j}|}\hat{\mathbf{r}}_j\cdot\widehat{\mathbf{n}}$$

where $\widehat{\mathbf{n}}$ is the outward unit normal. The signed, raw, and residual complete-cycle measures are

$$F_{\mathrm{signed}}(R)=\int_{T_0}^{T_0+T_{\mathrm{ret}}}\int_{S_R}\sum_j\sum_{T_t\in\mathcal{C}_j(T,\mathbf{X})}f_{j,T_t}(T,\mathbf{X})\,dA\,dT$$

$$F_{\mathrm{raw}}(R)=\int_{T_0}^{T_0+T_{\mathrm{ret}}}\int_{S_R}\sum_j\sum_{T_t\in\mathcal{C}_j(T,\mathbf{X})}|f_{j,T_t}(T,\mathbf{X})|\,dA\,dT$$

and

$$F_{\mathrm{res}}(R)=\int_{T_0}^{T_0+T_{\mathrm{ret}}}\int_{S_R}\left|\sum_j\sum_{T_t\in\mathcal{C}_j(T,\mathbf{X})}f_{j,T_t}(T,\mathbf{X})\right|\,dA\,dT$$

The raw measure takes absolute values before transmitter contributions are superposed. The residual measure superposes the signed contributions first and then takes the absolute value. Their ratio

$$\eta_{\mathcal{W},\mathrm{flux}}(R)=\frac{F_{\mathrm{res}}(R)}{F_{\mathrm{raw}}(R)}$$

is admitted only when $F_{\mathrm{raw}}(R)$ exceeds the predeclared positive floor. The triangle inequality then gives $0\le\eta_{\mathcal{W},\mathrm{flux}}(R)\le 1$. Values near zero indicate strong local signed cancellation over the complete cycle; values near one indicate that little of the raw normal wake flux cancels.

The instantaneous normal fluxes on two enclosing spheres need not agree. At the same absolute time, the inner and outer spheres are crossed by wake surfaces emitted at different transmitter phases. No individual wake front stalls: the difference is the time derivative of the integrated wake measure currently in transit between the spheres. For nested fixed volumes $V_1\subset V_2$ containing every transmitter path,

$$\Phi_{\mathrm{raw}}(R_2,T)-\Phi_{\mathrm{raw}}(R_1,T)=-\frac{d}{dT}N_{\mathrm{raw}}(V_2\setminus V_1,T)$$

If the prescribed paths, retained history, and in-transit wake measure all return after T_{ret}, integration over the complete cycle removes this storage difference. For fixed convex enclosing surfaces,

$$F_{\mathrm{raw}}(R) = T_{\mathrm{ret}} \sum_j |q_j|.$$

This identity is both the source-normalized reference and an independent implementation check. The signed global integral similarly equals $T_{\mathrm{ret}} \sum_j q_j$ and therefore vanishes for a polarity-neutral braid. The residual $F_{\mathrm{res}}(R)$ and its ratio may still depend on radius because the signed contributions superpose differently after different causal travel delays. A far-field plateau is a measured radial result, not an assumed invariance.

These quantities measure causal-wake crossings only. They are not energy, potential, realized work, braid depletion, intrinsic leakage, or stability. A packet must reject the accepted wake-flux measures when roots or history are incomplete, a transmitter leaves an enclosing surface, the raw cycle integral fails its source-normalized reference after refinement, or the primary and refined time-and-surface quadratures fail their declared tolerance.

Frequency-Resolved Normal Wake-Flux Cancellation

The complete-cycle scalar $\eta_{\mathcal{W},\mathrm{flux}}(R)$ combines every temporal frequency and angular pattern. It therefore cannot show whether one wake harmonic cancels strongly while another survives. The phase-sensitive reduction must occur before any absolute aggregation.

Let a identify a retained transmitter-root branch, let $Y_{\ell m}$ be the declared real orthonormal spherical-harmonic basis, and let $\Omega_0 = 2\pi / T_{\mathrm{ret}}$. Define

$$\tilde{f}_{a,\ell mn}(R) = \frac{1}{T_{\mathrm{ret}}} \int_{T_0}^{T_0+T_{\mathrm{ret}}} e^{-in\Omega_0(T-T_0)} \int_{S_R} f_a(T, \mathbf{X}) Y_{\ell m}(\widehat{\mathbf{X}})\, dA\, dT.$$

The coefficient retains temporal phase, angular mode, enclosing radius, transmitter identity, and root ordinal. Form the raw and net coefficient magnitudes only after every transmitter-root coefficient exists:

$$A_{\mathrm{raw},\ell mn}(R) = \sum_a \left| \tilde{f}_{a,\ell mn}(R) \right|, \qquad A_{\mathrm{net},\ell mn}(R) = \left| \sum_a \tilde{f}_{a,\ell mn}(R) \right|.$$

For $A_{\mathrm{raw},\ell mn}$ above the declared effective coefficient floor, define

$$\eta^{(\ell mn)}_{\mathcal{W},\mathrm{flux}}(R) = \frac{A_{\mathrm{net},\ell mn}(R)}{A_{\mathrm{raw},\ell mn}(R)}.$$

The triangle inequality gives $0 \le \eta^{(\ell mn)}_{\mathcal{W},\mathrm{flux}}(R) \le 1$. A value near zero identifies strong phase-sensitive cancellation in one temporal-harmonic and angular-mode channel. A value near one identifies little cancellation in that channel. The reducer also reports the Euclidean norm over the retained angular modes for each temporal harmonic and evaluates those rows across the declared enclosing radii.

The effective coefficient floor is the larger of a declared absolute floor and a declared fraction of the largest raw coefficient on that enclosing surface. Source-root coefficients below that floor remain available as diagnostic rows, but they do not receive accepted cancellation ratios. A logarithmic radial fit for a net coefficient or cancellation ratio additionally requires the net magnitude to exceed the same floor at every fitted radius. This prevents numerical zero from acquiring an arbitrary radial exponent.

The frequency ledger must report retained-band coverage. A coefficient is accepted only when transmitter-root tags reconstruct the sampled signed normal flux, primary and refined grids agree within tolerance, and the transmitter-tagged signal outside the retained harmonic band remains below its declared RMS fraction. A Fourier transform of the rectified trace $\int_{S_R} |\sum_a f_a|\, dA$ is a different diagnostic: rectification creates sum, difference, and multiple frequencies. Those created frequencies must not be reported as transmitter-emission frequencies.

These complex coefficients, coefficient magnitudes, and cancellation ratios are signal-processing wake diagnostics. They are not spectral energy, energy transport, or realized work.

Analytical Claim Boundary

The signed wake $\mathcal{W}$, unsigned wake $\mathcal{W}_{\mathrm{abs}}$, virtual-probe response $\mathbf{A}_p$, angular coefficients, exposure fraction η_{ext}, and complete-cycle normal wake-flux measures are the available analytical ledgers. None is an energy quantity. This method therefore does not report total energy, apparent energy, apparent-energy fractions, escaping energy, intrinsic leakage, or stability scores. It also does not include a Noether-sea response. Introducing any such quantity requires a separate definition and cannot be accomplished by relabeling a wake-exposure measure.

Analytical Evaluation Programs

The measures in this chapter require analytical programs that evaluate the declared formulas for an exact source record. These programs are not assembly-evolution simulations. They hold the prescribed paths fixed and calculate their consequences at the requested absolute-coordinate events.

The analytical program suite should have separable components for:

1. validating and evaluating the source paths, velocities, accelerations, periods, and taxonomy coordinates;
2. enumerating every retained causal root and recording its identity, topology, and D_t margin;
3. evaluating $\mathcal{W}$, $\mathcal{W}_{\text{abs}}$, $\chi_{\mathcal{W}}$, and $\mathbf{A}_p$ at internal and external probes;
4. reducing the event-level results into the separation, root, mismatch, exposure, complete-cycle normal wake-flux, angular, spectral, radial-scaling, symmetry, and sensitivity measures defined above; and
5. emitting a result packet keyed by the exact source hash and protocol hash.

Each component must expose numerical tolerances and convergence checks. Where a closed-form, symmetry-protected, static, or other independently known analytical case exists, it should be used as an independent check. Replaying output from the same program establishes reproducibility, not correctness.

Only after these programs can calculate the common measure set should a broad parameter campaign begin. Otherwise a sampling run merely produces many configurations without a controlled basis for comparing them.

Monte Carlo Configuration-Space Analysis

Let $\boldsymbol{\theta}$ contain the complete taxonomy coordinates, group-translation speed, phase origin, and any permitted prescribed-history coordinates. A sampling campaign must publish the domain Θ, units, constraints, and sampling measure. There is no coordinate-free meaning to “random braid”; uniform sampling in radius, logarithmic radius, speed, or frequency represents different candidate populations.

Degrees of Freedom by Braid Class

A degree of freedom is an independently variable source coordinate whose change can alter at least one prescribed worldline or its polarity-tagged contribution after the selected member’s constraints are imposed. A derived quantity is not counted again. In particular, only two coordinates in

$$R_a^2 = h_a^2 + \rho_a^2$$

are independent. Here R_a is the endpoint distance from the binary midpoint, h_a is the axial half-separation, and ρ_a is the transverse orbit radius measured from the binary axis. The phrase “orbit radius from the axis” therefore means ρ_a, not R_a, except on a zero-axial-offset locus where $h_a = 0$ and $\rho_a = R_a$.

The coordinate types recur across the taxonomy, but they are not all independently free in every member:

Coordinate type	Status across Families A, B, and C	Constraint or interpretation
Binary radius R_a and transverse orbit radius ρ_a	Present in every binary record	R_a and ρ_a coincide only when $h_a = 0$. An axial binary with $\rho_a = 0$ has no circular path even if $R_a > 0$.
Binary frequency f_a	Present in every binary record	The two endpoints of one neutral binary share a frequency. Equal-frequency and fixed-ratio members reduce several frequency coordinates to one scale. At $\rho_a = 0$, frequency remains a record label but does not change the path.
Binary phase ϕ_a	Present in every binary record and required in addition to radius and frequency	Phase is measured relative to the common braid-level zero point. Some members fix the relative phases. At $\rho_a = 0$, phase does not change the path.
Binary midpoint and axis data	Present in every braid record	Family A constrains three axes through λ_A; B1 makes the three axes and midpoints coincide; Family C orders twelve architrino worldlines on one common axis.

Coordinate type	Status across Families A, B, and C	Constraint or interpretation
Group velocity $\mathbf{V}_{\rm grp}$	Present at assembly level	The common scalar taxonomy coordinate is $s_{\rm grp} = \lVert\mathbf{V}_{\rm grp}\rVert$. Family A fixes its direction to $\hat{\mathbf{u}}_A$; axial B1 is a specialization rather than the whole B1 class.
Circulation sense and endpoint polarity assignment	Required discrete source choices	A member may lock circulation within or between braids. Neutrality fixes one electrino and one positrino per binary, but which persistent endpoint carries each polarity still changes the signed source record.
Architrino worldline count and binary grouping	Member-defining discrete choices	Families A and B contain six architrino worldlines in three neutral binaries. Family C contains twelve architrino worldlines in six neutral binaries and requires an explicit fixed-point-free counterpart map.
Axial spacing	Not universal	A3 and B1 use binary axial half-separations h_a along their respective binary axes. Family C carries the complete ordered spacing vector $\mathbf{d}_C$; C3 through C6 additionally carry the B1-component center separation d_C. General Family A has no single common axis on which all orbits can be spaced.
Orbit order along one axis	Not an independent universal coordinate	In a coaxial chart, order is derived by sorting the signed axial positions. Persistent binary indices do not change when two radii, frequencies, or axial positions cross. Order becomes a separate discrete choice only when assigning different path or polarity data to the ordered sites changes the source record.

Thus radius, frequency, phase, and group translation are the common kinematic coordinate types. Axis and midpoint data, circulation, and endpoint polarity assignment are also required source coordinates. Axial spacing and axial order belong only to charts that actually have a common axis; they must not be imposed on all A, B, and C candidates.

The member-level inventory below describes the admissible taxonomy space, not the single display coordinate selected by a catalog source record. In particular, the current Family-A Borg reference records select $\lambda_A = 0$; varying λ_A requires a campaign that explicitly includes the wider Family-A coordinate.

Braid class or catalog members	Independent continuous coordinates beyond the common radius, frequency, phase, and group-translation columns	Relations that add or remove freedom
`A1`	Family-A flattening λ_A	$h_a = 0$ for all three binaries; R_a, f_a, and ϕ_a may otherwise differ.
`A1.1`	λ_A	One common frequency; radii and phases remain independently assignable.
`A1.2`	λ_A	One radius, one frequency, fixed phases 0, $2\pi/3$, and $4\pi/3$.
`A1.3`, `A1.4`	λ_A	One base frequency with the indexed ratio $4{:}2{:}1$ or $3{:}2{:}1$; radii and phases remain independently assignable.
`A2`	λ_A and one common axial/transverse decomposition coordinate in addition to the common radius	All three binaries share R, h, ρ, f, and circulation; phases are fixed 120° apart.
`A3`	λ_A and one axial/transverse decomposition coordinate per binary in addition to R_a	Each binary may independently choose its geometry, frequency, and phase subject to $R_a^2 = h_a^2 + \rho_a^2$.
`A3.1`	The `A3` decomposition coordinates and λ_A	One common frequency; radii, decompositions, and phases remain independently assignable.
`A3.2`	The `A3` decomposition coordinates and λ_A	One common radius and frequency with fixed 120° phase spacing; the three decompositions may still differ.
`A3.3`, `A3.4`	The `A3` decomposition coordinates and λ_A	One base frequency with the indexed ratio $4{:}2{:}1$ or $3{:}2{:}1$; radii, decompositions, and phases remain independently assignable.
`B1.1`	One axial/transverse decomposition coordinate per binary in addition to R_a	One common midpoint, axis, frequency, and circulation; $h_a > 0$ and $\rho_a > 0$. Axial orbit-plane order is derived from the resulting signed offsets.
`B1.2`	The same B1 decomposition coordinates	The high-axial inequalities $h_a > \rho_a > 0$ further restrict the domain.
`B1.3`	No additional continuous internal coordinate beyond the common columns	The all-equatorial boundary fixes $h_a = 0$ and $\rho_a = R_a$; frequency and circulation are common.
`C1`, `C2`	Eleven positive spacings after fixing the common axial origin, twelve radii, twelve frequencies, twelve phases, and an explicit six-binary counterpart map	`C1` fixes one circulation sense across all twelve worldlines. `C2` fixes opposite senses on the two ordered six-index subsets. Equal radii, equal spacings, reflection symmetry, and B1 decomposition are additional strata rather than member relations.
`C3`, `C4`	Two inherited B1 coordinate sets, positive axial component-center separation d_C, and the relative transverse-frame/phase relation	Both components are coaxial. `C3` fixes equal component circulation senses and `C4` fixes opposite senses; equality of the two component frequencies is not required.
`C5`, `C6`	Two inherited B1.3 coordinate sets, positive axial component-center separation d_C, and the relative	Both components are coaxial and all-equatorial. `C5` fixes equal component circulation senses and `C6` fixes opposite senses; equality of the two component frequencies is not

Braid class or catalog members	Independent continuous coordinates beyond the common radius, frequency, phase, and group-translation columns	Relations that add or remove freedom
	transverse-frame/phase relation	required.

An overall shift of absolute-time origin changes the stored phase coordinates, and an overall global spatial placement changes the stored centers and frames. Whether those are sampled coordinates or fixed frame conventions depends on the probe and environment protocol. A campaign must state that convention before reporting a numerical degree-of-freedom count.

The active B1 sampling domain requires $\sum_a \rho_a^2 > 0$. The former `B1.4` source fixes $\rho_a = 0$ and $h_a = R_a$ for every binary, so its frequency and phase labels do not change its endpoint paths. Its immutable historical rows remain valid records of the deprecated axial-limit null control, but future active-candidate sampling and comparative rankings exclude it.

For C3 through C6, the axial component-center separation d_C is a required Monte Carlo coordinate in $\boldsymbol{\theta}$. Each sampled source must retain the coaxial constraint $\Delta\mathbf{C} = d_C\hat{\mathbf{n}}_C$ while varying d_C under the campaign's declared positive domain and sampling measure. The constrained display records use a dimensionless catalog length coordinate, so $d_C = 1.10$ means 1.10 catalog length units rather than a dimensional physical length. It is one reference point, not a fixed sampling value. A campaign must publish the minimum, maximum, unit conversion or normalized-unit convention, and probability measure for d_C before drawing samples.

Declared Full-Taxonomy Reference Measure

The compact campaign implementation `constraint-preserving-full-taxonomy/sha256-counter-v1` supplies a reproducible bounded reference measure over every coordinate type in the table above. "Full taxonomy" means that no independently variable coordinate type is silently fixed; it does not mean that this bounded measure is uniform in a coordinate-free sense or exhausts an unbounded family.

Coordinate group	Declared sampling rule
Overall geometry	Multiply the catalog reference geometry by a uniform scale in $[0.30, 0.42]$.
Binary radii	Multiply each permitted independent radius by an additional uniform factor in $[0.85, 1.15]$; equal-radius members share one factor.
Axial/transverse decomposition	Sample h/R uniformly in $[0.10, 0.90]$ for generic decompositions and in $[0.72, 0.98]$ for B1.2. Exact equatorial, axial, equal-decomposition, and member-specific boundary relations remain exact.
Frequencies	Draw positive integer return-period harmonics from $\{1, 2, 3\}$; common-frequency members share one harmonic and fixed-ratio members draw a base harmonic from $\{1, 2\}$ before applying their exact ratio.
Phases	Draw each free phase and braid offset uniformly on $[0, 2\pi)$; symmetry-fixed phase patterns remain exact.
Family-A flattening	Draw λ_A uniformly on $[0, 1]$.
General C1/C2 axial geometry	Draw eleven positive adjacent orbit-center gaps independently and uniformly in $[0.035, 0.075]$, center the ordered set on the common axis, pair adjacent centers into six neutral binaries, and assign persistent binary identities by a seeded permutation.
C3 through C6 component spacing	Multiply the reference coaxial component-center separation by a uniform factor in $[0.65, 0.80]$.
Circulation and polarity	Draw every permitted independent sign from a balanced two-point distribution, then impose exact same-sense or opposite-sense member relations.
Common translation	Draw a permitted direction and a speed uniformly from zero to one-half of the conservative envelope-safe speed. Family A uses its declared translation direction. The resulting exact source must remain inside radius 0.99 through the retained record.

The sampler constructs the constrained coordinates directly and then calls the canonical member validator. A validator failure is a sampler defect, not a Monte Carlo gate rejection. The seed, member identifier, sample ordinal, every drawn coordinate, the complete sampled source, and the validator result are retained.

For a family/member candidate M, define its admissible configuration space by

$$\Theta_M = \{\boldsymbol{\theta} : \boldsymbol{\theta} \text{ satisfies the taxonomy relations and declared analysis gates for } M\}\,.$$

A Monte Carlo campaign draws prescribed instantiations $\boldsymbol{\theta}^{(k)} \in \Theta_M$, builds the exact source record $S(\boldsymbol{\theta}^{(k)})$, and runs the analytical programs to obtain

$$\mathbf{G}^{(k)} = \mathbf{G}\left[S(\boldsymbol{\theta}^{(k)}); P\right].$$

The common protocol P must remain fixed across the compared sample. A changed source definition, measure, probe set, history depth, root policy, boundary, or normalization requires an impact review and invalidates every affected score. The campaign must recompute those scores before they re-enter the comparison population.

Balanced Per-Member Sampling Procedure

A complete initial campaign samples every catalog member rather than drawing the member identity from a probability distribution. If the catalog contains N_M members and assigns N initial cases to each member, the balanced campaign contains $N_M N$ cases before directed refinement. The execution order should be randomized so temperature, memory pressure, or other machine-time effects do not remain correlated with family order.

Before the first draw, freeze a versioned campaign declaration containing:

- every included family/member identifier;
- the bounds, units, constraints, and probability measure for each continuous coordinate;
- the probabilities or balanced quotas for each discrete source choice;
- the fixed-frame convention for coordinates removed as global spatial placement or absolute-time origin;
- the common analytical protocol P, including $c_f = 1$, numerical resolutions, tolerances, and gate definitions;
- the pseudorandom or randomized space-filling algorithm, seed, and stream-assignment rule; and
- the initial quota N, any later adaptive-allocation rule, and the stopping rule.

Then, for every included member M:

1. draw $\boldsymbol{\theta}^{(k)}$ from the declared measure on Θ_M, using a constraint-preserving parameterization or a recorded reject-and-redraw rule;
2. assign every discrete choice, including circulation and persistent endpoint polarity data, under the declared quota or probability rule;
3. construct and validate the exact source record $S(\boldsymbol{\theta}^{(k)})$;
4. attempt to evaluate the fixed metric and gate vector with protocol P;
5. append one compact, reproducible case row whether the evaluation succeeds or balks; and
6. repeat until the member has its declared initial quota.

The same procedure is repeated for all members. Equal initial quotas make the first family comparison transparent. Adaptive top-ups may then spend more evaluations near favorable regions, gate boundaries, or poorly resolved strata, but the adaptive rows must retain their selection rule and must not be mixed into estimates for the original sampling measure without the corresponding statistical weighting.

Compact Reproducible Case Row

"Store only the test case and its scores" is a valid coverage policy only when the test case is an exact rerun instruction. Each compact row must contain:

Record group	Required contents
Case identity	Campaign identifier, family/member identifier, case ordinal, and unique case identifier
Draw provenance	Sampling algorithm, seed, stream index, measure, stratum, and any rejection count or directed-selection rule
Exact source	Complete continuous parameter vector, all discrete choices, frame convention, source-schema version, and exact source hash
Analytical protocol	Protocol identifier and hash, $c_f = 1$, resolution tier, tolerances, and gate-definition version
Result	Evaluation status; metric values, gate outcomes, convergence and uncertainty rows, disposition, and score hash when evaluated; otherwise a null score plus the stage, reason code, error type, message, and structured unresolved details
Implementation provenance	Evaluator identifier and version plus an immutable implementation or build identifier
Measured cost	Wall time, processor time when available, peak memory, and retained-byte count
Evidence references	Independent-check receipt and content-addressed raw-artifact references when those artifacts were retained

The source vector, protocol hash, and implementation identifier are necessary because a seed alone does not guarantee that a later program version will reconstruct the same source or calculation. Recomputing an exact compact row establishes reproducibility. It does not establish correctness unless the recomputation includes the declared independent check.

Coverage and Full-Adjudication Lanes

The broad campaign should separate cheap configuration-space coverage from evidence-bearing adjudication:

1. **Coverage lane.** Evaluate every sampled source with a declared screening resolution and retain compact rows. Raw event ledgers may be omitted. These rows are diagnostic and may rank regions, reveal correlations, and identify obvious failures, but they cannot receive an acceptance grade that requires absent raw or independent evidence.
2. **Full-adjudication lane.** Rerun selected favorable points, points near gate boundaries, anomalies, and a stratified audit sample at the complete protocol resolution. Retain the raw ledgers and independent-check receipts required by the gates. Only this lane can support catalog acceptance.
3. **False-negative audit.** Full-adjudicate a declared sample of ordinary coverage-lane rejects. The observed disagreement rate measures whether the screening lane is discarding potentially favorable points and determines whether its resolution must be increased.

The coverage resolution must therefore be calibrated against the full protocol rather than assumed adequate. A faster grid that changes a frequency, radial-scaling, root-topology, or other gate remains useful for screening only. Local finite-difference sensitivity calculations should likewise be deferred to selected points unless they are an explicit initial-campaign objective; running them for every broad-coverage draw multiplies cost without increasing configuration-space coverage.

The compact calibration runner first compares coverage and full numerical resolution on identical sampled sources. It classifies both-pass, both-reject, coverage-false-negative, coverage-false-positive, and inconclusive-not-evaluated rows, with per-gate disagreements and exact source hashes. This is a measured resolution calibration, not independent acceptance, because compact rows omit the acceptance-bearing raw ledgers. A stratified raw-evidence audit remains necessary before any selected row can enter the accepted catalog.

An initial quota such as $N = 64$ per member is not a production rule merely because the runner accepts that integer. Production designation requires: successful constraint-preserving draws across every catalog member; no unexplained not-evaluated stratum; a declared false-negative audit large enough to bound the missed-candidate risk; stable wall-time and memory measurements under the intended worker count; and a frozen campaign declaration. Until those conditions are met, $N = 64$ is a capacity-planning value, not a statistically or evidentially calibrated quota.

Campaign storage should follow the same split. Compact rows belong in an append-oriented tabular store suited to filtering and aggregation. Large raw ledgers should be content-addressed and retained only for full-adjudication rows, anomalies, boundary cases, and the declared audit sample. The logical evidence contract is independent of whether the compact table is implemented as a database or a columnar or delimited file.

Performance Measurement

Cost is a measured property of the implementation and machine, not a consequence inferred from sample counts alone. A campaign pilot must profile at least one complete point and report stage-level wall time for source construction, root evaluation, surface reduction, metric reduction, hashing, serialization, compression, storage, independent checks, and sensitivity evaluation. It must also report median and upper-quantile point times across members, because one member need not represent the full catalog.

Optimization experiments must compare the same exact source and protocol and verify equality of the compact score record when claiming an output-preserving speedup. Lower resolutions, omitted sensitivity rows, or missing evidence artifacts are separate evaluation tiers, not output-preserving optimizations. Campaign-level parallel execution may reduce elapsed campaign time, but it does not reduce the processor cost of one point and must be evaluated under measured memory and storage contention.

Local and Cloud Throughput

One **test point** in this supplement means one exact source-protocol pair evaluated into one compact reproducible case row. Throughput is the number of completed points divided by total elapsed campaign time, including dispatch, retries, merging, and final verification:

$$R_{\text{test}} = \frac{N_{\text{verified}}}{t_{\text{elapsed}}}$$

where R_{test} is reported in verified tests per hour. A worker count is an implementation setting, not a throughput prediction. The useful count is the measured maximum before processor scheduling, memory pressure, compression, or storage contention makes another worker counterproductive.

Machine-specific benchmarks and dated price observations belong in operational campaign records rather than this reader-facing method. The portable rule is to use a bounded dynamic queue, measure worker scaling on every selected platform, and remeasure whenever the protocol, member mix, runtime, or machine changes. Interruptible cloud execution is appropriate only after every completed point is checkpointed independently, an interrupted point can be retried without changing its identity, and duplicate results are rejected by case hash. On-demand and interruptible runs must be priced and reported separately.

Deterministic Cloud Execution

Monte Carlo points are independent after the campaign declaration and random streams are frozen. The controller should construct the immutable test-point definitions, place them in a deterministic queue, and let each worker claim one point at a time. Each worker returns one compact case row to a single deterministic merger. Workers should not write concurrently into one shared database file. The merger sorts by family/member identifier and case ordinal, rejects conflicting duplicates, records retries, and performs the final hash and inventory checks.

Cloud execution does not change the coverage and full-adjudication distinction:

- ordinary coverage workers return compact rows and do not upload large raw ledgers;
- selected full-adjudication points retain the required content-addressed raw ledgers and independent-check receipts; and
- a preempted point contributes no result until one complete verified row is committed.

Before cloud results enter a comparison population, freeze the runtime, dependencies, evaluator implementation, source schema, campaign declaration, and analytical protocol. Run the same qualification fixture locally and on each selected cloud machine type, then require identical sampled-source definitions, source hashes, protocol hashes, compact score-record hashes, case hashes, aggregate hash, and gate inventory. Different processor, operating-system, and compression environments require byte identity to be tested rather than assumed. If any required identity differs, cloud coverage remains diagnostic-only and selected points must be rerun on the declared canonical platform before promotion. Same-output replay establishes determinism; it does not replace an independent correctness check.

Price-Performance Measurement

For a cloud run using instances indexed by i, define

$$K_{\text{compute}} = \sum_i p_i h_i$$

where p_i is the actual instance price in dollars per billed hour and h_i is its billed duration. Total campaign cost is

$$K_{\text{campaign}} = K_{\text{compute}} + K_{\text{storage}} + K_{\text{network}} + K_{\text{operations}}.$$

The measured price-performance quantities are

$$P_{\text{test}} = \frac{N_{\text{verified}}}{K_{\text{campaign}}}, \qquad C_{\text{million}} = \frac{10^6}{P_{\text{test}}}.$$

Thus P_{test} is verified tests per dollar and C_{million} is dollars per million verified tests. Billed startup time, idle capacity, failed or preempted attempts, retries, compact-output storage, network transfer, deterministic merge, and final verification all remain in the denominator. Quoting core count times a local single-worker rate is only a capacity estimate and must not be reported as measured cloud throughput.

The controlled cloud experiment should sweep worker counts from one through the selected machine's useful concurrency range, using one warm-up and at least three repetitions per setting. It should then compare several fleet sizes of identical instances on one fixed logical workload. Every run must report individual and median wall time, tests/hour, processor utilization, peak memory, retries, bytes transferred, total billed cost, tests/dollar, and exact-output comparison. The preferred execution mode is the one with the lowest measured cost per verified test that also meets the desired completion time and every evidence boundary.

The analytical campaign has three stages:

1. **Monte Carlo coverage.** Draw a reproducible, seeded sample from each declared measure over Θ_M. Use stratification so narrow coordinate regions are not lost by chance.
2. **Directed refinement.** Add targeted samples around strong external cancellation, admissible root margins, candidate optima, and boundaries where root topology or prescribed-period closure changes. Include deliberately adverse directions so the method does not optimize only one favorable projection.
3. **Robustness and sensitivity analysis.** Resample neighborhoods around leading instantiations, vary one declared coordinate at a time where useful, and report whether the apparent advantage survives small changes in coordinates, sampling measure, and numerical resolution.

Every result row must include the family/member identifier, full parameter vector, source grade, sampling measure, seed or directed-selection rule, root status, numerical resolution, and metric uncertainty.

The campaign output should include the distribution of every objective and gate, parameter-to-measure sensitivity, correlations that may reveal redundant coordinates, the non-dominated set under $\mathbf{G}_{\text{an}}$, and the location and width of robust favorable regions. A single best sampled point is not enough: the central question is whether a candidate has a reproducible favorable region in configuration space or only a narrowly tuned instantiation.

Common-Axis Architrino-Worldline Chart

The common-axis chart supplies a six-worldline Family-B dimension extension and the twelve-worldline Family-C parent geometry. Let $\hat{\mathbf{n}}$ be the oriented translation axis, with transverse orthonormal vectors $\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2$. Assign persistent architrino-worldline indices $m = 1, \dots, N_w$, ordered axial coordinates

$$\xi_1 < \xi_2 < \cdots < \xi_{N_w},$$

and spacings

$$d_m = \xi_{m+1} - \xi_m > 0.$$

For group-translation speed $0 \le s_{\text{grp}} < c_f$, architrino worldline m is

$$\mathbf{X}_m(T) = \mathbf{C}_0 + s_{\text{grp}} T \hat{\mathbf{n}} + \xi_m \hat{\mathbf{n}} + \rho_m \left[\cos\theta_m(T)\hat{\mathbf{e}}_1 + \sin\theta_m(T)\hat{\mathbf{e}}_2\right],$$

$$\theta_m(T) = q_m \omega_m T + \phi_m, \qquad q_m \in \{+1, -1\}.$$

The binary-counterpart map π must be a fixed-point-free involution,

$$\pi(\pi(m)) = m, \qquad \pi(m) \ne m,$$

and every pair must declare its polarities, radii, frequencies, phases, circulation relation, axial midpoint, axial separation, and exact constraint. A pairing label has no analytical effect unless it changes a declared path or polarity.

For an even ordered chart, adjacent-pair association slots may be declared as

$$P_k = (2k-1, 2k), \qquad \mu_k = \frac{\xi_{2k-1} + \xi_{2k}}{2}.$$

For a twelve-worldline Family-C source, six additional architrino worldlines may be declared as an Accessory Configuration only when all six polarities and complete paths are supplied. A three-worldline Family-B scaling control is not an Accessory Configuration. An additional path associated with slot P_k has the form

$$\mathbf{Y}_k(T) = \mathbf{C}_0 + s_{\text{grp}} T \hat{\mathbf{n}} + (\mu_k + \epsilon_k)\hat{\mathbf{n}} + \boldsymbol{\delta}_k(T),$$

where the axial offset ϵ_k and transverse path $\boldsymbol{\delta}_k(T)$ are exact source coordinates. The adjacent-pair association map and binary-counterpart map remain separate.

Write any declared architrino worldline as

$$\mathbf{Z}_a(T) = \mathbf{C}_0 + s_{\text{grp}} T \hat{\mathbf{n}} + \zeta_a \hat{\mathbf{n}} + \boldsymbol{\delta}_a(T).$$

Every retained positive causal delay from transmitter a to receiver b satisfies

$$\|(\zeta_b - \zeta_a + s_{\mathrm{grp}}u)\,\hat{\mathbf{n}} + \boldsymbol{\delta}_b(T) - \boldsymbol{\delta}_a(T-u)\| = c_f u, \qquad u > 0.$$

This equation covers every ordered transmitter-receiver pair in the declared source inventory, including Accessory Configuration sites when present. It is generally transcendental because the causally delayed transmitter phase contains u. A stationary transverse transmitter reduces the squared equation to a quadratic in u. Equal frequency, equal radius, rational frequency ratios, or reflection symmetry can reduce the number of distinct equations or pair contribution rows, but they do not generally remove the delayed phase. Rotating sectors therefore require certified retained-root enumeration.

For each declared worldline, compare prescribed acceleration with the master-equation acceleration from the complete declared source inventory:

$$\mathbf{R}_a(T) = \ddot{\mathbf{Z}}_a^{\mathrm{prescribed}}(T) - \mathbf{A}_a^{\mathrm{ME}}(T).$$

Report axial, radial, and tangential projections separately over the complete return period. Pointwise rows, signed cycle averages, RMS values, maxima, primary/refined differences, and source-resolved contributions are all required. Cancellation in one projection cannot conceal failure in another. A converged residual remains a prescribed-path analytical result; it is not stability, retention, binding, or physical realization.

Candidate Grading

The prescribed-record analytical grade is fail-closed and occurs in this order:

1. **Record validity:** complete provenance, finite values, legal coordinates, reproducible paths, and a current score for the exact source hash.
2. **Geometric admissibility:** no undeclared collision or coincidence, a complete declared period, and converged geometric extraction.
3. **Causal admissibility:** complete retained roots, declared self-hit treatment, resolved fold events, and converged root sums.
4. **Analytical wake comparison:** signed and raw exposure, complete-cycle normal wake flux and cancellation, anisotropy, spectra, peak response, and source-parameter sensitivity under one common protocol.

A prescribed chart receives only an analytical prescribed-record grade. Stability and energy are outside the method and outside its score.

Candidate Summary Publication

Candidate-specific coordinates, source hashes, protocol hashes, gate results, and metric values enter this chapter only from a complete accepted generation of the analytical database. A fresh generation must cover the entire registered candidate cohort under one declared protocol before any comparison row is published. Regeneration replaces the table as one unit; values from different database generations must not be mixed.

The reader-facing summary should remain compact. It may show named reference cases, the leader under an explicitly named measure, and operator-selected cases of analytical interest. Each row must carry its source hash, protocol hash, database-generation hash, acceptance state, and the reason it is included. A rejected case may be shown only when its failed gate is explicit. An undeclared combined score or global braid ranking is not permitted.

Each published table must state the enclosing radius or radius sequence, surface and time reductions, probe polarity, normalization, tolerance, and uncertainty attached to every scalar row. A cell may link to a fuller ledger when a scalar would hide root transitions, angular structure, or phase dependence.

Among prescribed candidates evaluated under the same protocol, report an analytical objective vector rather than hiding choices inside one number. One suitable starting vector is

$$\mathbf{G}_{\mathrm{an}} = \left(\eta_{\mathrm{ext}}, \eta_{\mathcal{W},\mathrm{flux}}, \epsilon_{\mathrm{aniso}}, A_{\mathrm{ext,peak}}, \chi_{\mathcal{W},\mathrm{peak}}, S_{\boldsymbol{\theta}}\right),$$

where $S_{\boldsymbol{\theta}}$ is the declared sensitivity of the wake measures to source-coordinate changes. Prescribed-period closure, minimum separation, and the root-transversality margin are validity gates or annotations rather than performance rewards.

One candidate dominates another only when it is no worse on every declared objective and better on at least one. A single weighted score is permitted only after the weights and normalization are fixed before inspecting the result. “Strongest analytical wake cancellation” is a legitimate comparison question. “Lowest apparent energy” is not a quantity defined by this methodology.

Separate grades are required for a family/member chart and for a particular instantiation. A strong instantiation supports existence within a sampled region; it does not establish that the family as a whole has the same performance.

Borg Analysis Surface

Borg should expose this method as a record-derived analysis surface. A user should be able to place fixed or moving probes at arbitrary $(T, \mathbf{X})$ coordinates and display:

- $\mathcal{W}$, $\mathcal{W}_{\text{abs}}$, and $\chi_{\mathcal{W}}$;
- positive- and negative-polarity virtual-probe responses;
- individual transmitter contributions and their vector sum;
- root count, root identity, D_t, and fold events;
- time graphs over the full return cycle;
- spatial slices, enclosing-surface maps, spectra, and angular coefficients;
- complete-cycle signed, raw, and residual normal wake flux together with $\eta_{\mathcal{W},\text{flux}}(R)$ and the raw emission-reference residual;
- transmitter-root-tagged complex normal wake-flux coefficients and $\eta^{(\ell mn)}_{\mathcal{W},\text{flux}}(R)$ across the declared enclosing radii; and
- source-parameter sensitivity, invalidated-score status, and the exact source and protocol hashes.

The graph must remain synchronized with animation time and preserve source-record provenance. Borg may also present a teaching sequence that highlights selected binaries, axes, wakes, envelopes, roots, or probes while explanatory text appears on the canvas. Teaching cues are annotations on the record; they are not evidence generated by the record.

Energy and stability controls should not appear as outputs of this analytical surface because the method does not define them.

Minimum Publication Packet

A publishable candidate analysis contains:

1. the complete source record and taxonomy row;
2. the superimposed causal-wake formula and all normalization choices;
3. the internal receiver-wake ledger through one complete return cycle;
4. the probe geometry and raw time-dependent curves;
5. prescribed-period closure, root, separation, cancellation, anisotropy, spectral, and source-sensitivity metrics;
6. an explicit analytical claim boundary that excludes energy and stability conclusions;
7. the Monte Carlo, directed-refinement, and robustness sampling declarations;
8. the gate result and multi-objective comparison vector; and
9. the exact observation that would falsify each promoted claim.

This packet makes analytical candidate comparison reproducible. A prescribed braid remains a prescribed geometry with analytically evaluated causal-wake properties; the method makes no claim about stability or physical retention.

Braid Envelope Geometry

This chapter is the canonical home for the geometric footprint of a Noether braid assembly: its dynamic exclusion envelope, the envelope forms of the named families, the canonical geometry variables, and the assembly-level deformation channels. It faces the Noether sea and effective-spacetime consumers because the geometry of many such envelopes is the local material out of which Noether sea density, strain, and delay variables are coarse-grained. The prescribed family coordinates belong to Braid Taxonomy, with Family A developed in Braid Family A, Family B in Braid Family B, and Family C in Braid Family C; delayed retention and deformation mechanisms belong to their mathematical and member-specific owners.

A Noether braid is not a static object. It is a dynamic system of six architrinos — twelve for a Family-C record — whose high-frequency paths sweep out a persistent volume of intense wake activity. That swept volume is the assembly's effective exclusion envelope.

In plain terms, this chapter explains what a retained braid "looks like" to neighboring assemblies and to the Noether sea. The envelope is not a hard surface. It is the region where the assembly's locked wake activity is strong enough that other histories are deflected, excluded, phase-disrupted, or forced to retune.

That is why this geometry matters downstream. Pressure, packing, clock/ruler response, effective metric behavior, and Noether sea density are all coarse readings of many such envelopes and their deformations. The page therefore keeps the geometric export rows separate from the proof that the branch itself is retained.

Document Role

This chapter is the envelope and export-interface chapter for braid geometry. It owns:

- the dynamic exclusion-envelope interpretation of a braid assembly,
- the envelope forms associated with the member coordinates — B1's common-axis envelope and the Family-A oblate spheroidal envelope,
- the role of the boundary layer in setting the leading envelope surface,
- and assembly-level deformation of the envelope under external effective fields, nearby wakes, and Noether sea conditions.

This chapter does not own:

- primitive architrino ontology; see Architrino,
- the prescribed family scaffolds; see Braid Taxonomy, Braid Family A, and Braid Family B,
- exact delay-root dynamics; see Master Equation,
- observer clocks and rulers; see Proper Time and Time Dilation,
- or metric reconstruction; see Emergent Metric.

The role boundary is practical: the family chapters and the retained-branch program decide whether a branch is retained; this chapter describes the envelope rows and deformation variables that a retained branch can emit into Noether sea, packing, clock/ruler, and effective-metric consumers.

Dynamic Exclusion Envelope

The architrinos within a Noether braid are in rapid orbital motion. The superposition of their fluctuating causal-wake contributions creates a region that is difficult for other architrinos or assemblies to penetrate without being strongly accelerated, deflected, or phase-disrupted.

This region acts as a dynamic **exclusion envelope**. It is not a solid object with a hard material surface. It is a coherent region of intense wake activity defined by the collective path history of the constituent architrinos.

Another Noether braid approaching this region does not encounter a classical wall. It encounters a rapidly varying causal-wake environment whose accelerations and phase constraints can prevent stable transit through the braid volume.

Exclusion Envelope As Pressure Source

The dynamic exclusion envelope also supplies the native route from assembly geometry to pressure. Pressure is not introduced as a separate primitive substance. It is an effective stress readout that appears when many stable assemblies cannot be moved closer without increasing wake disruption, branch deformation, or loss of stable closure.

For a compact region Ω, the first packing-pressure readout is the trace of the exclusion-stress tensor already carried by the packing channel:

$$P_{\text{pack}}(\Omega, T) = \frac{1}{3|\Omega|} \int_{\Omega} \operatorname{tr} S_{\text{excl}}(\mathbf{X}, T)\, d^3X$$

Here S_{excl} is the coarse-grained tensor assembled from the local entries $\mathcal{S}^{ab}_{j,\text{excl}}$ in the packing projector below. The factor $1/3$ extracts the isotropic pressure component in three spatial dimensions; anisotropic residuals remain in the stress tensor and must not be hidden when the local packing is directionally biased.

This is the Noether braid analogue of the familiar lesson from electron degeneracy: excluded state volume can become macroscopic pressure. The analogy is limited but useful. In ordinary electron matter, the observer-level pressure law also depends on the recovered fermionic exchange sign and momentum-state filling. In the Noether braid substrate, the corresponding pressure channel must be derived from the member-specific exclusion envelope, causal-wake disruption, and the same retained branch ledger that later recovers the fermionic exchange rule. A B1 consumer projects its envelope from the common-axis paths, while an A1 consumer uses its near-spherical-to-oblate response. Exclusion geometry can explain why closer packing becomes dynamically costly; spin-statistics closure is still required before the full electron pressure law has been recovered.

Assembly-Noether Sea Interface Diagnostic

The dynamic exclusion envelope supplies a spatial approximation to a deeper ledger boundary. At the exact level, an assembly is defined by the architrinos, closure labels, and wake-exchange records phase-locked to that assembly. The surrounding Noether sea is the neighboring neutral braid population and its ambient wake record after the assembly ledger has been excluded.

The bright-first question is operational: at a specified point and response channel, does wake activity tied to the assembly's accepted lock dominate, or does the ambient Noether sea dominate? That comparison locates usable clock corridors, packing boundaries, penetration regions, and interface layers before any sharp surface is inferred.

For an assembly a and a declared response channel X, let $\mathcal{W}^{\mathrm{locked}}_{a,X}(\mathbf{X},T)$ denote the local coarse-grained wake/exclusion contribution tied to the assembly's accepted closure label, and let $\mathcal{W}^{\mathrm{ambient}}_{\mathrm{sea},X}(\mathbf{X},T)$ denote the ambient Noether sea contribution in the same region. A practical interface diagnostic is

$$D_{a,X}(\mathbf{X},T)=\frac{\left\|\mathcal{W}^{\mathrm{locked}}_{a,X}(\mathbf{X},T)\right\|}{\left\|\mathcal{W}^{\mathrm{locked}}_{a,X}(\mathbf{X},T)\right\|+\left\|\mathcal{W}^{\mathrm{ambient}}_{\mathrm{sea},X}(\mathbf{X},T)\right\|}$$

The first computable form comes from the same causal-root flux used in the Master Equation. Fix a coarse-graining kernel K_ℓ, a channel X being tested, and a sample event $(\mathbf{X},T)$. For a transmitter constituent j at emission time T_t, define

$$r_{\mathbf{X}j}(T;T_t)=\|\mathbf{X}-\mathbf{X}_j(T_t)\|\,,\qquad g_{\mathbf{X}j}(T;T_t)=r_{\mathbf{X}j}(T;T_t)-c_f(T-T_t)$$

$$J_{\mathbf{X}j}(T;T_t)=1-\frac{\mathbf{V}_j(T_t)\cdot\hat{\mathbf{r}}_{\mathbf{X}j}(T;T_t)}{c_f},\qquad \mathcal{C}_{\mathbf{X}j}(T)=\{T_t<T: g_{\mathbf{X}j}(T;T_t)=0\}$$

Let $\mathcal{I}_a(T)$ be the architrino constituents and bound wake records belonging to assembly a, and let $\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)$ be the ambient Noether sea contributors in the same coarse window after excluding $\mathcal{I}_a(T)$. Let $w^{\mathrm{lock}}_{j,a}(T_t;T)$ retain the branches phase-locked to the assembly label, let $w^{\mathrm{sea}}_j(T_t;T)$ retain the ambient branches, and let $\alpha_{j,X}(\mathbf{X},T;T_t)\geq 0$ be the channel intensity inherited from branch-ledger exposure in channel X.

The receiver-side factor needs a declared probe state because the sample event $(\mathbf{X},T)$ is not itself an architrino worldline. It is retained for root playback and path-rate diagnostics, not as part of the acceleration weight. For clock, packing, and stationary interface-level scans, use a void-stationary probe, $\mathbf{V}_{\mathrm{probe},X}(\mathbf{X},T)=\mathbf{0}$, so $D^{(X)}_{r,\mathbf{X}j}=c_f$. For penetration along a declared test path, use $\mathbf{V}_{\mathrm{probe,penetration}}=v_{\mathrm{path}}\hat{\mathbf{u}}$ at the sample event. A moving reaction-corridor scan must declare its probe velocity before this diagnostic is evaluated. With that channel probe fixed, define

$$D_{t,\mathbf{X}j}(T;T_t)\equiv c_f-\mathbf{V}_j(T_t)\cdot\hat{\mathbf{r}}_{\mathbf{X}j}(T;T_t),\qquad D^{(X)}_{r,\mathbf{X}j}(T;T_t)\equiv c_f-\mathbf{V}_{\mathrm{probe},X}(\mathbf{X},T)\cdot\hat{\mathbf{r}}_{\mathbf{X}j}(T;T_t)$$

and

$$W^{\mathrm{acc},X}_{\mathbf{X}j}(T;T_t)\equiv\frac{c_f}{|D_{t,\mathbf{X}j}(T;T_t)|}$$

as the transmitter-side acceleration weight on the same root record. Then the simple-root diagnostic is

$$\mathcal{W}^{\mathrm{locked}}_{a,X}(\mathbf{X},T;\ell)=K_\ell*\sum_{j\in\mathcal{I}_a(T)}\sum_{T_t\in\mathcal{C}_{\mathbf{X}j}(T)}w^{\mathrm{lock}}_{j,a}(T_t;T)\frac{\alpha_{j,X}(\mathbf{X},T;T_t)W^{\mathrm{acc},X}_{\mathbf{X}j}(T;T_t)}{r^2_{\mathbf{X}j}(T;T_t)}$$

and

$$\mathcal{W}^{\mathrm{ambient}}_{\mathrm{sea},X}(\mathbf{X},T;\ell)=K_\ell*\sum_{j\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}\sum_{T_t\in\mathcal{C}_{\mathbf{X}j}(T)}w^{\mathrm{sea}}_j(T_t;T)\frac{\alpha_{j,X}(\mathbf{X},T;T_t)W^{\mathrm{acc},X}_{\mathbf{X}j}(T;T_t)}{r^2_{\mathbf{X}j}(T;T_t)}$$

These coefficients are not fit amplitudes. For each accepted causal root, define the root-selected branch record

$$\mathcal{B}^{(T_t)}_{\mathbf{X}j}=\left(j,\,T_t,\,\hat{\mathbf{r}}_{\mathbf{X}j},\,r_{\mathbf{X}j},\,J_{\mathbf{X}j},\,q_j,\,\mathcal{L}^{\mathrm{wake}}_j,\,\Lambda_j\right)_{(\mathbf{X},T;T_t)}$$

Here $\mathcal{L}^{\mathrm{wake}}_j$ is the wake-history ledger carried by the transmitter branch and Λ_j is the closure label or neutral braid label available on that branch. The locked weight is the assembly projector

$$w_{j,a}^{\mathrm{lock}}(T_t;T)=\mathbf{1}_{j\in\mathcal{I}_a(T)}\,\zeta_a\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)$$

where $\zeta_a\in[0,1]$ is one for an accepted phase-locked branch of $\Lambda_a(T)$ and zero for a rejected branch in the exact ledger limit. A regularized branch chart may replace this sharp value by

$$\zeta_a^{(\eta_\Lambda)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)=\exp\left[-\frac{d_{\Lambda_a}^2\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)}{\eta_\Lambda^2}\right]$$

where d_{Λ_a} measures closure-label, phase, and branch-provenance mismatch against the accepted assembly ledger. The ambient weight is the complement projector

$$w_j^{\mathrm{sea}}(T_t;T)=\mathbf{1}_{j\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}\,\zeta_{\mathrm{sea}}^{(\ell)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)$$

where $\zeta_{\mathrm{sea}}^{(\ell)}\in[0,1]$ retains branches belonging to the neutral braid equilibrium record in the coarse window after all resolved assembly ledgers have been removed. Thus a branch cannot contribute to the locked numerator and the ambient denominator by relabeling alone; it must pass the corresponding ledger projector.

The first symbolic form of this ambient projector comes from ledger complement plus local cadence smoothing. Let $\mathfrak{A}_{\mathrm{res}}(\Omega_\ell,T)$ be the resolved assembly ledgers inside the same coarse window, including matter assemblies and any resolved corridor ledger that has not been declared ambient Noether sea. Define the complement factor

$$\chi_{\mathrm{comp}}^{(\ell)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)=\mathbf{1}_{j\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}\prod_{a'\in\mathfrak{A}_{\mathrm{res}}(\Omega_\ell,T)}\left[1-\zeta_{a'}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)\right]$$

For any neutral braid branch quantity $f_k(T)$, write the ambient window average after resolved assembly ledgers have been removed as

$$\langle f\rangle_{\mathrm{sea},\ell}(\mathbf{X},T)=\frac{\sum_{k\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}K_\ell(\mathbf{X}-\mathbf{X}_k(T))f_k(T)}{\sum_{k\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}K_\ell(\mathbf{X}-\mathbf{X}_k(T))}$$

Let ν_k be the cadence variable of neutral braid k, let $\bar{\nu}_{\mathrm{sea}}^{(\ell)}=\langle\nu\rangle_{\mathrm{sea},\ell}$, and let $\sigma_{\nu,\ell}^2=\left\langle(\nu-\bar{\nu}_{\mathrm{sea}}^{(\ell)})^2\right\rangle_{\mathrm{sea},\ell}$. The cadence residual of the candidate branch is

$$\Delta_{\mathrm{cad}}^{(\ell)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)=\frac{\nu_j(T_t)-\bar{\nu}_{\mathrm{sea}}^{(\ell)}(\mathbf{X},T)}{\sqrt{\sigma_{\nu,\ell}^2+\epsilon_\nu^2}}$$

Let $\mathcal{N}_\ell^{\setminus\mathrm{res}}$ be the neutral-pairing residual and $\mathbf{P}_\ell^{\setminus\mathrm{res}}$ the orientation/polarization residual of the same window after resolved assembly ledgers have been removed. The window-balance residual is

$$\left(\Delta_{\mathrm{bal}}^{(\ell)}\right)^2=\frac{\left\|\mathcal{N}_\ell^{\setminus\mathrm{res}}\right\|^2}{\epsilon_N^2}+\frac{\left\|\mathbf{P}_\ell^{\setminus\mathrm{res}}\right\|^2}{\epsilon_P^2}$$

The ambient acceptance is then

$$\zeta_{\mathrm{sea}}^{(\ell)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)=\chi_{\mathrm{comp}}^{(\ell)}\left(\mathcal{B}_{\mathbf{X}j}^{(T_t)}\right)\exp\left[-\frac{1}{2}\left(\left(\Delta_{\mathrm{cad}}^{(\ell)}\right)^2+\left(\Delta_{\mathrm{bal}}^{(\ell)}\right)^2\right)\right]$$

This form rejects assembly-locked branches because any resolved locked projector $\zeta_{a'}=1$ drives the complement factor to zero in the exact ledger limit. It retains ambient Noether sea branches in the same coarse window when they remain outside all resolved assembly ledgers and agree with the locally smoothed neutral braid cadence and balance record. The tolerances ϵ_ν, ϵ_N, and ϵ_P are resolution tolerances for the chosen window and ledger chart; they are not channel-specific fit parameters. Channel differences still enter through Π_X and Q_X, while the assembly/complement split and neutral-equilibrium projector remain common to the diagnostic.

The channel intensity is the channel exposure of the same root-selected branch record:

$$\mathcal{E}_X\left(\mathcal{B}^{(T_t)}_{\mathbf{X}j}\right) = Q_X\left[\Pi_X \mathcal{B}^{(T_t)}_{\mathbf{X}j}\right], \qquad \alpha_{j,X}(\mathbf{X},T;T_t) = \left\|\mathcal{E}_X\left(\mathcal{B}^{(T_t)}_{\mathbf{X}j}\right)\right\|_X$$

The projection Π_X selects the channel being tested and Q_X removes only equivalences that preserve that channel's benchmark. The intensity $\alpha_{j,X}$ is dimensionless because the channel norms are tolerance ratios. The dimensional coupling κ and polarity factors enter only through retained channel entries that already require them, such as the signed acceleration used by penetration. Clock-coupling keeps cadence and phase entries that perturb the clock functional. Reaction-corridor calculations keep the oriented exchange, line-defect, color, weak, or provenance entries declared by that corridor. Packing keeps scalar or tensor exclusion-stress magnitude after acceleration signs are discarded. Penetration keeps the local acceleration and phase-disruption entries along the tested path. These channels may use different Π_X, but they must not change the causal-root kernel, the assembly/complement split, or the transmitter branch record.

The first concrete projector family can be stated as retained entries of $\mathcal{B}^{(T_t)}_{\mathbf{X}j}$ plus derived local entries computed from the same branch. For the clock channel,

$$\Pi_{\text{clock}}\mathcal{B}^{(T_t)}_{\mathbf{X}j} = \left(\delta\theta^{(j)}_{\text{clk}},\, \delta\omega^{(j)}_{\text{clk}},\, \delta\chi^{(\ell,j)}_{\text{sea}},\, J_{\mathbf{X}j},\, \Lambda_j,\, \mathcal{L}^{\text{wake}}_j\big|_{\text{phase}}\right)$$

where $\delta\theta^{(j)}_{\text{clk}}$ and $\delta\omega^{(j)}_{\text{clk}}$ are the branch-induced phase and cadence increments of the declared clock functional, and $\delta\chi^{(\ell,j)}_{\text{sea}}$ is the branch contribution to the coarse Noether sea delay factor. The quotient Q_{clock} may remove phase-origin choices and hidden constituent relabelings only when $\omega_{\text{clk}}/\omega_0$ is unchanged.

For a reaction corridor,

$$\Pi_{\text{corridor}}\mathcal{B}^{(T_t)}_{\mathbf{X}j} = \left(\hat{\mathbf{r}}_{\mathbf{X}j},\, q_j,\, \mathcal{L}^{\text{wake}}_j\big|_{\text{oriented}},\, \mathcal{L}^{\text{corr}}_j,\, \mathcal{P}^{\text{prov}}_j,\, \Theta^{\text{strain}}_j\right)$$

where $\mathcal{L}^{\text{corr}}_j$ is the declared strong, weak, color, electromagnetic, or material corridor ledger, $\mathcal{P}^{\text{prov}}_j$ is the provenance record of participating architrinos and energy entries, and Θ^{strain}_j is the line-defect or medium-strain entry when the corridor calculation requires one. The quotient Q_{corridor} may remove only corridor-basis relabelings that preserve the recovered reaction channel, provenance ledger, and line-defect energy.

For packing,

$$\Pi_{\text{packing}}\mathcal{B}^{(T_t)}_{\mathbf{X}j} = \left(\left\|\mathcal{L}^{\text{wake}}_j\right\|_{\text{excl}},\, \mathcal{S}^{ab}_{j,\text{excl}},\, R_{\parallel,j},\, R_{\perp,j},\, \lambda_j,\, \xi_j\right)$$

where $\mathcal{S}^{ab}_{j,\text{excl}}$ is the local exclusion-stress entry and $(R_{\parallel,j}, R_{\perp,j}, \lambda_j, \xi_j)$ are the envelope entries exposed by the branch. Packing deliberately discards attraction/repulsion sign after the exclusion magnitude and stress tensor are retained, because the benchmark is stable adjacency rather than signed acceleration along one path.

For penetration along a declared test path with tangent $\hat{\mathbf{u}}$ at $\mathbf{X}$,

$$\Pi_{\text{penetration}}\mathcal{B}^{(T_t)}_{\mathbf{X}j} = \left(\mathbf{a}_{\mathbf{X}\leftarrow j}(T;T_t),\, \mathbf{a}_{\mathbf{X}\leftarrow j}(T;T_t)\cdot\hat{\mathbf{u}},\, \Delta\phi^{(j)}_{\text{disrupt}},\, r_{\mathbf{X}j},\, J_{\mathbf{X}j},\, \Lambda_j\right)$$

where $\mathbf{a}_{\mathbf{X}\leftarrow j}$ is the signed branch acceleration obtained from the same causal-root law and $\Delta\phi^{(j)}_{\text{disrupt}}$ is the induced phase-disruption increment on the tested transit branch. Unlike packing, penetration keeps the signed line-of-action entry because the benchmark asks whether the transit path remains dynamically stable.

The first channel norms are dimensionless stability diagnostics on these retained records. Their denominator scales are declared resolution or benchmark tolerances for the channel chart; they are not per-observable fit parameters. For clock coupling,

$$\|\mathcal{E}_{\text{clock}}\|^2_{\text{clock}} = \frac{(\delta\omega_{\text{clk}}/\omega_0)^2}{\epsilon^2_\omega} + \frac{\text{dist}^2_{S^1}(\delta\theta_{\text{clk}},0)}{\epsilon^2_\theta} + \frac{\left(\delta\chi^{(\ell,j)}_{\text{sea}}/\chi^{(\ell)}_{\text{sea}}\right)^2}{\epsilon^2_\chi} + \frac{\left\|\mathcal{L}^{\text{wake}}_j\big|_{\text{phase}}\right\|^2_{\text{phase}}}{\epsilon^2_{\text{phase}}}$$

For a declared reaction corridor with oriented corridor record $\hat{\mathbf{c}}_X$,

$$\|\mathcal{E}_{\text{corridor}}\|^2_{\text{corridor}} = \frac{1-\hat{\mathbf{r}}_{\mathbf{X}j}\cdot\hat{\mathbf{c}}_X}{\epsilon^2_{\text{dir}}} + \frac{\left\|\mathcal{L}^{\text{wake}}_j\big|_{\text{oriented}}\right\|^2_{\text{oriented}}}{\epsilon^2_{\text{or}}} + \frac{\left\|\mathcal{L}^{\text{corr}}_j\right\|^2_{\text{corr}}}{\epsilon^2_{\text{corr}}} + \frac{d^2_{\text{prov}}(\mathcal{P}^{\text{prov}}_j, \mathcal{P}^{\text{prov}}_X)}{\epsilon^2_{\text{prov}}} + \frac{\left\|\Theta^{\text{strain}}_j\right\|^2}{\epsilon^2_\Theta}$$

For packing, signs of attraction and repulsion have already been quotiented out, but exclusion magnitude and shape remain:

$$\|\mathcal{E}_{\text{packing}}\|^2_{\text{packing}} = \frac{\left\|\mathcal{L}_j^{\text{wake}}\right\|^2_{\text{excl}}}{\epsilon^2_{\text{excl}}} + \frac{\left\|\mathcal{S}^{ab}_{j,\text{excl}}\right\|^2_S}{\epsilon^2_S} + \frac{\left(\Delta \ln R_{\parallel,j}\right)^2}{\epsilon^2_{\parallel}} + \frac{\left(\Delta \ln R_{\perp,j}\right)^2}{\epsilon^2_{\perp}} + \frac{\left(\Delta \ln \lambda_j\right)^2}{\epsilon^2_{\lambda}} + \frac{\left(\Delta \ln \xi_j\right)^2}{\epsilon^2_{\xi}}$$

Here each $\Delta \ln$ term is measured relative to the declared same-member branch reference for the channel: the retained rest branch of the member under test for clock/ruler calibration, the candidate neighboring braid for packing, or the pre-entry path branch for penetration. A weak homogeneous A1 record is one possible A1 calibration branch; it is not the reference for a B1 calculation.

For penetration along $\hat{\mathbf{u}}$, decompose the signed branch acceleration into tangent and transverse parts,

$$a_{\parallel,j} = \mathbf{a}_{\mathbf{X}\leftarrow j} \cdot \hat{\mathbf{u}}, \qquad \mathbf{a}_{\perp,j} = \mathbf{a}_{\mathbf{X}\leftarrow j} - a_{\parallel,j}\hat{\mathbf{u}}$$

The dominance norm is

$$\|\mathcal{E}_{\text{penetration}}\|^2_{\text{penetration}} = \frac{a^2_{\parallel,j}}{a^2_{\parallel,\text{tol}}} + \frac{\|\mathbf{a}_{\perp,j}\|^2}{a^2_{\perp,\text{tol}}} + \frac{\text{dist}^2_{S^1}(\Delta\phi^{(j)}_{\text{disrupt}}, 0)}{\epsilon^2_{\text{disrupt}}} + \frac{\left(\Delta \ln r_{\mathbf{X}j}\right)^2}{\epsilon^2_r} + \frac{\left(\Delta \ln |J_{\mathbf{X}j}|\right)^2}{\epsilon^2_J}$$

The signed entries in the penetration record remain available before the norm is taken, so a stabilizing tangent push and a destabilizing tangent push are not treated as the same path-history branch. The scalar norm is used only after the sign-sensitive admissibility test has decided which branch contributes to the penetration benchmark.

The tolerance scales must be inherited from declared ledger comparisons. Let $\mathcal{O}_X[\mathcal{B}]$ be the channel readout produced from the projected branch record, and let Δ^{tol}_X be the benchmark sensitivity fixed before the scan. For any retained scalar entry $y_\mu(\mathcal{B})$ in channel X, the first admissible scale is the local pullback of that readout tolerance,

$$\epsilon^2_{\mu,X} = \sup_{\delta y_\mu} \left\{ (\delta y_\mu)^2 : \frac{\|\mathcal{O}_X[\mathcal{B} + \delta_\mu \mathcal{B}] - \mathcal{O}_X[\mathcal{B}]\|_X}{\|\mathcal{O}_X[\mathcal{B}]\|_X + \varepsilon_X} \le \Delta^{\text{tol}}_X \right\}$$

This definition makes the ϵ values derived chart scales: they are how far a retained ledger entry may move before the declared channel readout changes by more than the accepted tolerance. The practical first estimates are:

$$\epsilon_\omega = \Delta^{\text{tol}}_\Gamma, \qquad \epsilon_\theta = \Delta^{\text{tol}}_\theta, \qquad \epsilon_\chi = \Delta^{\text{clk-sig,tol}}_\chi$$

for clock scans;

$$\epsilon_{\text{dir}} = 1 - \cos\theta^{\text{tol}}_X, \qquad \epsilon_{\text{prov}} = \Delta^{\text{tol}}_{\text{prov},X}$$

for corridor scans, with exact provenance closure represented by the limit $\Delta^{\text{tol}}_{\text{prov},X} \to 0$ after regularization; and

$$\epsilon_\parallel = \Delta \ln R^{\text{stab}}_\parallel, \qquad \epsilon_\perp = \Delta \ln R^{\text{stab}}_\perp, \qquad \epsilon_\lambda = \Delta \ln \lambda^{\text{stab}}, \qquad \epsilon_\xi = \Delta \ln \xi^{\text{stab}}$$

for packing scans, where the stable ranges are measured over accepted neighboring-braid branches rather than chosen per atom or line. For penetration over a trial path of duration T_{path} and speed v_{path},

$$a_{\parallel,\text{tol}} = \frac{v_{\text{path}}\Delta v^{\text{tol}}_\parallel}{T_{\text{path}}}, \qquad a_{\perp,\text{tol}} = \frac{v_{\text{path}}\theta^{\text{tol}}_{\text{path}}}{T_{\text{path}}}, \qquad \epsilon_{\text{disrupt}} = \Delta\phi^{\text{tol}}_{\text{path}}$$

Thus tolerance derivation is a ledger-replay problem. A hydrogen line, packing calculation, or penetration test may choose a different channel tolerance because it asks a different stability question, but it may not retune the tolerance after seeing the observable.

The mismatch metric used in the regularized locked projector must also be ledger-derived. Let $\mathcal{R}_a(T)$ be the accepted reduced record of assembly a containing its closure label, phase state, active causal roots, provenance entries, and conserved ledger increments. The first symbolic mismatch is

$$d^2_{\Lambda_a}\left(\mathcal{B}^{(T_i)}_{\mathbf{X}j}\right) = d^2_{\text{disc}} + \frac{\text{dist}^2_{S^1}(\phi_j - \phi_a)}{\epsilon^2_\phi} + \frac{d^2_{\text{root}}(\mathcal{R}_j, \mathcal{R}_a)}{\epsilon^2_{\text{root}}} + \frac{d^2_{\text{prov}}(\mathcal{P}_j, \mathcal{P}_a)}{\epsilon^2_{\text{prov}}} + \frac{\|\Delta\mathcal{N}_{j\to a}\|^2_{\text{cons}}}{\epsilon^2_{\text{cons}}}$$

Here $d_{\text{disc}} = 0$ when the discrete closure labels are compatible and $d_{\text{disc}} = \infty$ when they are incompatible; dist_{S^1} is phase distance; d_{root} compares active causal-root ledgers; d_{prov} compares participating-source provenance; and $\Delta\mathcal{N}_{j\to a}$ collects the energy, momentum, angular-momentum, polarity, and other conserved-increment residuals needed by the assembly ledger. This makes ζ_a a branch-admission test. If any term has to be chosen separately for clock, corridor, packing, and penetration benchmarks, the interface diagnostic has reverted to a fitted surface rather than a closure-ledger projection.

For regularized simulations, the branch sum is replaced by the corresponding finite-width integral with $\delta_\eta(g_{\mathbf{X}j})$. The important constraint is that the numerator and denominator of $D_{a,X}$ use the same channel X, the same causal-width rule, and the same coarse-graining window. Signed force cancellation belongs in acceleration calculations; interface dominance uses retained channel magnitude so that a cancellation in one direction is not mistaken for absence of wake activity.

Then the effective assembly-Noether sea interface for a declared stability threshold D_X is the level set

$$\partial\Omega_a(D_X, T) = \{\mathbf{X} \in \Sigma_T : D_{a,X}(\mathbf{X}, T) = D_X\}$$

The level-set threshold is not universal. A penetration calculation, packing calculation, clock-coupling calculation, and reaction-corridor calculation choose different D_X values because they test different stability criteria. A useful ordering of first thresholds is

$$0 < D_{\text{clock}} \le D_{\text{corridor}} \le D_{\text{packing}} \le D_{\text{penetration}} < 1$$

Clock-coupling can be sensitive to weak locked-wake tails. A reaction corridor needs a stronger coherent channel but need not coincide with the full exclusion envelope. Packing asks where another stable Noether braid or assembly can remain without persistent phase disruption. Penetration asks where transit through the assembly-dominated wake becomes dynamically unstable. What must remain invariant is the level distinction: exact assembly membership is a closure-ledger fact, while $\partial\Omega_a(D_X, T)$ is a spatial interface extracted from that ledger and the surrounding Noether sea response.

Envelope Forms

The envelope form is member data: the union of the swept constituent paths, together with any precession, sets the time-averaged boundary that neighbors and the Noether sea read. B1 sweeps a common-axis envelope at rest, with axial extent set by the h_a values and transverse extent set by the ρ_a values. B1 does not fix the sign of $R_\parallel - R_\perp$: an elongated, equatorial, or intermediate envelope can be selected by its binary coordinates. The Family-A response uses the **near-spherical-to-oblate envelope** described next. The moving Lorentz-projection target is a separate branch response and must not be inferred from a rest-shape sign.

Near-Spherical-to-Oblate Form (A1)

The A1 structure contains three persistently indexed binaries whose reference orbital planes are mutually orthogonal by definition. Near rest in a weak, homogeneous Noether sea, the working response hypothesis is a nearly spherical time-averaged envelope. Increased translation speed or gravitational gradient compresses the envelope along the Family-A $(1, 1, 1)$ translation direction, so the envelope becomes increasingly oblate as the three binary axes converge toward that direction. This is the prescribed Family-A response, not an EOM-solver-retained settling result.

No binary is assigned the leading boundary by the taxonomy. For a declared branch window W and direction $\hat{\mathbf{m}}$, define the directional support of binary a by

$$H_a(\hat{\mathbf{m}}; W) = \sup_{\substack{T\in W \\ j\in\{1,2\}}} \hat{\mathbf{m}} \cdot (\mathbf{X}_{aj}(T) - \mathbf{X}_{\text{grp}}(T)),$$

and the full path-history support by

$$H_{\text{env}}(\hat{\mathbf{m}}; W) = \max_{a\in\{1,2,3\}} H_a(\hat{\mathbf{m}}; W).$$

An index is boundary-leading in direction $\hat{\mathbf{m}}$ only when it attains this maximum on the retained record. The maximizer may depend on direction or time, may be nonunique, and does not relabel the binary. Under the prescribed compression response, the union of all six paths produces the flattened-pole, equatorial-bulge form: an **oblate spheroidal exclusion envelope**.

In low-stress A1 prose, “A1 envelope” means this effective path-history envelope, not a literal material surface.

Canonical Geometry Variables

For either family, use $R_\parallel$ for the semiaxis along the declared family axis or moving-branch drift axis and $R_\perp$ for the transverse semiaxis. The canonical shape ratio is

$$\xi \equiv \frac{R_\parallel}{R_\perp}$$

so $\xi = 1$ denotes a spherical envelope, $\xi > 1$ denotes a fusiform envelope elongated along the parallel axis, and $\xi < 1$ denotes an oblate spheroidal envelope compressed along the parallel axis. A family label must accompany any rest-envelope value of ξ.

Use

$$\lambda \equiv \frac{R_\perp}{R_{\perp,0}}$$

for the transverse scale ratio relative to a stated reference envelope. The pair (ξ, λ) belongs first to braid envelope geometry: ξ records shape and λ records scale.

Observer clock behavior is a downstream readout, not the definition of either geometry variable. In a successful homogeneous Lorentz-closure regime, the theory should derive

$$\frac{\omega_{\text{clk}}}{\omega_0} = \frac{d\tau}{dt_{\text{eff}}} \to \xi \to \frac{1}{\gamma}$$

but this is a moving-branch closure target linking the clock channel to the envelope projection. It should not be used to define ξ, and it does not determine B1's rest-envelope aspect ratio.

Lorentz Projection Role

For branch-quantized Lorentz response, the envelope variables (ξ, λ) are projection variables. They expose the geometry of a stable branch to external clocks, rulers, and nearby assemblies, but they do not by themselves contain the full branch state. The equations in this section state the family-general moving-envelope target; the A1 instantiation begins in Retuning Projection to Envelope Variables, while the B1 projection remains open.

The hidden branch state contains the member-specific binary radii, frequencies, speeds, axes, active causal-root ledger, and wake exchange. For A1 and B1 alike, the leading surface must be projected from all six paths. Therefore the observed ruler factor is extracted through the declared member envelope,

$$\gamma_{\text{rul}}^{(q)}(v) \equiv \frac{R_{\perp,q}(v)}{R_{\parallel,q}(v)} = \frac{1}{\xi_q(v)}$$

but the branch q is accepted only when all three binary ledgers also retune consistently with clock closure, conservation, and preferred-frame leakage bounds.

The direct Lorentz-to-geometry map comes from a closed return cycle. In a homogeneous cell, define

$$\gamma_{\text{eff}}(v) \equiv \frac{1}{\sqrt{1 - v^2/c_{\text{eff}}^2}}$$

Let T_{ref} denote the rest-branch reference period for the same homogeneous branch chart.
The longitudinal return time for an envelope semiaxis $R_\parallel$ is

$$T_\parallel = \frac{R_\parallel}{c_{\text{eff}} - v} + \frac{R_\parallel}{c_{\text{eff}} + v} = \frac{2R_\parallel}{c_{\text{eff}}}\gamma_{\text{eff}}^2$$

while the transverse causal-budget return time is

$$T_\perp = \frac{2R_\perp}{c_{\text{eff}}}\gamma_{\text{eff}}$$

Requiring $T_\parallel = T_\perp + O(\epsilon_{\text{LV}} T_{\text{ref}})$ gives

$$\xi_q(v) = \frac{R_{\parallel,q}(v)}{R_{\perp,q}(v)} = \frac{1}{\gamma_{\text{eff}}(v)} + O(\epsilon_{\text{LV}})$$

The role of the geometry chapter is to record this as an envelope projection, not as a primitive definition. The derivation and closure coefficients belong to Lorentz Kinematics.

This distinction prevents a single-binary shortcut. A branch-derived boundary-leading channel can estimate one visible deformation contribution, while a mature Lorentz closure must show that the same branch update also determines the clock factor

$$\gamma_{\text{clk}}^{(q)}(v) = \frac{T_q(v)}{T_{\text{ref}}}$$

and that the admitted branches satisfy

$$\gamma_{\text{clk}}^{(q)}(v) = \gamma_{\text{rul}}^{(q)}(v) + O(\epsilon_{\text{LV}})$$

The envelope is therefore the visible projection of the retained causal-root ledger, not an independently assigned Lorentz surface.

Retuning Projection to Envelope Variables

This section is the A1 instantiation of the envelope projection, stated on its cadence-scale retuning map (A1 Dynamics); the corresponding projection for B1 remains open.

The cadence-scale retuning map must project into (λ, ξ) through the envelope geometry, not by assigning those variables independently. Let

$$\mathbf{e}_q = \left(\ln R_{\parallel,q},\, \ln R_{\perp,q}\right)^T$$

denote the logarithmic semiaxis record of branch q. The envelope projection is a branch-dependent map

$$\mathbf{e}_q = \mathcal{P}_{\text{env}}^{(q)}(\ln R_1, \ln R_2, \ln R_3,\ \mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3,\ \mathcal{L}_{\text{root}}, \mathcal{L}_{\text{wake}})$$

where the axes, root ledger, and wake ledger are part of the branch data. The induced geometry increments are therefore

$$\Delta \ln \lambda = \Delta \ln R_{\perp,q}, \qquad \Delta \ln \xi = \Delta \ln R_{\parallel,q} - \Delta \ln R_{\perp,q}$$

If one binary a_{env} is uniquely boundary-leading over the relevant directions and window, the projection reduces to the useful estimate

$$\Delta \ln \lambda \approx \Delta \ln R_{a_{\text{env}}}, \qquad \Delta \ln \xi \approx \Delta \ln R_{\parallel,a_{\text{env}}} - \Delta \ln R_{\perp,a_{\text{env}}}$$

This approximation is a projection estimate, not a branch proof. It fails when the maximizer changes with direction or time, when more than one binary contributes at the same order, or when root-history, axis precession, or neighbor-induced strain changes the interface independently of a single radius. Those failures are informative: they identify which hidden ledger entries must be retained before the retuning map can be used for clock, ruler, or Noether sea transport calculations.

A1 Envelope Deformability

The oblate spheroidal envelope is deformable because it is generated by orbit paths, not by a rigid shell. Those paths depend on the superposition of:

- internal binary wakes,
- self-hit and partner-hit closure,
- nearby assembly wakes,
- Noether sea density and stress,
- and the braid's translational state through the Noether sea.

External effective fields, nearby assembly wakes, and dense local assemblies can perturb the binary paths. The most exposed channel must be derived from the branch response and need not be the same index in every direction or environment. A distortion of any boundary-leading path changes the exclusion envelope.

This gives A1 two distinct geometric roles:

1. As an assembly, it can deform while preserving A1 identity across a stable regime.
2. As a medium constituent, many deforming braids can contribute to coarse-grained Noether sea density, strain, and signal-propagation changes.

The claim that those coarse-grained changes reconstruct observer-level gravity is not owned here. It belongs to Emergent Metric, PPN Parameters, and Proper Time and Time Dilation.

For the special-relativity-facing comparison of this deformation channel, see the deformable Noether braid comparison. For the focused synthesis of the closed-return quantization claim, see Return-Cycle Lorentz Quantization.

Geometry Interfaces

For local assembly modeling, use this page as the geometric source for:

- a family-declared fusiform or oblate spheroidal envelope boundary,
- principal axes set by the retained family's orientation,
- deformation of the family-leading envelope paths under local gradients,
- and exclusion-volume changes relevant to packing, shielding, and collision channels.

For the Family-A definitions, use Braid Family A, where the prescribed flattening response is separated from the EOM-solver retention burden. For the Family-B definition, use Braid Family B; its moving-envelope projection remains open.

For Noether sea modeling, use Noether sea and Noether Sea Pro/Anti Coupling, where many Noether braids become a coupled medium rather than isolated assembly envelopes.

Summary Commitment

> **A1 Geometry Commitment:** A1 has a near-spherical weak-stress envelope that becomes oblate under increased translation speed or gravitational gradient. The exclusion envelope is generated by binary path histories and is dynamic and deformable, not a rigid surface. Its deformation is an assembly-level input to Noether sea state variables, while metric and gravity-language reconstruction belongs to the spacetime branch.

> **Member-Scoping Commitment:** B1's rest aspect ratio depends on its prescribed binary coordinates; A1 is near spherical in its weak-stress reference state and becomes increasingly oblate along its prescribed compression response. The moving Lorentz-projection target $\xi \to 1/\gamma$ is a branch-response statement and must be derived separately for each member.

> **Lorentz Projection Commitment:** In Lorentz closure, the full six-path envelope supplies the observable ruler projection, while the accepted branch state remains a retained causal-root ledger. The geometry chapter records ξ and λ as projection variables; it does not reduce clock, mass, or action-ledger closure to one binary path or to envelope shape alone.

Noether Braid Topological Charge

This chapter gives a first-class home to the candidate topological label of a Noether braid assembly. The label combines the causal-root ledger of the delayed dynamics with the phase-return degree data of a resonance-locked Family-A member. Its purpose is to state what can be computed from a retained branch chart, what is invariant inside a nondegenerate branch domain, and what remains a theorem target before the label can serve as a topological periodic table of assemblies. The general search domain that emits candidate Noether braid branch charts is developed in Noether Braid Configuration Space.

The reader-facing idea is that a topological charge is not a decorative name for a braid. It is a proposed invariant label carried by one retained branch chart. Root counts tell which self-hit and partner-hit channels are active; signed degrees say what survives fold-pair surgery; phase-return degree data say how the locked branch winds over one cycle. Only the combination can become a stable assembly label.

This page therefore starts from computation, not classification. A solver must first produce a retained branch with causal-root floors, finite memory, gluing, wake-boundary closure, and stability. The topological label is read from that branch; it does not certify the branch by itself.

The compact notation is

$$[\mathfrak{B}]_{\mathrm{top}} = (N_s,\, M_p,\, c_1)$$

where N_s counts active self-hit roots, M_p counts active partner-hit roots, and c_1 denotes the established phase-entry slot of the retained resonance lock. In this chapter that slot means return-map degree data unless a later two-torus curvature chart is explicitly supplied. For a promoted lock with a three-phase chart this last entry is usually a pair

$$c_1 = (m, n) \in \mathbb{Z}^2$$

rather than a scalar integer: m and n are the binary-2 and binary-1 winding numbers over one binary-3 reference period.

This compact form records the count data most directly emitted by a branch solver. The conserved refinement is

$$[\mathfrak{B}]_{\mathrm{deg}} = (D_{\mathrm{self}},\, D_p,\, c_1)\,,$$

where D_{self} and D_p are signed root degrees. The unsigned counts N_s and M_p can change by opposite-sign fold-pair birth or death, while D_{self} and D_p are the degree-like data preserved by generic fold surgery. A promoted report should therefore carry both the compact assembly topological charge and its signed-degree refinement.

This is a definition and closure target, not a completed classification theorem. It becomes a physical assembly label only after the same retained branch chart supplies positive root floors, finite memory, finite local-to-global gluing, stable return data, and a closed wake-history boundary ledger.

In the terminology of Noether Braid Configuration Space, a candidate for certified-braid promotion is the dynamical return-map status of the full retained branch. The assembly topological charge is the branch-intrinsic topological label carried by that candidate. It is not a Lorentz-dressed observer component: moving-assembly export may transform energy-momentum and angular-momentum readouts, but $[\mathfrak{B}]_{\mathrm{top}}$ changes only when the retained branch crosses a fold, reconnection, or declared surgery event.

Document Role

This chapter is the downstream classifier for retained Noether braid branch charts. It owns $[\mathfrak{B}]_{\mathrm{top}}$, the signed-degree refinement, invariance conditions, allowed transitions, and simulation extraction order for the topological label.

It does not certify branch retention by itself and does not create a base classification label. It consumes a same-record branch chart from the neutral-base, A/B/C-member, rank-three, or lower-rank proof effort; the label becomes physical only after the causal-root, phase-return, gluing, wake-boundary, and stability rows close on that same record.

Source Of The Three Entries

The first two entries come from the causal-root complex of the Master Equation. On a retained branch chart, active roots are split by transmitter identity and by Jacobian sign. Let b_ℓ denote the formal generator attached to active root row ℓ. The modules below are free $\mathbb{Z}$-modules, so the ledger invariant is their rank. For the self-hit sector,

$$C_{s,+}(\mathfrak{B}) = \mathbb{Z}\langle b_\ell : \text{self root},\ J_\ell > 0\rangle, \qquad C_{s,-}(\mathfrak{B}) = \mathbb{Z}\langle b_\ell : \text{self root},\ J_\ell < 0\rangle.$$

For the partner-hit sector,

$$C_{p,+}(\mathfrak{B}) = \mathbb{Z}\langle b_\ell : \text{partner root},\ J_\ell > 0\rangle, \qquad C_{p,-}(\mathfrak{B}) = \mathbb{Z}\langle b_\ell : \text{partner root},\ J_\ell < 0\rangle.$$

The unsigned ledgers are

$$N_s = \mathrm{rank}_{\mathbb{Z}}\, C_{s,+} + \mathrm{rank}_{\mathbb{Z}}\, C_{s,-}, \qquad M_p = \mathrm{rank}_{\mathbb{Z}}\, C_{p,+} + \mathrm{rank}_{\mathbb{Z}}\, C_{p,-}.$$

The signed degrees

$$D_{\mathrm{self}} = \mathrm{rank}_{\mathbb{Z}}\, C_{s,+} - \mathrm{rank}_{\mathbb{Z}}\, C_{s,-}, \qquad D_p = \mathrm{rank}_{\mathbb{Z}}\, C_{p,+} - \mathrm{rank}_{\mathbb{Z}}\, C_{p,-}$$

are not extra entries in the compact assembly topological charge, but they are required side data and form the conserved-degree refinement $[\mathfrak{B}]_{\mathrm{deg}}$. A solver that reports only N_s and M_p has counted roots without proving which opposite-sign pairs can be born, die, or persist under deformation.

Equivalently, each source sector is a $\mathbb{Z}_2$-graded two-term root module, inheriting the signed causal-root-complex reading from Master Equation:

$$C_{\sigma,\bullet} = C_{\sigma,+} \oplus C_{\sigma,-}, \qquad \sigma \in \{s,p\}.$$

The unsigned ledgers N_s and M_p are ranks of a chosen presentation. They are useful live-channel counts, but they are not the conserved quantities across fold-pair surgery. The conserved local degree is the Euler characteristic

$$\chi(C_{\sigma,\bullet}) = \operatorname{rank}_{\mathbb{Z}} C_{\sigma,+} - \operatorname{rank}_{\mathbb{Z}} C_{\sigma,-} = D_\sigma.$$

A generic fold birth adds one positive and one negative generator, so the presentation rank changes by two while $\chi(C_{\sigma,\bullet})$ is unchanged.

The geometric reading is intersection-theoretic. On a lifted finite-memory strip, each connected retained causal-locus component has an oriented intersection number with a generic receiver-time fiber. Let $\mathcal{L}_\sigma$ be the retained causal-locus chain in sector $\sigma \in \{s,p\}$ and let F_{T_*} be a generic receiver-time fiber at fixed absolute time T_*. Then

$$D_\sigma = \langle [\mathcal{L}_\sigma], [F_{T_*}] \rangle \,.$$

On a regular one-parameter family with parameter μ,

$$\frac{d}{d\mu} \langle [\mathcal{L}_\sigma(\mu)], [F_{T_*}] \rangle = 0.$$

Fold-pair births and deaths appear as null-homologous bigons with local contributions $+1-1=0$. Summing oriented intersections in the self and partner sectors gives D_{self} and D_p; summing their absolute values gives N_s and M_p. This sector restriction is $D_\sigma = \chi_{\mathrm{root}}|_\sigma = \chi(C_{\sigma,\bullet})$ for $\sigma \in \{s,p\}$, the self and partner parts of the causal-root ledger in Absolute Timespace. This is also the bridge to Causal Action Functional: the same causal-locus components that carry action-counting weight supply the signed root degrees used by the assembly topological charge.

The third entry comes from the phase-return chart of a resonance-locked Noether braid. Let $\theta_1, \theta_2, \theta_3$ be the phase coordinates attached to the persistent binary indices. Exact integer closure over one binary-3 reference period P_3 means

$$\theta_3(T+P_3) = \theta_3(T) + 2\pi,$$

$$\theta_2(T+P_3) = \theta_2(T) + 2\pi m, \qquad \theta_1(T+P_3) = \theta_1(T) + 2\pi n.$$

Equivalently, the relative-phase one-forms

$$\vartheta_2 = d\theta_2 - m\, d\theta_3, \qquad \vartheta_1 = d\theta_1 - n\, d\theta_3$$

have integer holonomy and become flat on a promoted phase-locked branch. Let $\rho_3 : S^1_3 \to \mathfrak{B}$ be one retained binary-3 return cycle. The shorthand

$$c_1[\theta_1, \theta_2, \theta_3] = (\deg(\theta_2 \circ \rho_3),\, \deg(\theta_1 \circ \rho_3)) = (m,n)$$

records this phase-return degree data. The doubling-frequency `4:2:1` candidate is the binary-3-normalized case $(m,n) = (2,4)$, equivalently $f_1 : f_2 : f_3 = 4:2:1$.

The symbol c_1 is retained as the established phase-entry notation, but it should not be read here as a literal first Chern class of principal circle bundles over the binary-3 phase circle. Such bundles over S^1_3 are topologically trivial because $H^2(S^1_3; \mathbb{Z}) = 0$. The claim is the degree-pair claim

$$(m,n) \in [S^1_3, S^1] \times [S^1_3, S^1] \cong \mathbb{Z}^2,$$

with flat relative-phase recurrence on the retained return chart. If a later chart supplies a genuine two-torus curvature form, its first Chern number can be compared with this degree pair. Until then, $c_1 = (m,n)$ means return-map degree data, not a curvature integral.

The doubling-frequency data $(m, n) = (2, 4)$ belong specifically to the frequency-separated A3.3 member and its A1.3 zero-axial-offset locus. They are not generic Noether braid data. In particular, B1 is common-frequency on one common-axis phase chart: its three path families do not supply three independent orbital-plane normals, so the rank-three phase entry defined here is suspended rather than assigned $(1, 1)$ or $(2, 4)$. A B1 branch may still report the partial charge (N_s, M_p); a B1 lower-rank return invariant would require a separate definition and certificate.

The phase entry is also conditional on the three support-row planes remaining independent. Use the canonical determinant D_{plane} defined in Noether Braid Configuration Space.
The degree pair is admissible only when

$$|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0.$$

When this floor fails, the three phases no longer supply an independent return chart, so c_1 must be suspended rather than compared across the degeneracy.

Candidate Definition

For a finite-η branch chart $\mathfrak{B}$, the assembly topological charge is admissible only when the following data are present on the same retained row set:

1. Active root rows split by transmitter identity: self-hit and partner-hit.
2. Jacobian-sign grading for those rows: $C_{s,+}, C_{s,-}, C_{p,+}, C_{p,-}$.
3. Positive transversality floors away from declared finite caustic transits.
4. Finite memory depth and positive inactive-root gaps.
5. A finite local-to-global gluing result for the branch chart, or an explicit finite multistability family.
6. For a rank-three branch, integer phase closure, flat relative-phase connection, and a plane-independence floor $|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0$.
7. A return-map stability certificate, such as a Floquet or Conley-style branch certificate, after quotienting only true symmetry directions.
8. If a binary $h \in \{1, 2, 3\}$ is treated as a caustic-grazing carrier, regulator-stable carrier rows showing that the reported root degrees and phase-return entry do not depend on the finite-η convention in the promoted limit. The index h is a branch diagnostic, not a taxonomy assignment.

Under those conditions the compact assembly topological charge is

$$[\mathfrak{B}]_{\text{top}} = (N_s,\ M_p,\ c_1[\theta_1, \theta_2, \theta_3]) \in \mathbb{Z}_{\geq 0} \times \mathbb{Z}_{\geq 0} \times \mathbb{Z}^2.$$

For a Noether braid branch without a phase-return chart, the partial assembly topological charge (N_s, M_p) may be recorded, but c_1 is not assigned until that chart exists.

A useful refinement is a branch-preserving chirality label

$$\chi_{\text{fr}} \in \mathbb{Z}_2.$$

The richer ordered-braid chirality label χ_c is introduced in Reduced A1 Closure Label. In this chapter, χ_{fr} is the certified $\mathbb{Z}_2$ projection of that richer chirality data when the same branch chart supplies a deformation-stable handed marker, such as a framed self-linking sign or a certified maximal-curvature-binary circulation sign. The marker's canonical source is the framing row of the retained-branch certificate, which carries the framed-path record $Lk = \mathrm{Wr} + \mathrm{Tw}$, the framing sign, and its positive conditioning floor on the same ledger identity as the root and phase-return data. It is not an independent competitor to χ_c, and it is not part of the base triple until the projection is certified. It must be invariant under the same branch-preserving deformations that keep (N_s, M_p, c_1) fixed, and it may flip only at an independent framing wall Σ_{frame} where the nonsingular framing floor fails. It is the natural place to record handedness, but it must not be substituted for the root and phase-return data. The two signs of the maximal-curvature-binary circulation are introduced in Binary Dynamics.

Invariance And Allowed Transitions

The assembly topological charge is designed to be locally invariant. Between branch boundaries, the implicit-function theorem transports each simple active root continuously, so N_s, M_p, D_{self}, and D_p remain constant. At a generic fold, one positive and one negative root are created or annihilated. Therefore

$$(\Delta N_s, \Delta M_p) \in \{(\pm 2, 0), (0, \pm 2)\}, \qquad \Delta D_{\text{self}} = \Delta D_p = 0$$

for an ordinary fold-pair event. In the sector where the fold occurs, the unsigned count changes by ± 2 while both signed degrees remain unchanged.

Cusp or higher singular strata are not automatically governed by the generic fold law. They require a separate regularized normal form before their ledger surgery can be promoted. Likewise, $c_1 = (m, n)$ remains fixed under deformation only while the return-map degree pair is unchanged, the relative-phase connection stays flat, and the plane-independence floor remains positive. A loss of resonance lock, a plane-degeneracy transition, or a branch-fold event that changes the return chart can change the phase entry.

Near generic walls the transition stratification is product-like:

$$\Sigma_{\text{charge}} = \Sigma_{\text{root}} \cup \Sigma_{\text{phase}} \cup \Sigma_{\text{plane}},$$

with Σ_{frame} added when χ_{fr} is part of the certified report. Away from intersections these are transverse codimension-one walls, so exactly one entry of the compact label or one certified refinement changes. Codimension-two intersections encode simultaneous events, such as a cusp, a root-plus-phase transition, or a plane-plus-phase transition; those require their own normal form before any ledger surgery is inferred.

The transition catalogue therefore has a native form:

Event	Codimension	Assembly topological charge effect	Required certificate
Branch-preserving deformation	0 on the retained chart	No change to (N_s, M_p, c_1) or $(D_{\text{self}}, D_p, c_1)$	Positive floors, finite memory, stable gluing
Self-root fold	1 generically	$\Delta N_s = \pm 2$, $\Delta D_{\text{self}} = 0$ generically	Fold normal form and post-transit chart
Partner-root fold	1 generically	$\Delta M_p = \pm 2$, $\Delta D_p = 0$ generically	Fold normal form and post-transit chart
Phase-lock jump	1 for a resonance crossing	$\Delta c_1 \neq 0$	Degree/holonomy change and return-map transition
Plane-degeneracy transition	1 generically, higher with imposed symmetry	Phase-return chart may lose rank before c_1 can be compared	Orbital-plane determinant and return-chart continuation
Framing or chirality flip	1 or higher, depending on the framing chart	$\Delta \chi_{\text{fr}} \neq 0$	Framed-linking or handedness transition certificate
Cusp or deeper singular stratum	2 or higher generically	Not inferred from fold law	Singular-stratum chart and regulator-stable transition data

This is why the triple belongs in one object. The root ledgers describe which delayed causal channels are live, while the phase-return entry describes how the multi-layer branch returns to itself. Both are characteristic data of the same retained causal-root sheaf: local root sections, overlap gluing, and phase degree/holonomy must agree before an assembly label is promoted.

Role In The Assembly Atlas

The topological atlas of assemblies should not classify objects by visual similarity alone. It should classify retained branches by deformation-stable integers that can be extracted from the same simulation record used to test the dynamics. The candidate atlas entry for a stable assembly is therefore

$$\mathcal{Q}_{\text{asm}} = (N_s,\ M_p,\ c_1,\ \chi_{\text{fr}} \text{ when certified})$$

together with its stability margins, energy/wake ledger, and gluing status.

The intended use is constrained:

- (N_s, M_p) records the binding-channel census: self-hit channels, partner-hit channels, and their signed degrees.
- $c_1 = (m, n)$ records the resonance-lock return-map degree pair of a promoted rank-three branch; $(2, 4)$ is the A3.3 doubling-frequency candidate, including its A1.3 zero-axial-offset locus, not a family-general value.
- χ_{fr} records handedness only after a framed handed marker is certified.
- Physical particle identity, generation structure, spin-statistics, exclusion, and Standard Model quantum numbers are downstream mappings, not consequences of the notation alone.

Thus (N_s, M_p, c_1) is the candidate conserved label that says when two assemblies occupy the same topological sector. It is not yet a proof that a given sector is an electron analogue, photon analogue, or quark analogue.
Strictly, the compact count triple is locally conserved only inside one nondegenerate branch domain. Across generic fold-pair surgery the degree-refined data $(D_{\text{self}}, D_p, c_1)$ are the conserved part, while N_s and M_p record how many live channels the retained branch currently carries.

Simulation Extraction

A branch solver should extract the assembly topological charge in this order:

1. Build the finite-η retained branch chart and declare its memory window.
2. Find active causal roots on the same retained row set.
3. Label each root by transmitter identity: self or partner.
4. Record the Jacobian sign and compute $C_{s,+}, C_{s,-}, C_{p,+}, C_{p,-}$.
5. Compute N_s, M_p, D_{self}, and D_p.
6. Compute the lifted-strip fiber-intersection degrees that realize D_{self} and D_p whenever the causal-locus chart is available.
7. Track fold, caustic, cusp, or inactive-gap transition metadata.
8. For branches with a Noether braid phase-return chart, compute phase degree/holonomy (m, n) from the returned phase chart, verify the floor $|D_{\text{plane}}| \geq \delta_{\text{plane}} > 0$, and show that (m, n) comes from the return map rather than from frequency ratios alone.
9. If a caustic-grazing carrier h is used, test that the signed degrees and phase-return entry are stable under the declared η refinement.
10. Test gluing and finite continuation cardinality for the local charts.
11. Test the return-map stability gap off true symmetry directions.
12. Report $[\mathfrak{B}]_{\text{top}}$ only after the same retained rows pass these checks.

The failure modes are equally important. A candidate is not promoted if the roots are counted without signs, if self and partner rows are mixed, if the phase lock is inferred from frequency ratios without holonomy recurrence, if local branch charts do not glue, or if the continuation family is empty, infinite, or unlabeled.

Status

The established pieces are local:

- The delay-map theorem pack in Master Equation proves signed degree invariance on regular families and the generic opposite-sign fold-pair law.
- The signed causal-root complex in Master Equation supplies the local chain-complex reading of active roots.
- Binary Dynamics supplies the self-hit and partner-hit ledger notation used by (N_s, M_p).
- A3.3 Doubling-Frequency Resonance Lock supplies the A3.3 integer phase-closure data whose return-map degree pair is recorded as $c_1 = (m, n)$; A1.3 is its zero-axial-offset locus, and B1 does not inherit that rank-three entry.
- Effective Lagrangian uses the same topological sector in the action and mass-gap theorem target.

The open proof burden is global:

- prove that a stable assembly realizes a fixed assembly topological charge over a finite branch domain;
- prove gluing of the local causal-root charts into a finite labeled continuation family;
- prove a positive stability gap for the assembly topological charge sector;
- determine whether the entries are independent or constrained by radial balance, phase flatness, and Noether sea response, starting with the reachable theorem target that for a layer winding $k_a \in \{1, m, n\}$ the layerwise self-hit degree obeys a parity or lower-bound law $D_{\text{self}}^{(a)} \equiv f(k_a) \pmod 2$ derived from the circular self-hit fold-birth sequence and the lifted-strip fiber-intersection formula;
- prove that any caustic-grazing carrier rows have regulator-stable signed degrees and phase-return entries, so the assembly topological charge does not depend on the finite-η convention used to regularize the field-speed transition;
- map any certified sectors to observer-level particle quantum numbers without fitting the labels afterward.

The chapter should therefore be read as the canonical definition and proof target for assembly topological charge, not as the completed topological periodic table.

Noether Sea and Effective Spacetime

Noether Sea

This chapter defines the **Noether sea** as the physical medium inside the fixed background in $\mathbb{AAA}$. It explains what the medium is, how it differs from the Euclidean void, which state variables describe it, and where detailed assembly, metric, clock, and cosmology work belongs.

The Noether sea is not the substrate. The substrate is absolute timespace: absolute time together with the Euclidean void. The Noether sea is physical content inside that background: an emergent, coupled population of neutral Noether braid assemblies whose collective response appears to physical observers as spacetime behavior.

The easiest mistake is to treat the Noether sea as another name for space. It is not. Space is the fixed container. The Noether sea is the organized medium inside that container. Effective spacetime is the observer-level reconstruction built from how that medium changes clocks, rulers, signals, and matter response.

This is why the reader path introduces Noether braid scaffold and geometry before observer-level spacetime. The intended picture is a fixed container populated by organized assemblies, not a flexible container that curves by itself. At the roadmap level, the physical Noether braid density can be read as a coarse-grained population field,

$$\rho_{\rm NS}(\mathbf{X},T) \sim \sum_s W_\ell(\mathbf{X}-\mathbf{X}_s(T))$$

where W_ℓ is a smoothing window over Noether braid center variables $\mathbf{X}_s(T)$. The Noether sea stress, delay factor, and orientation variables then depend on each braid's closure label, orientation, and envelope deformation. The Noether sea is therefore introduced before effective metric language because its state variables are coarse-grained functions of Noether braid geometry, not primitive geometric postulates.

The homogeneous Noether sea also supplies the first constructive convergence case for the infinite many-source wake sum. In a statistically homogeneous, isotropic, locally neutral population with neutrality correlation length ℓ, receiver-centered shell contributions have square-summable fluctuations: a shell of radius $r_n \sim n\ell$ contains $O(n^2)$ neutral cells, signed fluctuations scale as $O(n)$, and inverse-square wake dilution contributes $O(n^{-2})$. The shell variance is therefore $O(n^{-2})$. The required mixing condition is summable cross-shell covariance,

$$\sum_{n\neq m} |\mathrm{Cov}(\mathbf{\Delta A}_n, \mathbf{\Delta A}_m)| < \infty,$$

where $\mathbf{\Delta A}_n$ is the signed fluctuation of shell n's wake-acceleration contribution about its neutral ensemble mean. The condition prevents correlations from rebuilding a divergent coherent tail from individually decaying shells. Under that condition the neutral far-population contribution converges in the receiver-centered exhaustion sense. This exhaustion is fixed by the receiver event's causal-root ledger and expanding receiver-centered shells, not by an arbitrary rearrangement of a conditionally convergent spatial series. This is a weak homogeneous medium result, not a blanket convergence claim for coherent strong-field regions or unneutralized source populations.

The spacetime recovery stack depends on four load-bearing hypotheses that must remain visible:

Hypothesis	Role	Current status
Family-A Lorentz-link	Identifies moving-envelope flattening as the carrier of clock and ruler retuning.	Kinematic closure target; no confirmation from evolved moving branches.
Shared clock/signal delay	Sets $\Delta_\chi^{\text{clk-sig}} = 0$ so clocks and Shapiro delay consume one scalar delay response.	Conditional weak-field branch, not a derived identity.
Local clock/sea cadence tracking	Identifies a matter-clock cadence change with the local $C_N = \Gamma_N^{-1}$ readout in the same cell.	Same-record closure target, with mismatch retained explicitly.
Family-A ambient selection	Selects Family-A carriers as the physical Noether sea population.	Comparative selection hypothesis; not established by prescribed geometry alone.

Core Definition

The **Noether sea** is the ambient physical medium formed by dense, balanced populations of coupled neutral Noether braids in the Euclidean void.

It is:

- **Emergent:** it is built from architrino assemblies, not added as a second primitive substance.
- **Physical:** it carries energy, stress, density, orientation, and response properties.
- **Dynamic:** it can flow, strain, polarize, compress, relax, and support propagating disturbances.

- **Ambient:** it surrounds and couples to matter assemblies, clocks, rulers, photons, and strong-field regions.
- **Medium-level:** it is neither the empty void nor the observer-level effective metric.

The bridge term **spacetime medium** may be used when translating toward effective spacetime language. The canonical ontology name remains **Noether sea**.

In prose, use **Noether sea** both as the standalone proper noun and as the compound modifier before another noun, as in **Noether sea density** or **Noether sea delay factor**. Reserve **Noether Sea** for title contexts and never hyphenate the term.

Boundary With the Euclidean Void

The Euclidean void and the Noether sea must remain distinct. The void is the fixed spatial container; the Noether sea is the active content whose state changes inside it.

Layer	Status	What It Owns
Euclidean void	Fundamental substrate	Fixed spatial container $\mathbb{R}^3$, metric $h_{ij} = \delta_{ij}$, coordinate identity
Noether sea	Emergent physical medium	Density, stress, flow, orientation, energy storage, delay-factor response
Effective spacetime	Observer-level reconstruction	Clock rates, ruler behavior, signal propagation, effective metric

The void does not curve, expand, contract, or carry energy. The Noether sea, as physical content, can carry energy and stress, flow, strain, compress, relax, and change its response variables. Effective curvature and effective expansion are therefore derived descriptions of Noether sea response, not curvature or expansion of the void itself.

At a fixed coordinate point $\mathbf{X}$ and absolute time T, the Noether sea state may change:

$$\rho_{\mathrm{NS}}(\mathbf{X}, T), \quad \Sigma_{\mathrm{sea}}(\mathbf{X}, T), \quad \mathbf{u}_{\mathrm{sea}}(\mathbf{X}, T)$$

without changing the identity of the underlying void point.

Absolute Record and Observer Readout

The complete substrate description is the universe state

$$\mathbb{U}_{\mathrm{now}} \equiv S(T)$$

This state is not an observer frame. It is the absolute-time record of positions, velocities, assemblies, causal wakes, Noether sea variables, and path-history ledgers inside the Euclidean void. Physical observers recover clock rates, photon frequencies, energies, distances, and effective geometry only after their local assemblies couple to part of that record.

This distinction matters most in redshift language. The void does not stretch, and absolute time does not slow. A source assembly emits a photon-channel packet with a local emission ledger; the packet follows a definite path history through the Noether sea; and the receiver assembly samples the packet using its own local cadence. The measured energy is therefore a receiver-coupling result,

$$E_{\mathrm{obs}} = h\nu_{\mathrm{obs}}$$

not a primitive frame-free photon scalar. The redshift task is to compute the endpoint cadence, launch geometry, and path-history propagation terms from the same $S(T)$ record rather than changing explanation between gravitational, relative-motion, and cosmological cases.

Composition

The Noether sea is composed of neutral Noether braid assemblies. The best-developed prescribed case is Family A, made from three indexed electrino:positrino binaries. A Noether braid itself is not elementary; its stability is a downstream assembly result.

This composition statement is a theorem target, not a permission to ignore other possible architrino assemblies. The universe-state inventory may contain many finite assembly classes: bare binaries, transient multi-body reaction corridors, larger N-site branches, charged assemblies, photon-channel packets, neutrino-like near-photon assemblies, and strong-field branch variants. Most of those may be physically real without being the ambient Noether sea population. The medium claim is that one neutral assembly class supplies the weak homogeneous background whose coarse variables recover clocks, rulers, signal speeds, pressure, inertia, and effective metric behavior.

For a candidate ambient assembly class $\mathfrak{C}$, define the selection residual

$$\mathcal{R}_{\text{sea-class}}(\mathfrak{C}) = \max(\mathcal{R}_{\mathrm{ret}}, \mathcal{R}_{\mathrm{neutral}}, \mathcal{R}_{\mathrm{conv}}, \mathcal{R}_{\mathrm{pack}}, \mathcal{R}_{\mathrm{trans}}, \mathcal{R}_{\mathrm{resp}}, \mathcal{R}_{\mathrm{build}}, \mathcal{R}_{\mathrm{abund}})$$

The entries are, respectively: retained-branch closure; local polarity neutrality and pro/anti balance; convergence of the far-population wake sum; dense packing without uncontrolled branch disruption; weak homogeneous transparency to ordinary matter, photon-channel packets, and neutrino-like assemblies; a shared constitutive response for n, χ_{sea}, Γ_N, stress, and effective metric channels; compatibility with the particle-building branch program; and a production, recycling, or relaxation route that gives the class sufficient abundance.

Transparency is therefore a bounded-response condition, not a claim of zero interaction. The Noether sea has to keep direct scattering and loss below tolerance while still supplying the response assigned to clocks, photons, matter, and neutrino-like channels. For a channel family $X \in \{\gamma, \mathrm{clk}, \mathrm{mat}, \nu\}$, where clk denotes the physical-clock channel whose observer readout is derived clock time τ, the Noether sea must make direct loss, scattering, and preferred-frame visibility small while still supplying the constitutive response that the channel is supposed to recover. A compact two-row check is

$$\mathcal{R}_{\mathrm{vis/resp},X} = \max\left(\frac{\mathcal{R}_{\mathrm{loss/scat},X} + \mathcal{R}_{\mathrm{LV},X}}{\epsilon_{\mathrm{vis},X}}, \frac{\|O_X^{\mathrm{eff}} - \Pi_X[\Theta_{\mathrm{sea}}, \mathcal{L}_X]\|}{\epsilon_{\mathrm{resp},X}}\right).$$

The first term enforces weak homogeneous transparency and hides ordinary medium-drift leakage; the second term enforces that clocks, photon transport, matter response, or neutrino-like propagation still consume the same retained Noether sea record. A candidate class that sets the coupling to zero passes neither row: it may become invisible, but it no longer reconstructs the effective observables assigned to the Noether sea.

The Family-A-centered Noether sea claim is therefore the statement that the corresponding class $\mathfrak{C}_A$—prescribed one-braid records whose three axes run from mutual orthogonality toward the group-translation direction along λ_A—can drive $\mathcal{R}_{\text{sea-class}}(\mathfrak{C}_A)$ below the accepted tolerance while other candidate classes either fail one of the rows or are classified as localized matter, radiation, reaction, or strong-field branches. This is stronger than saying that Family-A exclusion envelopes are visually plausible. It is a comparative selection problem over assembly classes, not a consequence of the taxonomy definition.

The large-scale Noether sea is modeled as a balanced population of complementary Noether braid orientations.

This pro/anti distinction is the geometric and topological ordered-orientation label, not polarity conjugation, matter/antimatter, or a net electric-charge distinction. Global polarity conjugation leaves a braid's worldlines and therefore its pro/anti orientation unchanged. Both orientations are electrically and polarity neutral at the braid level. Their coupled orientation balance is part of the working explanation for how the Noether sea remains comparatively transparent and non-reactive at large scales while still carrying stress and response; it does not assert a matter/antimatter population balance.

Transparency has a candidate mechanism at the level of a single transiting assembly, offered here at effective grade. A propagating assembly is sub-field-speed, so its wake runs ahead of it and reaches the medium before the body does; the sea assemblies do not move aside like obstacles but re-phase — reorient in response to the forerunning wake, then relax. Transparency is then *elastic parting*: the medium opens ahead through wake-induced polarization and closes behind, leaving no net transit excitation, so no energy or momentum is deposited by the completed passage and the transit is lossless. The wake-level statement is that the transiting and ambient wakes superpose, while the assembly-level statement is that the perturbation produced by passage is reversible. Imperfect closure — a residual excitation left downstream — is the microscopic content of the loss, scattering, and preferred-frame-visibility terms the selection residual above bounds: a fully transparent class is one whose parting is elastic to the required tolerance.

This reversible transit row does not erase persistent gravitational loading. A source assembly that remains in a region supplies a quasi-stationary boundary condition and maintains a polarized Noether sea response; a transiting assembly supplies a time-dependent perturbation about that loaded state. Lossless closure requires the latter perturbation to relax after passage, not the former source-supported polarization to vanish. The constitutive map must derive both responses from the same wake record and distinguish them by source persistence and response timescale rather than by changing the coupling law.

The detailed pro/anti basis, density split, imbalance stability, local coupling law, and candidate cluster motifs belong in Noether Sea Pro/Anti Coupling. This page only fixes the Noether sea ontology those assembly hypotheses serve.

Local Branches in the Medium

The Noether sea changes how isolated assembly calculations should be read. A truly isolated Noether braid or matter assembly is a limiting seed chart, not the generic physical situation. The physical target is a local branch retained inside the surrounding Noether sea state and nearby-assembly record.

Assembly-Medium Metabolism

At the ontology level, a matter braid embedded in the Noether sea is an open assembly, not an isolated clockwork object. It exchanges angular momentum and causal-wake structure with neighboring neutral braids while preserving its own closure ledger. The exact boundary between assembly-locked and ambient contributions is the channel-dependent assembly-Noether sea interface diagnostic, $D_{a,X}$; spatial proximity alone does not decide which record owns a contribution.

The current B1 evidence sharpens that picture without closing the full medium problem. B1 here means the prescribed chart with one common midpoint, one coincident binary axis, one common frequency, and one common circulation sense; per-binary radii, axial half-separations, transverse orbit radii, and phases remain independent. At measurement level, the forward torque to the source-record circulation channel and the axial support supplied by a phase-matched responsive sea are readings of the prescribed response records, pending a linked instrument record; the tested axially organized responses do not supply the missing equatorial support. At mechanism-estimate level, this motivates an angular-momentum metabolism: the sea feeds an assembly channel, internal wake transport redistributes that input, and outgoing wake returns angular momentum to the sea's orientation order. A self-consistent closed loop has not yet been derived, so the metabolism is a constitutive closure target rather than a retained-branch theorem.

The static cage result gives the complementary effective picture. When a braid's support deficit selects a polar-covering neighbor cage, the acceleration-balanced candidate is a braid-plus-cage complex (stability ledger open), closer to a molecule in a solvent than to a point object fixed at a lattice site. That comparison is effective framing, not ontology: the underlying objects remain Noether braid assemblies and causal wakes, and the cage still requires its own reciprocal acceleration and stability ledger. Together, the metabolism and cage pictures explain why the Noether sea is part of the assembly's physical boundary conditions rather than decorative background.

For a candidate local branch B, the stronger closure form is not

$$\mathcal{R}_{\text{branch}}(B) = 0$$

in empty surroundings. It is

$$\mathcal{R}_{\text{branch}}\left(B; \Theta_{\text{sea}}, \Theta_{\text{asm}}, \mathcal{H}_{\partial\Omega}\right) = 0$$

where Θ_{sea} records the local Noether sea density, cadence, orientation, strain, and delay-response state; Θ_{asm} records nearby resolved assemblies, including assemblies that later map to Standard Model particle language; and $\mathcal{H}_{\partial\Omega}$ records the causal-wake and event data entering the local region through its boundary. These are not extra fit parameters. They are the retained part of the same absolute record $S(T)$ needed to decide whether the local branch persists.

At the acceleration-ledger level this means that a local architrino row should be understood schematically as

$$\mathbf{A}_i = \mathbf{A}_{i,\text{internal}} + \mathbf{A}_{i,\text{sea}} + \mathbf{A}_{i,\text{asm}} + \mathbf{A}_{i,\partial\Omega}$$

with every non-internal contribution either computed from the surrounding Noether sea state and assembly record or explicitly assigned a residual. The isolated equation is recovered only when $\mathbf{A}_{i,\text{sea}}$, $\mathbf{A}_{i,\text{asm}}$, and $\mathbf{A}_{i,\partial\Omega}$ vanish, are homogeneous enough to collapse into fixed boundary data, or are below the declared tolerance.

Reaction records use the same embedding discipline. The Noether sea is not a passive stage when a vertex recruits neutral Noether braid content, returns unbound or reclassified content to the ambient medium, changes local cadence or excitation, or absorbs recoil and remnant energy. For a finite reaction window Ω, the Noether sea participation row can be written schematically as

$$\Delta N_{\text{sea}}^{\Omega} = N_{\text{return}} - N_{\text{recruit}} + N_{\text{prod}} - N_{\text{dissoc}} - N_{\text{reclass}} + N_{\text{relax}} + R_{N,\Omega}.$$

Each term must be tied to the same identity, energy, momentum, angular-momentum, and causal-wake ledger used by the local reaction. If a reaction changes apparent particle inventory while leaving the Noether sea row undeclared, the source story is incomplete rather than closed.

This does not require solving the entire universe before studying one assembly. It does require a controlled embedding record. The useful analytic hierarchy is:

1. solve or approximate a homogeneous Noether sea record;
2. solve the candidate branch against that local medium and nearby-assembly record;
3. check the branch's back-reaction on ρ_{NS}, f_N, χ_{sea}, cadence, orientation, and event ledgers.

Assembly emergence is therefore not emergence from empty isolation. It is local retention inside an already populated Noether sea, with isolated analytical branches serving as seed charts, symmetry limits, or comparison cases.

State Variables

The spacetime branch uses the following canonical total-density symbols:

$$\rho_{\text{NS}}(\mathbf{X}, T)$$

with normalized density

$$n(\mathbf{X}, T) = \frac{\rho_{\text{NS}}(\mathbf{X}, T)}{\rho_{\text{NS},0}}$$

The Noether sea delay factor is written

$$\chi_{\text{sea}}(\mathbf{X}, T) = \frac{c_f}{c_{\text{eff}}(\mathbf{X}, T)}$$

It plays the role that refractive index plays in ordinary optical analogies, but it is a native Noether sea response variable. Do not use n for this delay factor; n is reserved for normalized Noether braid density.

Clock and spectral comparisons may also extract the Noether sea cadence-stretch diagnostic

$$\Gamma_N(\mathbf{X},T)=\frac{\Omega_{N0}}{\Omega_N(\mathbf{X},T)},\qquad C_N(\mathbf{X},T)=\Gamma_N^{-1}(\mathbf{X},T)$$

Here Ω_N is a representative local Noether sea braid cadence and C_N is the corresponding clock-rate factor. This pair is not a new density or delay factor: n tracks normalized Noether braid density, χ_{sea} tracks effective causal delay, and Γ_N tracks cadence stretch. The clock extraction and hydrogen spectral use of this diagnostic belong in Proper Time and Time Dilation.

When a calculation needs pro/anti subcomponents, orientation imbalance, or coupling-regime stability thresholds, use Noether Sea Pro/Anti Coupling.

Medium Properties

The Noether sea is characterized by collective variables, not by a new point-particle inventory.

Important medium properties include:

- **Noether braid density:** $\rho_{\text{NS}}(\mathbf{X},T)$ and normalized density $n(\mathbf{X},T)$.
- **Energy density:** approximately $\rho_{\text{NS}}E_{\text{braid}}$ at the coarse level, with corrections from stress, excitation, and coupling.
- **Orientation and strain:** local ordering of braid axes and deformation away from equilibrium.
- **Flow or drift:** collective motion of the Noether sea relative to the absolute frame.
- **Compliance:** how strongly the Noether sea responds to compression, shear, polarization, and alignment loading.
- **Delay-factor response:** how χ_{sea}, signal propagation, clock behavior, and effective light speed depend on local Noether sea state.

These are medium variables. They are not properties of the Euclidean void.

Continuum Balance and Constitutive Closure

The first continuum obligation for the Noether sea is local bookkeeping of conserved or slowly relaxing coarse variables. For a fixed control region $V\subset\Sigma_T$, a density variable is mature only when its integral changes by boundary flux, declared source, and residual:

$$\frac{d}{dT}\int_V \rho_{\text{NS}}\,dV+\int_{\partial V}\rho_{\text{NS}}\mathbf{u}_{\text{sea}}\cdot\hat{\mathbf{n}}\,dA=\int_V S_\rho\,dV+R_{\rho,V}$$

Equivalently, on resolved windows,

$$\partial_T\rho_{\text{NS}}+\nabla\cdot(\rho_{\text{NS}}\mathbf{u}_{\text{sea}})=S_\rho+r_\rho$$

The same standard applies to cadence, orientation, strain, and energy variables. A continuum equation is therefore not added because fluids are a good analogy; it is admitted only when it is the low-moment projection of the resolved Noether braid population and the residual decreases under refinement.

The source term should be decomposed before it is used in cosmology or reaction provenance:

$$S_\rho=S_{\text{prod}}+S_{\text{return}}-S_{\text{recruit}}-S_{\text{dissoc}}-S_{\text{reclass}}+S_{\text{relax}}.$$

Production, return, recruitment, dissociation, reclassification, and relaxation are not separate ontologies. They are bookkeeping channels for how neutral Noether braid content enters, leaves, breaks apart, or changes class inside the local Noether sea population. A long-time Noether sea model is credible only when these rows share one continuity ledger with the energy and reaction records.

Strong-field recycling and pair-channel activity sharpen the production row in the same requirement. A compact source may be a net source, sink, or reclassifier of Noether sea content only after the local balance separates diffuse medium loading from collimated release and from visible pair-channel products. One useful refinement is

$$S_{\text{prod}}=S_{\text{BH,diff}}+S_{\text{BH,col}}+S_{\text{pair}},$$

which gives the full source balance

$$S_\rho=S_{\text{BH,diff}}+S_{\text{BH,col}}+S_{\text{pair}}+S_{\text{return}}-S_{\text{recruit}}-S_{\text{dissoc}}-S_{\text{reclass}}+S_{\text{relax}}.$$

Here $S_{\text{BH,diff}}$ denotes broad medium loading, $S_{\text{BH,col}}$ denotes collimated or jet-like release that later couples back to the medium, and S_{pair} denotes pair-channel participation controlled by local density, cadence, excitation, and threshold state. None of these terms creates substrate from nothing. Each is a projection of architrino and Noether braid inventory through a declared reaction, release, or relaxation record.

The hydrodynamic comparison also has a domain warning: quantizing the coarse variable does not by itself reveal the microscopic contents. In a medium analogy, phonon quantization recovers collective excitations of the continuum; it does not recover the atoms. For the Noether sea, this means that a quantized effective metric, scalar, or vector channel is a recovery benchmark for long-wavelength behavior, while the microscopic derivation still has to come from Noether braid population dynamics, causal wakes, and branch ledgers.

The same guardrail applies to superfluid analogies. A Noether sea passage should use literal superfluid language only if it supplies a technical analogue such as an order parameter, transport equation, critical criterion, quantized-circulation analogue, or two-state response split. Otherwise the safe translation is medium response: density, flow, cadence, orientation, strain, delay factor, and excitation variables carried by a resolved Noether sea record.

The kinetic-theory lesson is that hydrodynamic variables are the slow variables associated with conserved quantities. For the Noether sea, the candidate slow state is

$$\mathcal{N}_{\text{sea}} = (\rho_{\text{NS}}, \mathbf{u}_{\text{sea}}, e_{\text{sea}}, \boldsymbol{\theta}_{\text{sea}}, f_N)$$

where e_{sea} is the retained medium energy density and $\boldsymbol{\theta}_{\text{sea}}$ packages the declared orientation, delay, and envelope variables as a reduced projection of the full state. The moment-closure residual is

$$\mathcal{R}_{\text{mom}} = \max_a \frac{\|\partial_T M_a[\mathcal{N}_{\text{sea}}] + \nabla \cdot J_a[\mathcal{N}_{\text{sea}}] - S_a[\mathcal{N}_{\text{sea}}]\|}{\|\partial_T M_a\| + \|\nabla \cdot J_a\| + \|S_a\| + \varepsilon}$$

with a ranging over the retained density, momentum, energy, cadence, and orientation moments. This residual is the guardrail against closing the Noether sea by naming a fluid-like equation while hiding unresolved causal-wake memory in fitted coefficients.

Analogue-gravity comparisons sharpen this point. In an ordinary acoustic medium, the effective metric seen by small sound perturbations is fixed by medium density, flow, and sound speed, for example schematically

$$(g_{\text{ac}})_{\mu\nu} \propto \frac{\rho_0}{c_s} \begin{pmatrix} -(c_s^2 - \|\mathbf{u}_{\text{fluid}}\|^2) & -u_{\text{fluid},j} \\ -u_{\text{fluid},i} & h_{ij} \end{pmatrix}$$

The comparison is useful because it keeps the levels separated: the perturbation metric is a constitutive readout, while the underlying medium still obeys its own dynamics. The Noether sea target has the same form of obligation,

$$g^{\text{eff}}_{\mu\nu} = \mathcal{G}_{\mu\nu}[\mathcal{N}_{\text{sea}}] + \mathcal{R}_{\text{metric}}$$

where $\mathcal{G}_{\mu\nu}$ must be derived from the retained density, flow, cadence, orientation, strain, and causal-wake records. A metric row that fits clock, signal, pressure, or lensing behavior with separate coefficients for each observable is not yet a Noether sea constitutive law.

Hu's stochastic-gravity comparison sharpens the next rung above moment closure. Mean-field variables are not enough; fluctuations and correlations carry information about the mesoscopic state. Let δT^{eff}_A denote observer-level stress, cadence, or response-channel fluctuations induced by a branch record θ, and let $C^{\theta}_{AB}(x, y)$ be the corresponding two-point correlation:

$$C^{\theta}_{AB}(x, y) = \left\langle \delta T^{\text{eff}}_A(x)\, \delta T^{\text{eff}}_B(y) \right\rangle_\theta$$

The Noether sea side must supply this from unresolved deterministic histories, not from an independent stochastic metric postulate. A compact correlation-hierarchy residual is

$$\mathcal{R}_{\text{corr},n}(\theta) = \frac{\left\| C^{(n)}_{\text{obs}} - \Pi^{(n)}_{\text{corr}}[\mu_{\Omega,\theta}, \mathcal{N}_{\text{sea}}, \mathcal{H}^W_\Omega] \right\|}{\epsilon_n}, \qquad n = 2, 3, \ldots$$

Here $\Pi^{(n)}_{\text{corr}}$ is the declared projection from retained Noether sea histories to the n-point observer-level correlation. Passing the $n = 2$ test is the analogue of the noise-kernel step in stochastic gravity; higher n tests are the kinetic-theory route toward mesoscopic closure.

Constitutive response must be stated as a map from the same state variables. A weak linear row has the schematic form

$$\delta Y_A(\omega, \mathbf{k}) = \sum_B \chi_{AB}(\omega, \mathbf{k})\, \delta X_B(\omega, \mathbf{k}) + R^\chi_A$$

where X_B are declared perturbations of $\mathcal{N}_{\text{sea}}$ and Y_A are observer-channel readouts such as delay factor, stress, cadence, or clock response. Causality requires the time-domain kernel to have delayed support only, which becomes an analyticity and dispersion check in frequency space. The practical residual is

$$\mathcal{R}_{\text{KK}}(\chi_{AB}) = \frac{\|\mathrm{Re}\, \chi_{AB}(\omega) - \mathcal{H}(\mathrm{Im}\, \chi_{AB})\, (\omega)\|_\omega}{\|\mathrm{Re}\, \chi_{AB}\|_\omega + \|\mathcal{H}(\mathrm{Im}\, \chi_{AB})\|_\omega + \varepsilon}$$

where $\mathcal{H}$ is the principal-value Hilbert transform used by the packet. A nonzero residual means the proposed response row is not yet a causal Noether sea constitutive law.

Equilibrium Transport Hypothesis

A provisional cosmology-facing hypothesis treats the Noether sea as a dense neighbor-coupled population of Noether braids whose individual action transactions are discrete while the ensemble response can be smooth. Most braids in a weak deep-space region have other Noether braids as their nearest dynamical neighbors. Photons and neutrinos can traverse the population, and gravitational waves can perturb it, but the baseline relaxation law is a braid-to-braid medium law.

Let ν_N denote an ordinary frequency extracted from a representative Noether braid cadence state. The local braid energy scale is then

$$E_N = h\nu_N$$

The point of this expression is not to add a new quantum postulate at the Noether sea level. It records the same closed-cycle action accounting used in the Cadence-Scale Retuning Hypothesis: a cadence state carries energy as action per cycle times cycles per unit absolute time. A single Noether braid may cross a neighboring branch through an h-scale ledger step, while a large asynchronous ensemble can produce an apparently smooth drift in the coarse variables.

At the single Noether braid level, each accepted h-scale transfer requires the braid to retune its cadence-scale closure. The retuning may appear as a cadence shift, indexed-binary radius shift, envelope-scale change, envelope-ratio change, orientation or strain update, or modified coupling to neighboring braids. In the simplest fixed-speed indexed-binary approximation,

$$v_N \sim 2\pi R_N \nu_N, \qquad R_N \nu_N \approx \text{constant}$$

so a higher accepted cadence corresponds to a smaller representative scale, while a lower accepted cadence corresponds to a larger representative scale. A full Family-A record can partition the same transaction across its three indexed binaries, so this relation is a first estimate rather than a complete closure law.

At the ensemble level, let $f_N(\nu, \mathbf{X}, T)$ be the local distribution of Noether braid cadence states. The cadence-space current is the coarse-grained flux of many branchwise retunings:

$$J_\nu \sim f_N \, \langle \dot{\nu}_N \rangle_{\Delta A_{\text{cyc}} = \pm h}$$

where the average is taken over accepted h-scale transactions inside the coarse-graining cell. Once the single-braid retuning map $\mathcal{R}_{\text{cyc}}^{(q,\varsigma)}$ is specified, the first current estimate is

$$J_\nu(\nu, \mathbf{X}, T) = \sum_{\varsigma=\pm 1} f_N(\nu, \mathbf{X}, T) \, r_\varsigma(\nu, \mathbf{X}, T) \, \Delta\nu_N^{(q,\varsigma)} + O\big((\Delta\nu_N)^2 \partial_\nu f_N\big)$$

where r_ς is the local rate density of accepted ς transactions per braid and $\Delta\nu_N^{(q,\varsigma)}$ is the cadence component extracted from $\mathcal{R}_{\text{cyc}}^{(q,\varsigma)}$. Deep space can therefore look smooth without making the underlying transactions continuous. Moving from deep space toward a solar-system environment should not be modeled as a scalar temperature increase alone; it is a bias in the local population toward higher cadence, stronger strain, stronger alignment, and larger gradients. Near a proton or other matter assembly, the neighboring Noether braids see a sharper boundary condition and retune more discretely around the assembly.

Temperature-Conditioned Branch Transition Target

A temperature channel can enter this transport law only through the same retained ensemble record used to define temperature. It is not a property of one Noether braid, and it does not change h. The braid-level event remains an accepted branch-ledger transition with $\Delta A_{\text{cyc}} = \pm h$; temperature can only bias the rates at which those admissible transitions are accepted inside a declared coarse-graining cell.

When the retained record licenses a temperature variable $T_{\mathcal{Q},W}$, the temperature-conditioned part of the cadence current has the candidate form

$$J_\nu^{(T)}(\nu, \mathbf{X}, T) = \sum_{\varsigma=\pm 1} f_N(\nu, \mathbf{X}, T) \, r_\varsigma(\nu, \mathbf{X}, T; T_{\mathcal{Q},W}) \, \Delta\nu_N^{(q,\varsigma)} + O\big((\Delta\nu_N)^2 \partial_\nu f_N\big)$$

where $r_\varsigma(\nu, \mathbf{X}, T; T_{\mathcal{Q},W})$ is the accepted rate for the ς branch transition under the same temperature-availability record. The detailed-balance residual for a neighboring $+h/-h$ pair is

$$\mathcal{R}_{\text{db}}^{(T)}(\nu, \mathbf{X}, T) = f_N(\nu, \mathbf{X}, T) \, r_+(\nu, \mathbf{X}, T; T_{\mathcal{Q},W}) - f_N(\nu + \Delta\nu_N^{(q,+)}, \mathbf{X}, T) \, r_-(\nu + \Delta\nu_N^{(q,+)}, \mathbf{X}, T; T_{\mathcal{Q},W})$$

This pair test assumes the reverse increment returns to the starting cadence, $\Delta\nu_N^{(q,-)}(\nu + \Delta\nu_N^{(q,+)}) = -\Delta\nu_N^{(q,+)}(\nu)$, so the second rate is evaluated on the paired reverse branch rather than an unrelated local decrement.

If $\mathcal{R}_{\text{db}}^{(T)} = 0$ after coarse-graining, individual $+h$ and $-h$ ledger transitions may still occur, but the temperature channel produces no net cadence-space drift. If the residual is nonzero, the signed imbalance contributes to $J_\nu^{(T)}$ and therefore biases cadence-scale retuning. In the fixed-speed indexed-binary approximation above, positive cadence drift trends toward smaller representative scale, while negative cadence drift trends toward larger representative scale. The full theorem target is to derive the rates r_ς, the retuning increments $\Delta\nu_N^{(q,\varsigma)}$, and the indexed-binary partition of the same action transaction from a closed Family-A branch record rather than treating temperature as an external driver.

Ambient-Branch Acceptance

The same smoothing record supplies the ambient-branch acceptance used at assembly boundaries. For a neutral-braid quantity $f_k(T)$ in a coarse window Ω_ℓ, define

$$\langle f\rangle_{\mathrm{sea},\ell}(\mathbf{X},T)=\frac{\sum_{k\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}W_\ell(\mathbf{X}-\mathbf{X}_k(T))f_k(T)}{\sum_{k\in\mathcal{I}_{\mathrm{sea}}(\Omega_\ell,T)}W_\ell(\mathbf{X}-\mathbf{X}_k(T))}$$

The branch-level equilibrium test is not that every Noether braid has the same cadence. It is that, after all resolved assembly ledgers have been removed, an ambient branch belongs to the local neutral-braid population when its cadence lies within the smoothed distribution and the remaining pro/anti orientation balance is small. In symbolic form,

$$\zeta^{(\ell)}_{\mathrm{sea}}=\chi^{(\ell)}_{\mathrm{comp}}\exp\left[-\frac{1}{2}\left(\Delta^2_{\mathrm{cad}}+\Delta^2_{\mathrm{bal}}\right)\right]$$

where $\chi^{(\ell)}_{\mathrm{comp}}$ removes branches phase-locked to resolved assemblies, Δ_{cad} compares the branch cadence with $\langle\nu\rangle_{\mathrm{sea},\ell}$, and Δ_{bal} measures the residual neutral-pairing and orientation imbalance of the same window. The assembly-facing definition is given in Braid Envelope Geometry. The conceptual point is that a matter Noether braid can sit inside the same coordinate window as ambient Noether sea braids without becoming part of the ambient Noether sea record; ledger complement, not mere spatial proximity, makes the separation.

A candidate equilibrium-transport equation is

$$\partial_T f_N+\nabla\cdot(\mathbf{u}_{\mathrm{sea}}f_N)+\partial_\nu J_\nu=S_{\mathrm{BH}}+S_{\mathrm{GW}}-R_{\mathrm{eq}}[f_N]$$

Here J_ν is the current through frequency or cadence state space, S_{BH} is loading from black-hole recycling regions, S_{GW} is the perturbative contribution from gravitational-wave disturbances, and $R_{\mathrm{eq}}[f_N]$ is the local neighbor-equilibration operator. This equation is a derivation target, not a completed constitutive law. It becomes relevant to redshift only if the same f_N record also determines Γ_N, χ_{sea}, and the path-history propagation term $\mathcal{P}_{E\to R}$ used in the cosmology chapters.

Absolute-Record Transport Target

The first absolute-record transport target packages those requirements into one map. For a photon-channel or spectral family X emitted at E and received at R, let $\mathcal{S}_{X,E\to R}$ be the restriction of $S(T)$ to the source branch, receiver branch, endpoint Noether sea cadence records, medium flow, causal wakes, and the path-history ledger relevant to that packet. The candidate transport map is

$$\mathfrak{T}_X[\mathcal{S}_{X,E\to R}]=(\Gamma_{N,E},\,\Gamma_{N,R},\,B_X(E),\,D_v,\,Y_{X,E\to R}),\qquad \mathcal{P}_{E\to R,X}=\exp(Y_{X,E\to R})$$

The factor $B_X(E)$ is the source-branch emission factor for family X: it relates the actual emitted line frequency in the source branch at E to the reference frequency $\nu_{X,0}$, with $B_X(E)=1$ on the reference branch. It is fixed by the source emission or calibration record, not by endpoint cadence, launch geometry, or path propagation.

The minimal state needed for the first executable closure is a projection of the absolute record, not a new ontology. For a segmented path $\gamma_{E\to R}=\{\Delta s_j\}_{j=1}^N$, use

$$\mathcal{S}^{\mathrm{min}}_{X,E\to R}=\left(\mathcal{G}_E,\,\mathcal{G}_R,\,\mathcal{V}_{E,R},\,B_X(E),\,\{\mathcal{K}_{X,j},\Delta s_j\}_{j=1}^N\right)$$

with endpoint records

$$\mathcal{G}_Q=(\mathbf{g}_N(Q),\mathcal{R}_{\Gamma,Q}),\qquad Q\in\{E,R\}$$

launch record

$$\mathcal{V}_{E,R}=\left(\mathbf{v}_E,\mathbf{v}_R,\hat{\mathbf{k}},\mathcal{R}_v\right)$$

and segment record

$$\mathcal{K}_{X,j}=(\mathbf{d}_{\theta,j},\,f_{N,j},\,S_{\mathrm{BH},j},\,S_{\mathrm{GW},j},\,R_{\mathrm{eq},j},\,\partial_\nu J_{\nu,j},\,\delta_{u,j},\,\sigma_{X,j},\,\mathcal{R}_{\mathrm{coh},X,j})$$

Here $\mathbf{d}_{\theta,j}=D_\gamma\boldsymbol{\theta}_{\mathrm{sea}}|_j$, $\delta_{u,j}=(\nabla\cdot\mathbf{u}_{\mathrm{sea}})_j$, and $\sigma_{X,j}=\hat{k}_a\hat{k}_b\Sigma^{ab}_{\mathrm{sea},X,j}$. The transport coefficients are one fixed row for the line family,

$$\Theta_X=(\mathbf{b}_N,\,\mathbf{p}_X,\,p_{\nu,X},\,p_{u,X},\,p_{\sigma,X})$$

so the no-case-switch requirement is simply

$$\Theta^{\mathrm{grav}}_X=\Theta^{\mathrm{motion}}_X=\Theta^{\mathrm{deep}}_X\equiv\Theta_X$$

The three cases may supply different restrictions of $S(T)$: a strong endpoint deformation record, a launch-velocity record, or a long weak path-history record. They fail the absolute-record transport target if the coefficient row or explanatory class changes between those restrictions.

The endpoint cadence factors are extracted from the same local deformation record used by the clock program:

$$\Gamma_{N,Q} = \exp[\mathbf{b}_N \cdot \mathbf{g}_N(Q) + \mathcal{R}_{\Gamma,Q}], \qquad Q \in \{E, R\}$$

where $\mathbf{g}_N = (\ln n, \ln \chi_{\text{sea}}, \ln \lambda, -\ln \xi, \ln(R_{\text{braid}}/R_{\text{braid},0}))^T$ in the local endpoint cell. The launch term is the causal-root compression of the emitted phase train. In the first weak-velocity form,

$$D_v = \frac{1 - \boldsymbol{\beta}_R \cdot \hat{\mathbf{k}}}{1 - \boldsymbol{\beta}_E \cdot \hat{\mathbf{k}}} \exp(\mathcal{R}_v), \qquad \boldsymbol{\beta}_Q = \frac{\mathbf{v}_Q}{c_{\gamma,Q}}$$

where $\hat{\mathbf{k}}$ points from transmitter to receiver, $c_{\gamma,Q}$ is the local photon-channel speed used for the endpoint comparison, and $\mathcal{R}_v$ carries higher-order and multi-root Jacobian corrections from the exact causal ledger.

The path-history term is a line integral over the packet path through the Noether sea:

$$Y_{X,E\to R} = \int_{\gamma_{E\to R}} \alpha_{\text{prop},X}[S(t_s)]\ ds$$

A first local path-rate ansatz is

$$\alpha_{\text{prop},X} = \mathbf{p}_X \cdot \frac{d\boldsymbol{\theta}_{\text{sea}}}{ds} - p_{\nu,X} \frac{\partial_\nu J_\nu}{f_N + \epsilon_f} + p_{u,X} \nabla \cdot \mathbf{u}_{\text{sea}} + \mathcal{R}_{\text{coh},X}$$

with $\boldsymbol{\theta}_{\text{sea}} = (\ln n, \ln \chi_{\text{sea}}, \ln \lambda, -\ln \xi)^T$. The endpoint-only entry $\ln(R_{\text{braid}}/R_{\text{braid},0})$ is deliberately absent: it is a local assembly-clock readout, not a continuum medium field transported along the photon path. If a future constitutive derivation promotes a path-resolved braid-radius field, it must extend both $\boldsymbol{\theta}_{\text{sea}}$ and $\mathbf{p}_X$ explicitly rather than allowing that channel to leak into $p_{\nu,X}$ or $p_{u,X}$. The sharper continuity form replaces the isolated current-divergence term with the source-balanced cadence residual. Along a photon path, let

$$D_\gamma = c_\gamma^{-1} \partial_T + \hat{\mathbf{k}} \cdot \nabla$$

where $\hat{\mathbf{k}}$ is the path tangent and s is path length. The transport equation defines

$$\mathcal{C}_N[f_N] = \frac{S_{\text{BH}} + S_{\text{GW}} - R_{\text{eq}}[f_N] - \partial_\nu J_\nu}{f_N + \epsilon_f}$$

Away from the regularization floor,

$$(\partial_T + \mathbf{u}_{\text{sea}} \cdot \nabla) \ln f_N \approx \mathcal{C}_N[f_N] - \nabla \cdot \mathbf{u}_{\text{sea}}$$

Here $\mathcal{C}_N[f_N]$ is a cadence-space continuity residual for the distribution f_N; it is not the endpoint clock-rate factor $C_N = \Gamma_N^{-1}$.

The continuity-disciplined path rate is therefore

$$\alpha_{\text{prop},X} = \mathbf{p}_X \cdot D_\gamma \boldsymbol{\theta}_{\text{sea}} + p_{\nu,X} \mathcal{C}_N[f_N] + p_{u,X} \nabla \cdot \mathbf{u}_{\text{sea}} + p_{\sigma,X} \hat{k}_a \hat{k}_b \Sigma^{ab}_{\text{sea},X} + \mathcal{R}_{\text{coh},X}$$

Here $\Sigma^{ab}_{\text{sea},X}$ is the channel-X, trace-free projection of the Noether sea stress Σ_{sea} and vanishes in the isotropic weak limit. It is not a separate stress ontology. In a segmented calculation this is the computable update

$$\alpha_{\text{prop},X,j} = \mathbf{p}_X \cdot \mathbf{d}_{\theta,j} + p_{\nu,X} \frac{S_{\text{BH},j} + S_{\text{GW},j} - R_{\text{eq},j} - \partial_\nu J_{\nu,j}}{f_{N,j} + \epsilon_f} + p_{u,X} \delta_{u,j} + p_{\sigma,X} \sigma_{X,j} + \mathcal{R}_{\text{coh},X,j}$$

The coefficient rows $\mathbf{b}_N$ and $(\mathbf{p}_X, p_{\nu,X}, p_{u,X}, p_{\sigma,X})$ must be fixed from the declared Noether sea constitutive response and then reused across gravitational, relative-motion, and deep-space cases. A deep-space contribution may come from a persistent $\mathcal{C}_N[f_N]$, flow-divergence, or anisotropic-response record, but not from switching to a generic photon-energy-loss explanation.

The endpoint coefficient-row constraints are recovery constraints, not a fit to one redshift case. This transport chapter consumes the clock-row extraction owned by Proper Time and Time Dilation: the homogeneous moving Noether braid branch fixes the coefficient of $-\ln \xi$ by requiring $\Gamma_N \to 1/\xi \to \gamma_\star$, while the weak static endpoint branch fixes the scalar normalization

$$b_n a_n + b_\chi a_\chi + b_\lambda a_\lambda + b_R a_R = 1$$

Under shared clock/signal delay closure, Proper Time and Time Dilation supplies $a_\chi = 1 + \gamma_{\text{eff}}$, so the endpoint condition consumed here is

$$b_n a_n + b_\chi(1 + \gamma_{\text{eff}}) + b_\lambda a_\lambda + b_R a_R = 1$$

In the GR-matching weak branch this is $b_n a_n + 2b_\chi + b_\lambda a_\lambda + b_R a_R = 1$. If the shared-delay residual is nonzero, the unconstrained equation with a_χ must be used and the residual must remain visible in the clock, Shapiro-delay, pressure-response, and redshift packets.

The minimal shared-delay packet is likewise imported from the clock-row owner. For $\gamma_{\text{eff}} = 1$, it gives $a_\chi = 2$ and $b_\chi = 1/2$. Nonzero n, λ, or R_{braid} contributions remain admissible only as a compensated static family that preserves the endpoint sum and the inverse clock-rate row; they are not free redshift-fit parameters.

The relative-motion recovery fixes the separation between launch geometry and transport coefficients. In a homogeneous weak record with $\mathbf{g}_N(E) = \mathbf{g}_N(R) = 0$, $B_X(E) = 1$, and $\mathcal{K}_{X,j} = 0$ for every segment,

$$Z_X = \ln(1 + z_X) = -\ln D_v, \qquad Y_{X,E\to R} = 0$$

Thus the launch factor carries the ordinary first-order Doppler or phase-compression term; no component of $(\mathbf{p}_X, p_{\nu,X}, p_{u,X}, p_{\sigma,X})$ may be adjusted to recover a pure relative-motion redshift.

Endpoint-subtracted redshift gives the corresponding isolation test for the path row. From

$$\ln(1 + z_X) = \ln \Gamma_{N,E} - \ln \Gamma_{N,R} - \ln D_v + Y_{X,E\to R} - \ln B_X(E)$$

the replayed propagation term is

$$Y^{\text{sub}}_{X,E\to R} = \ln(1 + z_X) - (\ln \Gamma_{N,E} - \ln \Gamma_{N,R}) + \ln D_v + \ln B_X(E)$$

In a weak static endpoint comparison,

$$\ln \Gamma_{N,Q} = (b_n a_n + b_\chi a_\chi + b_\lambda a_\lambda + b_R a_R) \frac{U_Q}{c_0^2} + O\left(\frac{U_Q^2}{c_0^4}\right), \qquad Q \in \{E, R\}$$

Endpoint-subtracted replay therefore constrains the propagation row only after the endpoint scalar is fixed. A compensated static family is invisible to this first-order subtraction when it preserves $b_n a_n + b_\chi a_\chi + b_\lambda a_\lambda + b_R a_R = 1$; it becomes disfavored only if it leaves an endpoint residual that the path-history row must repair.

The deep-space continuity packet constrains the remaining path row by endpoint-subtracted replay:

$$Z_{\text{prop},X} = \sum_{j=1}^{N} \left[\mathbf{p}_X \cdot \mathbf{d}_{\theta,j} + p_{\nu,X} \mathcal{C}_{N,j} + p_{u,X} \delta_{u,j} + p_{\sigma,X} \sigma_{X,j} + \mathcal{R}_{\text{coh},X,j}\right] \Delta s_j$$

with

$$\mathcal{C}_{N,j} = \frac{S_{\text{BH},j} + S_{\text{GW},j} - R_{\text{eq},j} - \partial_\nu J_{\nu,j}}{f_{N,j} + \epsilon_f}$$

This equation fixes the sign convention and the shared-row obligation for deep-space transport, but it does not yet determine $\mathbf{p}_X$, $p_{\nu,X}$, $p_{u,X}$, or $p_{\sigma,X}$ individually. They remain constitutive freedoms until independent segment records vary the corresponding Noether sea gradients, cadence residual, flow divergence, and anisotropic response. The first observable falsifiers are the existing transport diagnostics: chromaticity residuals for line-family dependence, time-dilation residuals for frequency/cadence splitting, image-bundle variance for anisotropic or flow-induced beam spread, and directional residuals for unmodeled large-scale Noether sea structure.

The coherence residue is admissible only if the same Y_X passes the observational transport tests,

$$\text{Var}_\perp(Y_X) \le \epsilon^2_{\text{img},X}, \qquad |\partial_{\ln \nu_X} Y_X| \le \epsilon_{\text{chrom},X}, \qquad \left|Y_X^{\text{freq}} - Y_X^{\text{dur}}\right| \le \epsilon_{\text{td},X}$$

The path term is thus phase-cadence retiming read from $S(T)$: it may change the energy a receiver assigns through $E = h\nu_{\text{obs}}$, but it is not an untracked energy sink along the path.

With this map, the received frequency is

$$\nu_{\text{obs},X} = \nu_{X,0} B_X(E) \frac{\Gamma_{N,R}}{\Gamma_{N,E}} D_v \exp(-Y_{X,E\to R})$$

so no factor is interpreted as untracked photon energy loss. The packet energy read by the receiver is $E_{\text{obs},X} = h\nu_{\text{obs},X}$ after source branch, endpoint cadence, launch compression, and path-history propagation have all been extracted from the same absolute record.

The expansionary reading is therefore conditional. Local equilibrium by itself does not imply an effective expansion history. A Hubble-like redshift slope appears only if the coarse-grained transport has a signed, persistent cadence-space current or source-relaxation imbalance that projects into the photon path-rate functional while preserving image sharpness, line coherence, and packet time-dilation consistency.

Refractive Gravity and Effective Metric

Massive assemblies polarize and load the surrounding Noether sea. In weak-field language, this changes the normalized density, stress, and effective signal speed:

$$c_{\mathrm{eff}}(\mathbf{X}, T) < c_f$$

in denser or more strongly loaded regions — a constitutive hypothesis of the weak-field map, not a derived result, whose falsifier is wrong-sign Shapiro-delay or redshift recovery.

Physical observers reconstruct this behavior as gravitational redshift, lensing, Shapiro delay, and curved effective geodesics. In the substrate description, the void remains flat; the observed curvature is a constitutive summary of how clocks, rulers, and signals behave in the Noether sea.

The canonical metric bridge is Emergent Metric. Clock extraction belongs in Proper Time and Time Dilation. PPN-facing tests belong in PPN Parameters.

Matter Coupling and Inertia

Matter assemblies are not isolated objects moving through nothing. They are stable architrino assemblies embedded in the Noether sea.

Their observed inertia and mass are expected to depend on:

- internal energy storage,
- shielding depth,
- exposure of declared indexed-binary structure,
- medium-dressed compliance and inertial response,
- and how the assembly closes its causal ledger relative to the surrounding Noether sea.

The canonical mass-side treatment is Particle Masses: Emergent Inertia in the Noether sea. This page only states that the Noether sea is the ambient medium against which those assembly responses are defined.

Cosmological Role

The Noether sea also carries cosmological state. In this framework, cosmological expansion language is not substrate expansion. The void remains fixed; cosmological observables are interpreted through medium evolution, clock-rate comparison, signal propagation, and the large-scale state of the Noether sea.

For cosmology, the relevant medium-level variables include:

- baseline density,
- energy density,
- pressure or compliance,
- relaxation history,
- large-scale anisotropy,
- and coupling to black-hole recycling and strong-field regions.

The cosmology-level translation belongs in Cosmology Ontology, Expansion Mechanism, and Dark Energy.

Terminology Discipline

Use these terms consistently:

Term	Use
Euclidean void	Fixed spatial container and substrate geometry
Absolute timespace	Product background of absolute time and Euclidean void
Noether sea	Canonical physical-medium name
Spacetime medium	Bridge term for the Noether sea when translating toward effective spacetime language
Effective spacetime	Observer-level metric reconstruction from clocks, rulers, and signals

Avoid using **vacuum** alone. It is ambiguous between empty substrate, QFT vacuum language, and the actual Noether sea. If the intended meaning is the physical substrate contents, use **Noether sea**.

Ownership Boundary

This page owns:

- the Noether sea as canonical medium ontology,
- the distinction between void, medium, and effective spacetime,
- the main Noether sea state variables,
- and the routing map for downstream spacetime work.

This page does not own:

- Noether braid internal architecture; see Noether Braid.
- Noether braid exclusion-envelope geometry; see Braid Envelope Geometry.
- Pro/anti coupling hypotheses and cluster motifs; see Noether Sea Pro/Anti Coupling.
- Effective metric derivation; see Emergent Metric.
- Clock and ruler behavior; see Proper Time and Time Dilation.
- Cosmological scale-factor translation; see Expansion Mechanism.
- Strong-field recycling regimes; see Black Holes.

Summary Commitment

> **Medium Commitment (Noether sea):** The Noether sea is the emergent physical medium formed by coupled neutral Noether braid assemblies occupying the Euclidean void. It carries density, stress, energy, orientation, flow, and response properties. Effective gravity, clock dilation, signal delay/refraction, inertia, and cosmological behavior are reconstructed from Noether sea dynamics and assembly coupling, not from curvature or expansion of the void itself. Matter assemblies and Noether braid branches are physically meaningful as local retained branches embedded in this medium record; isolated branch calculations are seed charts or limiting cases unless their Noether sea state and nearby-assembly boundary residuals are statused. The claim that Family-A neutral assemblies dominate the weak homogeneous medium remains a comparative selection target: other architrino assembly classes must be rejected, subordinated, or classified by the same ambient selection residual before Noether sea composition is closed.

Noether Sea Pro/Anti Coupling

This note states a bounded working hypothesis for the Noether sea: the sea is not a passive geometric background. It is an active medium built from persistent Noether braid assemblies with internal structure and coupling rules. The fixed background remains absolute time and the Euclidean void; this chapter is about the contents that occupy that background and supply medium response. It is the assembly-hypothesis continuation of Noether sea, Euclidean Void, and Noether Braid.

For the canonical medium ontology, total-density boundary, and terminology discipline, see Noether sea. This chapter is the canonical home for the more specific pro/anti Noether braid coupling details: orientation basis, density decomposition, imbalance stability, local coupling hypotheses, and cluster-organization motifs. The distinction between this orientation label and polarity conjugation is fixed in Terminology Usage.

The claim level is intentionally narrower than the Noether sea ontology page. The ontology page says what the medium is. This page asks whether complementary pro/anti orientation populations are part of how that medium stays transparent, balanced, and responsive.

Pro/Anti Noether Braid Basis

The starting picture is deliberately simple. A Noether sea carrier is a Noether braid whose state can appear in two complementary orientations:

- pro-Noether braid orientation
- anti-Noether braid orientation

For Noether braid consumers, the working orientation convention is:

- pro-Noether braid orientation: indexed-frame order $1 \to 2 \to 3$ in time;
- anti-Noether braid orientation: indexed-frame order $1 \to 3 \to 2$ in time.

The indices are persistent record identities, not a sorting by radius, frequency, energy, speed, or dynamical role. Their coordinate values may cross without relabeling the frame. This ordered convention is the reader-facing orientation basis, but the carrier for its two-valued sign is not the index naming convention by itself. A completed pro/anti assignment must be a deformation-stable orientation row $o_{\mathrm{PA}} \in \{+1, -1\}$ in the retained indexed path or angular-momentum-frame record, such as the indexed Noether braid chirality and causal-writhe or framed-topology candidates discussed in Constructing the Absolute Frame and Horizon Chirality.

The orientation label does not assign matter versus antimatter. Global polarity conjugation C leaves the indexed 123/132 worldline order unchanged, while parity P reverses it. A matter branch and its polarity-conjugate antimatter branch may therefore each occur on either pro/anti orientation once the full retained branch and charged-sector ledgers are supplied. This sea-level orientation balance is distinct from the visible-sector matter-antimatter asymmetry question, which belongs to polarity-conjugate branch populations, weak-sector asymmetry, early-state boundary conditions, and reaction-ledger bias. The key claim is that stable large-scale Noether sea behavior may require both orientations to coexist and couple, so the Noether sea does not drift into one ordered-frame handedness.

At the assembly level, a useful physical picture is antiparallel pairing. Complementary orientations can suppress exposed axial circulation when their open circulation channels face each other in the right way. That gives the Noether sea a second kind of neutrality beyond each braid's own internal polarity neutrality: local polar-site leakage is mutually suppressed, so the composite remains comparatively transparent and non-reactive.

At the continuum-medium level, represent local Noether braid density with canonical symbols (ρ_{NS}, n) as two coupled components:

$$\rho_{\mathrm{NS}}(\mathbf{X},T) = \rho_{+}(\mathbf{X},T) + \rho_{-}(\mathbf{X},T)$$

$$n(\mathbf{X},T) \equiv \frac{\rho_{\mathrm{NS}}(\mathbf{X},T)}{\rho_{\mathrm{NS},0}}$$

The total density can stay smooth while the two orientation populations differ locally. Here the subscripts $+$ and $-$ label pro/anti orientation populations, not architrino polarity and not matter/antimatter. Their difference is represented by a bounded imbalance

$$\Delta\rho_{\mathrm{NS}}(\mathbf{X},T) = \rho_{+}(\mathbf{X},T) - \rho_{-}(\mathbf{X},T)$$

where long-lived Noether sea regions require $|\Delta\rho_{\mathrm{NS}}|$ to remain below a stability threshold set by the local coupling regime. In plain terms, the sea may tolerate local orientation bias, but not unlimited domination by one ordered orientation. At the diagnostic level, the Δ_{bal} term in the ambient-branch acceptance diagnostic of Noether sea is the coarse-grained, normalized window readout of $\Delta\rho_{\mathrm{NS}}$ over Ω_{ℓ} after resolved assembly ledgers have been excluded; the open coupling-law work is to derive that normalization and its stability threshold from pro/anti orientation dynamics.

The Noether sea page names the Noether sea and its total state variables; this chapter owns the pro/anti split and the hypotheses about how those subcomponents couple.

2 Pro + 2 Anti Coupling Hypothesis

A recurring speculative motif is a minimal neutral cluster built from two pro-Noether braid constituents and two anti-Noether braid constituents. The intuition is a compact four-member arrangement: enough pieces to balance orientation, suppress exposed circulation, and resist a one-constituent perturbation. Geometrically, this is often pictured as a compact four-body bound state analogous in shape intuition, but not in nuclear force mechanism, to a helium-like $2\mathrm{p} + 2\mathrm{n}$ nucleus: two of one type plus two of the complementary type in a tightly coupled arrangement.

The analogy is structural:

- helium-like count balance $(2 + 2)$,
- compact low-moment configuration,
- enhanced robustness against single-constituent perturbation.

The analogy is not identity:

- no claim that baryonic protons/neutrons are being reused,
- no claim that QCD binding equations directly apply.

Instead, the model uses the helium-like picture as a design intuition for why a four-member pro/anti cluster may minimize net torque, suppress long-term precession drift, and provide a resilient seed unit for medium-level tiling. The count balance is the useful part; the nuclear analogy is not a claim about the acceleration law.

Why This Matters for Effective Spacetime Phenomenology

If the local Noether sea is assembled from balanced pro/anti Noether braid populations, then curvature-like behavior is read as collective reconfiguration of assembly states rather than purely geometric deformation of an otherwise structureless manifold. In that interpretation:

- weak-field behavior tracks smooth perturbations in normalized density n as used in Emergent Metric,
- strong-field behavior tracks approach to alignment and saturation limits,
- wave channels track propagating phase disturbances through the coupled Noether braid assembly network.

This is consistent with the framework's broader assemblies-first stance. Equations are read as effective descriptors of deeper assembly dynamics, and the medium response is carried by organized Noether braid populations rather than by the Euclidean void itself.

Ownership Boundary

This chapter owns:

- pro-Noether braid and anti-Noether braid orientation basis,
- local density decomposition into ρ_+ and ρ_-,
- orientation imbalance $\Delta\rho_{\mathrm{NS}}$,
- coupling-regime stability thresholds,
- the $2+2$ pro/anti cluster hypothesis,
- and medium-level Noether braid assembly motifs that could support effective spacetime behavior.

This chapter does not own:

- the Noether sea as medium ontology; see Noether sea,
- the internal Noether braid architecture; see Noether Braid,
- the effective metric map; see Emergent Metric,
- clock and ruler extraction; see Proper Time and Time Dilation,
- or cosmological scale-factor translation; see Expansion Mechanism.

Claim Scope

This is a hypothesis note, not a closed derivation. The chapter's claim is limited to the organizing possibility that local pro/anti Noether braid motifs may support effective spacetime behavior through Noether sea response. A completed version must derive the orientation-classification invariant, derive the local coupling law, test whether the $2+2$ pro/anti cluster is an energy minimum or only a design intuition, and extract weak-field, strong-field, or cosmological signatures from the same Noether sea variables used by the effective-metric program.

Molecular Exclusion and Noether Sea Response

This chapter analyzes volume exclusion across ordinary matter and medium-level propagation. It complements Condensed Matter, Molecular Geometry, Noether Sea Pro/Anti Coupling, and Gravitational Waves by asking how ordinary exclusion boundaries coexist with deeper Noether sea response.

The guiding distinction is ordinary occupancy versus medium availability. Molecules exclude one another through electron-envelope and bonding structure, but that does not decide how photon, neutrino-like, gravitational-wave, clock, or Noether sea response channels propagate through the same Euclidean volume. A tiny molecular hard-core packing fraction is therefore useful background, not a proof that every channel sees empty space.

When chemists use the **van der Waals (VdW) volume** of a molecule, they mean the space excluded by its electron distribution: the effective hard-core volume a molecule presents to its neighbors. Atomic van der Waals radii, such as the Bondi radii, set a common hard-sphere convention; a molecular van der Waals volume then depends on the molecular geometry and the rule used to subtract bonded overlaps. The estimate below therefore declares the one molecule it uses rather than treating a multi-molecule lookup table as source authority. The unit conversion is $1\,\mathrm{\AA}^3 = 10^{-24}\,\mathrm{cm}^3$.

Molecular Occupancy Baseline

How Much Volume Do Gas Molecules Actually Occupy in Air?

At everyday conditions, about $1\,\mathrm{atm}$ and room temperature, air is extremely sparse. A quick estimate using van der Waals volumes shows why:

Take nitrogen $(\mathrm{N_2})$ as representative. Using two equal Bondi spheres with radius $r_N = 1.55\,\mathrm{\AA}$ and center separation $d = 1.10\,\mathrm{\AA}$, the bonded overlap is

$$V_\cap = \frac{\pi(4r_N + d)(2r_N - d)^2}{12} \approx 7.64\,\mathrm{\AA}^3.$$

The declared union rule therefore gives

$$V_{\mathrm{VdW}} = 2\frac{4\pi r_N^3}{3} - V_\cap \approx 23.6\,\mathrm{\AA}^3$$

per molecule. One mole then presents a hard-core volume of about
$23.6 \times 10^{-24},\mathrm{cm}^3 \times N_A
\approx 14.2,\mathrm{cm}^3$. One mole of an ideal gas occupies about $24{,}000\,\mathrm{cm}^3$ at $298\,\mathrm{K}$ and $1\,\mathrm{atm}$.
The packing fraction is therefore about $14.2\,\mathrm{cm}^3/24{,}000\,\mathrm{cm}^3 \approx 0.06\%$.

Intuition scales:

- Average intermolecular spacing is about 3 to $4\,\mathrm{nm}$ (from the number density above).
- Mean free path in air is about 60 to $70\,\mathrm{nm}$ (standard kinetic estimate).

Conclusion: gas molecules occupy well under one-tenth of a percent of the available Euclidean volume as molecular hard cores; most gas volume is not molecularly occupied compared with liquids and solids.

Representative Number Densities in Air

Using the ideal gas law, dry air at $1\,\mathrm{atm}$ and $298\,\mathrm{K}$ contains about 2.46×10^{19} molecules per cm^3. A few representative components are enough to set the scale:

- Nitrogen (N_2, 78.084%): about 1.92×10^{19} per cm^3
- Oxygen (O_2, 20.946%): about 5.16×10^{18} per cm^3
- Carbon dioxide (CO_2, about $420\,\mathrm{ppm}$): about 1.03×10^{16} per cm^3

Notes:

- Dry air omits water vapor. At $25^\circ\mathrm{C}$ and 50% relative humidity, $\mathrm{H_2O}$ is about 1.6% by volume, or about 3.9×10^{17} per cm^3. At saturation near $25^\circ\mathrm{C}$, it is about 3.1% by volume.
- Trace constituents scale by their volume fraction and do not change the packing conclusion.
- Despite high number densities, the hard-core geometric occupancy is only about 0.06% of the volume under the declared N_2 union-of-spheres rule. In $\mathbb{AAA}$ terms, ordinary molecular exclusion occupies only a small fraction of the available Euclidean volume, while deeper Noether sea implementation layers remain available for medium-level propagation.

This gives a **geometric baseline** for how much space a molecule excludes. In real matter, the effective boundary is also affected by bonding, compression, temperature, pressure, and the channel being probed.

The kinetic baseline is not just occupied volume; it is also the collision length compared with the scale being probed. For a dilute molecular species with number density n_m and effective hard-core diameter d_m, the order-of-magnitude mean free path is

$$\lambda_m \sim \frac{1}{\pi d_m^2 n_m}$$

up to the usual order-one correction for relative molecular motion. A probe of size L is in a continuum regime only when

$$\mathrm{Kn}_m \equiv \frac{\lambda_m}{L} \ll 1$$

When Kn_m is not small, a molecular continuum pressure or viscosity description is a poor model even if the geometric occupancy is tiny.

This distinction is useful for $\mathbb{AAA}$ because molecular exclusion and Noether sea response answer different questions. Molecular packing fraction estimates what ordinary matter blocks geometrically. Mean-free-path and Knudsen estimates say whether a gas can be treated as a continuum at the scale of the probe. Neither estimate determines whether a photon, neutrino, gravitational-wave channel, or clock-rate comparison couples strongly to the Noether sea. Those channels require their own coupling and propagation records.

For any simulation or synthetic-observable packet that compares ordinary matter with medium-level propagation, the minimal separation is

$$\phi_{\mathrm{VdW}} = n_m V_{\mathrm{VdW}}, \qquad \mathrm{Kn}_m = \frac{\lambda_m}{L}, \qquad \mathcal{C}_X = \text{declared coupling record for channel } X$$

A low ϕ_{VdW} or high Kn_m may explain molecular sparsity or gas-kinetic behavior; it is not evidence by itself for transparency of channel X.

Levels of Excluded Volume

Geometric VdW volume is the radius-and-overlap estimate: it is tied to tabulated radii and molecular geometry, not to the gas pressure or temperature in the worked example. Effective excluded volume is more flexible. Neighboring molecules can compress, stretch, or reorganize electron density, and hydrogen bonding, solvation shells, or π-π stacking can alter the apparent space occupied. Raising T usually increases vibration and loosens structures; raising P can compress electron distributions slightly and reduce the effective excluded volume.

Macroscopic boundaries are large-scale manifestations of those exclusions, but they remain channel-specific. At an air-water boundary, visible photons mostly pass while molecules from one side cannot enter the other without surface disruption. At an air-skin boundary, oxygen molecules are excluded by cellular membranes unless aided by proteins. At a metal-skin boundary, copper atoms in a wire do not freely diffuse into biological tissue, while infrared and visible photons can still cross or reflect at the boundary.

Propagation Across Excluded Regions

Maximally packed van der Waals volumes define exclusion domains for ordinary atoms and molecules. They do not automatically block every observer-level channel or every deeper medium-level propagation mode. Ordinary matter is blocked by electron-envelope and bonding structure; that is the channel that forms the material boundary. Photons may pass, reflect, or be absorbed depending on frequency and material: visible light moves through water and glass but not metal, X-rays probe deep into flesh but are stopped more strongly by bone, and gamma rays can penetrate meters of concrete.

Neutrinos pass almost completely unhindered through ordinary matter; compare Neutrinos for the assembly-level channel picture. Hypothetical WIMPs, axions, or gravitons belong only to standard-comparison language here: if such channels exist, their ordinary-matter coupling is weak enough that molecular hard-core exclusion is not the blocking rule. Compare Dark Matter for the cosmological inference side and Gravitational Waves for the effective propagation layer.

The effective spacetime comparison has the same lesson. In standard GR language, matter changes the metric rather than blocking spacetime as a substance. In $\mathbb{AAA}$, the Euclidean void remains fixed; the relevant implementation layer is Noether sea response and effective metric reconstruction.

Absolute Timespace vs. Implemented Medium

- Absolute-timespace background: the mathematical arena in this project is absolute timespace, the product of one global time and Euclidean 3-space. It is fixed, non-dynamical, and does not curve.
- Noether sea implementation layer: effective spacetime behavior is realized by coherent assembly architecture at scales far smaller than molecules. In bridge prose this can be called a spacetime medium layer, but it is not a separate substrate inventory. Its microstructure can modulate effective propagation, boundaries, and coherence without altering the background kinematics.

This is the same implementation layer developed in Emergent Metric and Noether Sea Pro/Anti Coupling.

The van der Waals volume is an exclusion region mainly for **ordinary fermionic matter**. At the molecular level it defines exclusion for atoms and molecules; at the material level, boundaries such as air-water, skin-air, and metal-skin are large-scale manifestations of those exclusions. At the cosmic scale and observer level, photons, neutrinos, dark matter candidates, gravitational waves, clock comparisons, and effective metric descriptions interact through different coupling mechanisms. Molecular hard-core exclusion is therefore a matter-channel fact, not a universal medium-availability rule.

The worked air estimate makes the chapter's conclusion concrete. A molecular occupancy of only about 6×10^{-4} does not predict a photon, neutrino-like, clock, or gravitational-wave response. Each channel still requires its own $\mathcal{C}_X$ record; geometric sparsity alone establishes neither transparency nor opacity.

Observer Framework

This chapter explains what an observer can access in $\mathbb{AAA}$. It separates the complete ontic universe-state perspective from Physical Observers, then shows how absolute simultaneity, operational simultaneity, derived clock time, and effective metric descriptions fit together.

The key split is simple:

- The $\mathbb{U}_{\text{now}}$ **universe-state perspective** is the theory-side complete-state perspective on an absolute-time slice.
- A **Physical Observer** is an embedded assembly inside the Noether sea, using physical clocks, rulers, detectors, records, and finite-speed signals.

This page owns the level distinction. The clock law itself belongs in Proper Time and Time Dilation, and the effective metric bridge belongs in Emergent Metric.

This is not an idealist or measurement-created ontology. The complete state exists whether or not any Physical Observer reads it. The point is that any actual observer is made of assemblies and can only infer the world through finite records, local clocks, signals, calibrations, and access boundaries.

The $\mathbb{U}_{\text{now}}$ Universe-State Perspective

The $\mathbb{U}_{\text{now}}$ **universe-state perspective** is the theory's complete ledger for one slice of absolute timespace. It represents complete knowledge of the architrino microstate on that slice, including the history data needed for the next step of deterministic evolution.

In principle, it includes:

- the position and velocity of every architrino,
- each architrino identity and polarity,
- the complete path-history ledger needed for deterministic evolution,
- source provenance for causal wakes,
- emission times for active wake intersections,
- and the branch-history information needed by the dynamics.

It is not a physical device or observer. It does not measure, signal, compute with finite resources, or occupy a local assembly state. It is the bookkeeping perspective used to state the ontology and deterministic laws while keeping those laws separate from what an embedded observer can recover.

Physical Observers

A **Physical Observer** is any observer, detector, clock, ruler, or measuring apparatus composed of architrino assemblies. The term is physical before it is psychological: a lab apparatus, atom, detector medium, or human observer all count only through the records their assemblies can produce and preserve.

Examples include:

- laboratory clocks and interferometers,
- atoms and detector media,
- humans and biological sensors,
- planets, stars, and other large assemblies when treated as measurement systems.

Physical Observers are embedded in the Noether sea. Their clocks, rulers, detector thresholds, records, and synchronization conventions are therefore outputs of assembly dynamics, not external primitives placed outside the system.

A Physical Observer has access only through:

- local interactions,
- finite-speed signals,
- derived clock time measured by physical clocks,
- coarse-grained effective fields,
- finite records,
- and statistical summaries of unresolved microstate structure.

No Physical Observer can be promoted into a global, outside-the-universe vantage point. The $\mathbb{U}_{\mathrm{now}}$ universe-state perspective can define the complete state for theory construction, but a Physical Observer can only assemble finite records across a declared access region and communication history.

This limitation becomes especially important in strong-gravity and cosmology comparisons. Standard quantum-gravity discussions also run into the fact that an observer cannot be placed outside the entire universe as a massless, energy-free measuring device. A real observer supplies a clock, a location, finite records, and an access region. In $\mathbb{AAA}$ this does not make reality observer-created. It means that black-hole entropy, de Sitter thermodynamics, horizon access, and quantum state descriptions must be stated relative to what an embedded Physical Observer can actually clock, probe, and record.

For the same reason, an expectation value, covariance, or correlation function is not automatically an ontic claim about an effective metric, the Noether sea, or the complete microstate. It is an observer-level summary for a declared observation region, readout channel, and boundary-data model. A comparison packet may use such summaries, but it must say which Physical Observer records and boundary wake data make the summary meaningful.

Strong-gravity information claims require the same declared-access discipline. A local field-theory expression such as a horizon-crossing correlation, a reduced density matrix, or a fine-grained radiation entropy is not yet a substrate statement. It becomes a legitimate comparison object only after the Physical Observer, reference resources, access region, finite boundary wake data, and record channel have been specified. This keeps black-hole information accounting from smuggling in an external observer at infinity, a literal boundary CFT, or an unrecorded many-copy measurement idealization.

The same discipline applies when one Physical Observer uses another Physical Observer's report. The report is not a disembodied update rule. It is a physical record carried by signals, memory states, documents, detector logs, or other assemblies, and it can be imported only through a declared communication channel with finite latency, calibration, and persistence. If two observers appear to certify incompatible conclusions, the first diagnostic question is whether both conclusions belong to the same declared record channel and access model. A mismatch in readout channel, missing reference resources, or failed record autonomy is an observer-layer failure, not evidence that the complete ontic state has become contradictory.

Purpose-built precision experiments add a practical record rule. A Physical Observer does not record only a number. The observer records an apparatus protocol, a modulation or timing method, calibration references, and a nuisance model. For a precision-gravity channel A, write the retained record as

$$\Theta_A^{(O,W)} = \Big(Y_A(t_{\mathrm{eff}}), \mathcal{K}_A, \mathcal{M}_A, C_A, \mathcal{N}_A, \mathcal{B}_{\partial\Omega}^{(O)}(W)\Big)$$

where $Y_A(t_{\mathrm{eff}})$ is the measured readout, $\mathcal{K}_A$ is the apparatus response kernel, $\mathcal{M}_A$ is the modulation or timing protocol, C_A is calibration covariance, $\mathcal{N}_A$ is the declared nuisance family, and $\mathcal{B}_{\partial\Omega}^{(O)}(W)$ is the retained boundary-wake family defined below. Redshift measurements, torsion balances, preferred-frame clock tests, CMB radiometers, and interferometric gravitational-wave detectors differ mainly in these record fields. A comparison that keeps $Y_A(t_{\mathrm{eff}})$ while replacing $\mathcal{K}_A$, $\mathcal{M}_A$, C_A, or $\mathcal{N}_A$ after seeing the result is not the same Physical Observer record.

Photon-distance records need the same separation. For an emission event E, reception event R, and transported photon-channel packet γ, a Physical Observer should not collapse three different quantities into one distance:

$$d_{\mathrm{void}}(E,R) = \|\mathbf{X}_R(T_R) - \mathbf{X}_E(T_E)\|, \qquad L_\gamma(E \to R) = \int_{T_E}^{T_R} \left\| \frac{d\mathbf{X}_\gamma}{dT} \right\| dT,$$

and

$$D_O(E,R) = \mathcal{I}_O\left(z_\gamma, \Theta_\gamma^{(O,W)}, \mathcal{K}_O, \mathcal{N}_O\right).$$

Here d_{void} is the Euclidean coordinate separation of the two recorded events in the fixed void, L_γ is the photon-channel path-history length through the Noether sea, and D_O is the Physical Observer's inferred distance under a declared inference map. In this expression $\mathcal{K}_O$ and $\mathcal{N}_O$ are inference-stage kernel and nuisance choices, distinct from the apparatus-stage response and nuisance fields already retained inside $\Theta_\gamma^{(O,W)}$. Redshift may constrain D_O, but it is not by itself a measurement of either absolute separation or photon path length unless the endpoint clock, launch, path-history, and calibration rows are held fixed in the same record.

This is the central observational warning for cosmology: photons are the dominant observation channel, but a photon record is a transport record through the Noether sea before it is a direct distance label.

Ontic and Epistemic Levels

$\mathbb{AAA}$ uses a two-level distinction:

Level	What It Means	Typical Description
Ontic	What exists and evolves in the complete microstate	Architrinos in absolute timespace with path-history dynamics
Epistemic	What embedded assemblies can access and summarize	Derived clock time, measured distance, effective fields, wavefunctions, thermodynamic quantities

The ontic level is not observer-dependent. It is the complete state of the modeled world at absolute time T, together with the path-history information needed for deterministic continuation.

The epistemic level is observer-dependent because Physical Observers are built from assemblies and must infer the world through finite signals, local records, and internal clocks. This is a limit on access, not a claim that observers create the substrate.

This distinction protects several recurring claims:

- Wavefunction updates are not fundamental discontinuities in the substrate; they are observer-level state-description updates.
- Effective spacetime curvature is not curvature of the Euclidean void; it is a reconstruction from clocks, rulers, and signal paths.
- Relativity of simultaneity is not a failure of absolute simultaneity; it is an operational constraint on Physical Observers.

For the quantum side of this distinction, see Wavefunction Ontology and Measurement Ontology.

Formal note: a local subsystem is not generally closed under the primitive dynamics. A Physical Observer may model a region as though it were isolated, but finite-speed wake history still crosses the boundary. Let $\Omega \subset \Sigma_T$ be the spatial region resolved by a Physical Observer, let $X_\Omega(T)$ be the internal assembly state represented inside that region, and let $\mathcal{H}_\Omega^{<T}$ be the retained path-history data for internal trajectories and locally resolved causal wakes before T. The missing exterior influence is represented by the accumulated incoming boundary-wake ledger

$$\mathcal{B}_{\partial\Omega}(T) = \mathcal{B}_{\partial\Omega}^{\mathrm{in}}(\leq T) = \{(j, T_t, T_{\mathrm{cross}}, \mathbf{X}_{\mathrm{cross}}, \mathbf{X}_j(T_t), \mathbf{V}_j(T_t), q_j) \ : \ \mathbf{X}_j(T_t) \notin \Omega, \quad T_t < T_{\mathrm{cross}} \leq T, \quad \mathbf{X}_{\mathrm{cross}} \in \partial\Omega, \quad \|\mathbf{X}_{\mathrm{cross}} - \mathbf{X}_j(T_t)\| = c_f(T_{\mathrm{cross}} - T_t)$$

The crossing time T_{cross} separates instantaneous influx from already admitted exterior history. An interior receiver at T may depend on a boundary entry with $T_{\mathrm{cross}} < T$, so the boundary ledger is accumulated rather than only evaluated at the present boundary. For non-convex Ω, the ledger retains each boundary-crossing event rather than assuming that the active exterior isochron still intersects $\partial\Omega$ at the evaluation time.

The subsystem evolution therefore has the schematic form

$$\frac{dX_\Omega}{dT} = F_\Omega\big(X_\Omega(T), \mathcal{H}_\Omega^{<T}, \mathcal{B}_{\partial\Omega}(T), N_{\mathrm{sea}}|_\Omega(T)\big)$$

where $N_{\mathrm{sea}}|_\Omega(T)$ denotes the locally resolved Noether sea state. A Physical Observer who models only $X_\Omega(T)$ has omitted finite-speed signals, incoming causal wakes, and path-history branches crossing the boundary. That omission can make local prediction fail without implying indeterminism in the $\mathbb{U}_{\mathrm{now}}$ universe-state perspective, because the complete state includes the boundary wake data and the path-history ledger needed for deterministic continuation.

The same finite-boundary form is the local substitute for placing a hypothetical observer at infinity in compact strong-field comparisons. For black-hole and cosmology problems, $\mathcal{B}_{\partial\Omega}$ is the controlled interface between what a Physical Observer can access and what the complete state must carry for deterministic continuation.

The following diagnostics have different status. The ambiguity indicator $\Delta_P^{(O,W)}$ and the boundary-wake family $\mathcal{B}_{\partial\Omega}^{(O)}$ are consumed by validation, effective-metric, and local-horizon comparison arguments as observer-record discipline. The covariance split, causal-order residual, reconstruction-uniqueness residual, and process-table mismatch are comparison scaffolds unless an apparatus-specific benchmark or closure proof consumes them. None of these objects adds substrate ontology; each tests whether one declared Physical Observer record is being reused rather than refit.

Global-Reconstruction Ambiguity

Finite observer records can underdetermine global reconstruction even when the local data are extremely rich. A record can be precise and still fail to select a unique global reconstruction. For a declared Physical Observer O, observation window W, data-product family $\mathcal{D}$, and tolerance ϵ, let $\Pi_{\mathcal{D}}^{(O,W)}(\theta)$ be the data-product projection of a candidate closure record θ. Relative to the promoted closure set $\mathcal{C}_{\mathbb{AAA}}$ from Failure Criteria, define

$$[\theta]_{\mathcal{D},\epsilon}^{(O,W)} = \left\{\theta' \in \mathcal{C}_{\mathbb{AAA}} : d_{\mathcal{D}}\left(\Pi_{\mathcal{D}}^{(O,W)}(\theta'), \Pi_{\mathcal{D}}^{(O,W)}(\theta)\right) \le \epsilon\right\}$$

For a proposed global claim P, the observer-side ambiguity indicator is

$$\Delta_P^{(O,W)}(\theta) = \mathbf{1}\left[\exists \theta_1, \theta_2 \in [\theta]_{\mathcal{D},\epsilon}^{(O,W)} \text{ with } P(\theta_1) \neq P(\theta_2)\right]$$

If $\Delta_P^{(O,W)}(\theta) = 1$, the Physical Observer has not measured P as a global fact. The data product may still be valid, but P remains an effective reconstruction or comparison interpretation unless an independent $\mathbb{AAA}$ derivation selects it from the same complete-state and boundary-wake record.

For local-horizon thermodynamic comparisons, the countable object is not the raw boundary history by itself. It is the retained boundary-wake label family after the Physical Observer's record channel has identified histories that cannot be distinguished on the declared window:

$$\mathcal{B}_{\partial\Omega}^{(O)}(\theta; W) = \widehat{\mathcal{B}}_{\partial\Omega}(T; \theta)\Big|_W / \sim_{O,\theta,W}$$

Here $\widehat{\mathcal{B}}_{\partial\Omega}(T;\theta)$ denotes the boundary wake history retained by the observer model record, and $\mathcal{B}_1 \sim_{O,\theta,W} \mathcal{B}_2$ means that the two retained boundary histories give the same Physical Observer clock, ruler, detector, and readout records on W within the declared tolerance. This quotient is an observer-accessible coarse-graining of deterministic boundary data, not a new substrate boundary. It is the object later counted in local-horizon entropy targets.

Boundary-Wake Covariance Scaffold

The boundary term above also supplies the native home for covariance matrices used by observer-level measurement diagnostics. A covariance is not fundamental randomness. It is a finite-access summary of boundary wake histories, detector states, and Noether sea variables not resolved by a Physical Observer.

With this notation, the unresolved boundary residual is

$$\delta\mathcal{B}_{\partial\Omega}(T;\theta) = \mathcal{B}_{\partial\Omega}(T) - \widehat{\mathcal{B}}_{\partial\Omega}(T;\theta)$$

For a readout channel $Y_A(t_{\text{eff}})$, define the residual induced by unresolved boundary histories as

$$\delta Y_A(t_{\text{eff}}; \mathcal{B}, \theta) = Y_A(t_{\text{eff}}; \mathcal{B}, \theta) - \langle Y_A(t_{\text{eff}}; \mathcal{B}, \theta)\rangle_{\mu_{\Omega,\theta}}$$

Here $\mu_{\Omega,\theta}$ is a coarse-grained conditional measure over complete states whose resolved projection agrees with the Physical Observer's record θ. It is an epistemic measure over unresolved deterministic histories, not a new substrate law.

The boundary-wake covariance is then

$$\mathsf{N}_{AB}^{\text{bw}}(t_{\text{eff}}, t'_{\text{eff}}; \theta) = \int \delta Y_A(t_{\text{eff}}; \mathcal{B}, \theta)\, \delta Y_B(t'_{\text{eff}}; \mathcal{B}, \theta)\, d\mu_{\Omega,\theta}(\mathcal{B})$$

It is positive semidefinite by construction as a channel covariance:

$$\iint f_A(t_{\text{eff}})\, \mathsf{N}_{AB}^{\text{bw}}(t_{\text{eff}}, t'_{\text{eff}}; \theta)\, f_B(t'_{\text{eff}})\, dt_{\text{eff}}\, dt'_{\text{eff}} \ge 0$$

for every resolved test channel $f_A(t_{\text{eff}})$ on the observation window. A model that violates this condition has broken the covariance decomposition rather than discovered a new observer-layer effect.

A detector model may add separately calibrated residuals,

$$\mathsf{N}_{AB}(t_{\text{eff}}, t'_{\text{eff}}; \theta) = \mathsf{N}^{\text{bw}}_{AB}(t_{\text{eff}}, t'_{\text{eff}}; \theta) + \mathsf{N}^{\text{det}}_{AB}(t_{\text{eff}}, t'_{\text{eff}}) + \mathsf{N}^{\text{env}}_{AB}(t_{\text{eff}}, t'_{\text{eff}})$$

The same decomposition should be reused across weak-probe, interferometric, and precision-gravity comparisons. If a proposed measurement model must retune the unresolved boundary covariance separately for each branch or observable, the observer-level closure has failed rather than discovered a new ontology.

For weak-field GR comparisons, this page treats the ADM/Cartan projection defined by Emergent Metric as an input consumed by the observer record. The observer layer should carry the whole channel bundle at once:

$$\Theta^{(O,W)}_{\text{weak}} = \left(N_{\text{sea}}|_{\Omega,W}, O_W, \mathcal{B}^{(O)}_{\partial\Omega}(W), \widehat{\mathcal{B}}_{\partial\Omega}(W), \mu_{\Omega,\theta}, \mathsf{N}^{\text{bw}}_{AB}, \mathsf{N}^{\text{det}}_{AB}, \mathsf{N}^{\text{env}}_{AB}, \Pi_{\text{ADM}}\right)$$

where Π_{ADM} is the observer-level projection, owned by the effective-metric map, to $(N, u^i_{\text{sea,eff}}, e^a{}_i, \gamma^{\text{eff}}_{ij}, \Phi_{\text{eff}}, \chi_{\text{sea}})$. The lapse N inside Π_{ADM} and the medium-state notation N_{sea} are distinct from the covariance kernels, which consistently use the sans-serif symbol N_{AB}. Redshift, Shapiro delay, lensing, weak-field acceleration, and preferred-frame residuals must be read from $\Theta^{(O,W)}_{\text{weak}}$ with the same covariance and boundary-data model. A channel-specific replacement of $\mu_{\Omega,\theta}$, $\mathsf{N}^{\text{bw}}_{AB}$, or the imported Π_{ADM} is therefore a retuning residual, not an improved observer model.

The same declared-measure discipline applies to observer-level probability tables and ensemble summaries. For a Physical Observer record θ, observation window W, readout channel Y_A, and event set B, the probability assigned to that readout should be a pushforward of the conditional measure already tied to retained boundary data:

$$P_{\Omega,\theta,W}(Y_A \in B) = \mu_{\Omega,\theta}(\{\mathcal{B} : Y_A(t_{\text{eff}}; \mathcal{B}, \theta) \in B \text{ on } W\})$$

If a comparison requires different measures for branch weights, thermodynamic noise, observer selection, or readout covariance while holding the same observer record θ, it is a set of separately fitted summaries rather than one observer-model closure.

Absolute and Operational Simultaneity

At the ontic level, simultaneity is absolute. Two events

$$(T_1, \mathbf{X}_1) \qquad \text{and} \qquad (T_2, \mathbf{X}_2)$$

are simultaneous exactly when

$$T_1 = T_2$$

The simultaneity slice is

$$\Sigma_T = \{T\} \times \mathbb{R}^3$$

This is a statement about the substrate foliation of absolute timespace. It is not a statement that any Physical Observer can operationally reconstruct the whole slice.

Physical Observers define simultaneity through clocks, rulers, and signal exchanges. Because those clocks and rulers are assemblies and because signals propagate at finite speed, different moving observers may assign different operational simultaneity surfaces.

The disagreement is epistemic rather than ontological:

- The $\mathbb{U}_{\text{now}}$ universe-state perspective has one absolute slice Σ_T.
- Physical Observers recover only operational synchronization conventions.
- In validated regimes, those operational conventions must reproduce Lorentz-consistent clock, ruler, and two-way signal phenomenology while bounding preferred-frame leakage below observational limits.

Effective Causal-Order Recovery

External causal-order reconstruction theorems provide a useful comparison discipline: effective causal relations can determine much of an observer-level geometry, but not the local scale by themselves. In this framework, that scale is supplied by Physical Observer clocks, rulers, and signal channels. All three are assembly and Noether sea outputs rather than substrate intervals.

For a declared GR comparison metric supplied by the effective-metric map and a candidate Noether sea state and observer-state parameter record θ, let $\prec_{\text{eff}}(\theta)$ be the causal order inferred by Physical Observers from photon-channel records and clock synchronization, and let $\prec_{\text{GR}}$ be the causal order of the target effective metric. A compact observer-layer recovery diagnostic is

$$\mathcal{R}_{\text{causal}}(\theta) = d_{\text{ord}}(\prec_{\text{eff}}(\theta), \prec_{\text{GR}}) + \lambda_\tau \left\| \frac{d\tau_{\text{eff}}}{dt_{\text{eff}}}(\theta) - \frac{d\tau_{\text{GR}}}{dt_{\text{eff}}} \right\|_W + \lambda_{\text{PF}} \sum_{i=1}^{3} \alpha_i(\theta)^2$$

Here d_{ord} measures mismatch of inferred causal order on the comparison domain, the clock term supplies the missing local scale, and the preferred-frame term penalizes residual PPN drift coefficients. The labels τ_{eff} and τ_{GR} mark the candidate observer-record clock readout and the

GR comparison clock readout; they are not additional substrate time variables. This is a closure target for the observer layer, not a claim that substrate spacetime is Lorentzian.

A causal-set comparison adds a useful uniqueness discipline after the effective-metric map has supplied the candidate metric family. It is not enough for Physical Observer records to fit one effective metric; the same causal-order, clock, ruler, and preferred-frame data should not also fit macroscopically distinct effective metrics at the same declared coarse-graining scale. For a scale ℓ and tolerance ε, let $\mathcal{G}_{\ell,\varepsilon}(\theta)$ be the family of GR comparison metrics on the domain whose coarse-grained causal-order and clock/ruler diagnostics satisfy $\mathcal{R}_{\text{causal}}(\theta; g) \le \varepsilon$, using the same residual above with g supplying the target causal order and GR proper-time terms. Define the observer-side reconstruction-uniqueness residual

$$\mathcal{H}_{\text{eff}}(\theta; \ell, \varepsilon) = \sup_{g_1, g_2 \in \mathcal{G}_{\ell,\varepsilon}(\theta)} d_{\text{geom},\ell}(g_1, g_2)$$

Small $\mathcal{H}_{\text{eff}}$ says that the observer record determines a unique effective geometry up to the declared coarse-graining scale. Large $\mathcal{H}_{\text{eff}}$ means the observer layer has not supplied enough scale, transport, or preferred-frame information to identify a stable GR comparison geometry. This residual is unrelated to the path-history ledger $\mathcal{H}_{\Omega}^{<T}$ above. It is an effective-reconstruction test only; it does not promote a Lorentzian metric to substrate ontology.

Process-matrix and indefinite-causal-order formalisms are useful here only as comparison frameworks. They test whether operational records can be represented without assuming a prior observer-level causal order, but their generalized process object is not a substrate replacement for absolute timespace. For settings or interventions $\mathbf{s}$ and records $\mathbf{r}$, let $P_{\text{proc}}(\mathbf{r}|\mathbf{s})$ be the external process-table benchmark and let $P_{\text{rec}}^{\theta}(\mathbf{r}|\mathbf{s})$ be the record distribution derived from Physical Observer laboratories, boundary wake data, apparatus kernels, and the candidate observer-state record θ. A compact diagnostic is

$$\Delta_{\text{proc}}(\theta) = D_{\text{TV}}\left(P_{\text{proc}}(\mathbf{r}|\mathbf{s}), P_{\text{rec}}^{\theta}(\mathbf{r}|\mathbf{s})\right) + \lambda_{\text{causal}} \mathcal{R}_{\text{causal}}(\theta)$$

Small process-table mismatch with large $\mathcal{R}_{\text{causal}}$ is a warning that the observer layer has not recovered an effective causal order. It is not evidence that the ontic substrate lacks absolute time. The admissible lesson is diagnostic: preserve the operational record constraint while forcing the Physical Observer account to say how causal order, clocks, and records are recovered together.

Physical Observer Clocks and Rulers

A Physical Observer clock measures **derived clock time** τ (standard bridge term: proper time), not the substrate parameter T directly. A ruler is likewise an assembly whose measured length depends on its internal dynamics and medium coupling. In this observer-layer use, `proper` means clock-carried in the relativity comparison sense; it does not mean substrate-level or exemplary time.

The same rule applies to every observer tool. A clock, ruler, detector, telescope, or notebook is an assembly record. It is not a transparent window onto the substrate unless the clock, ruler, signal, and calibration channels have been declared.

This page does not own the clock law. Once a discussion asks how an internal clock frequency changes with velocity, Noether sea density, effective potential, or clock geometry, use Proper Time and Time Dilation.

Likewise, this page does not own the full Lorentz comparison. Once a discussion asks whether moving clocks and rulers reproduce Lorentz transformations, use Lorentz Kinematics.

Preferred-Frame Hiding

The ontology contains absolute time, a Euclidean void, and a real medium. Therefore the framework must still explain why Physical Observers do not see unacceptable preferred-frame effects.

The requirement is:

> Physical Observer clocks, rulers, and signal transport must keep preferred-frame signatures below current experimental bounds in validated low-energy and weak-field regimes.

This is not an optional rhetorical claim. It is a closure burden distributed across:

- Proper Time and Time Dilation for clock behavior,
- Lorentz Kinematics for moving-observer comparison,
- PPN Parameters for preferred-frame leakage coefficients,
- Constraint Ledger for empirical thresholds,
- and Known Tensions for the current unresolved burden.

Ownership Boundary

This chapter owns:

- the $\mathbb{U}_{\text{now}}$ universe-state perspective as complete-state bookkeeping,
- the Physical Observer definition,

- the ontic/epistemic distinction,
- the absolute-versus-operational simultaneity split,
- and the routing map for observer-level closure.

This chapter does not own:

- primitive substrate definitions; see Absolute Time, Euclidean Void, and Absolute Timespace,
- clock laws; see Proper Time and Time Dilation,
- effective metric construction; see Emergent Metric,
- PPN bounds; see PPN Parameters,
- or quantum measurement ontology; see Measurement Ontology.

Summary Commitment

> **Observer Commitment:** $\mathbb{AAA}$ distinguishes the complete ontic state on an absolute-time slice from the measurements available to embedded Physical Observers. Physical Observers are assemblies inside the Noether sea, so their clocks, rulers, synchronization procedures, and records are dynamical outputs. Effective relativity and quantum state descriptions belong to this observer-accessible layer, not to the primitive substrate itself.

Proper Time and Time Dilation

This chapter explains how clock time is recovered from assembly dynamics. Absolute time T is the substrate evolution parameter used by the $\mathbb{U}_{\text{now}}$ universe-state perspective in the Euclidean void. Derived clock time τ is the readout of physical clocks built from Noether braid assemblies. The theorem target is to derive the map between them and show how GR-like time dilation and gravitational redshift arise as effective behavior when the clock map closes.

This chapter keeps `proper time` as the standard relativity bridge term for clock time along a timelike record. In $\mathbb{AAA}$, the native claim is more specific: τ is a derived clock readout, not a second substrate time and not a more fundamental or exemplary time. The word `proper` should therefore be read only in the inherited physics sense of belonging to the physical clock record.

This chapter is the canonical home for derived clock time, observer clocks, clock slowing, and the clock map from absolute time T to measured clock readout τ. Foundation and ontology pages should point here once the discussion becomes a clock law, frequency extraction, observer-clock comparison, or Lorentz/GR time-dilation recovery.

For the detailed comparison between special-relativistic clock language and the deformable Noether braid implementation story, see the special-relativity bridge.

The practical rule is to never ask only how fast two clock centers move relative to each other. Ask which assembly cycle is being counted, what local Noether sea state it samples, how the clock is oriented and drifting, and which effective observer chart receives the record. Relative velocity becomes the familiar time-dilation variable only after those native records collapse to the homogeneous weak-field limit.

The primary clock law is phase extraction from a declared assembly channel. A clock is usable only when some internal cycle remains stable enough to count:

$$\frac{d\tau_{\mathcal{A}}}{dT} = \frac{\Omega_{\mathcal{A}}\left(\mathbf{w}, \mathcal{N}_{\text{sea}}, R_{\mathcal{A}}, H_{\mathcal{A}}\right)}{\Omega_{\mathcal{A}}^{(0)}}, \qquad d\tau_{\mathcal{A}} = \frac{d\varphi_{\mathcal{A}}}{\Omega_{\mathcal{A}}^{(0)}}$$

Here $\varphi_{\mathcal{A}}$ is the counted clock phase, $\Omega_{\mathcal{A}}^{(0)}$ is its rest-branch reference rate, $\mathcal{N}_{\text{sea}}$ is the retained Noether sea state, $R_{\mathcal{A}}$ is the clock geometry/orientation record, $H_{\mathcal{A}}$ is the relevant path-history ledger, and $\mathbf{w}$ is the clock drift relative to local Noether sea flow. A broad native expression such as $d\tau/dT = F(\mathbf{w}, n, \chi_{\text{sea}}, \Phi_{\text{eff}}, \text{clock geometry})$ is only a shorthand after this phase channel has been declared; observer comparisons must project it to $d\tau/dt_{\text{eff}}$.

For a two-clock comparison, the native input is not the relative velocity of the two clock centers by itself. It is the pair of local clock records

$$\mathcal{D}_{\tau}^{AB} = \left(\mathbf{w}_A, \mathbf{w}_B, \mathcal{N}_{\text{sea},A}, \mathcal{N}_{\text{sea},B}, R_A, R_B, H_A, H_B\right), \qquad \mathbf{w}_K = \mathbf{V}_{K,\text{cm}} - \mathbf{u}_{\text{sea},K}.$$

Ordinary relative-velocity time dilation is the weak homogeneous limit of this record after the clock, ruler, and signal channels hide any observer-accessible preferred-frame leakage. If two clocks sample different Noether sea cells, a formula using only $\mathbf{V}_{A,\text{cm}} - \mathbf{V}_{B,\text{cm}}$ has already discarded part of the clock map.

A transported clock supplies a path-integrated test of the same record. For a clock carried around a spatial loop C between shared departure and reunion events and compared on return with a reference clock that remained on worldline C_0, define

$$\Delta\tau_{C:C_0} = \int_C F_{\mathcal{A}}(\mathbf{w}_C, \mathcal{N}_{\text{sea},C}, R_C, H_C)\, dT - \int_{C_0} F_{\mathcal{A}}(\mathbf{w}_0, \mathcal{N}_{\text{sea},0}, R_0, H_0)\, dT,$$

where $F_{\mathcal{A}} = d\tau_{\mathcal{A}}/dT$ is the same clock map used above. Oppositely directed circumnavigation paths provide the transported-clock benchmark exemplified by Hafele-Keating-type comparisons, while fiber-linked stationary clocks can supply the endpoint reference without turning photon transport into the carried matter clock. This is distinct from the photon-loop Sagnac row: both loops sample the same declared Noether sea flow, but one integrates a material clock cadence and the other integrates signal propagation. The terrestrial $\mathbf{u}_{\text{sea}}$ working profile in PPN Parameters must be used along both paths. CMB-comoving and locally entrained profiles are discriminated by the annual, sidereal, east-west, and altitude dependence of $\Delta\tau_{C:C_0}$.

The target is to reproduce, in the appropriate regime,

$$\frac{d\tau}{dt_{\text{eff}}} \approx \sqrt{1 + \frac{2\Phi_N}{c_0^2} - \frac{\|\mathbf{w}\|^2}{c_0^2}}$$

and to generalize this map to strong-field and high-velocity conditions.

Notation convention used in this chapter: $n(\mathbf{X}, T) \equiv \rho_{\text{NS}}(\mathbf{X}, T)/\rho_{\text{NS},0}$ is the canonical medium-density variable.
The Noether sea delay factor is $\chi_{\text{sea}}(\mathbf{X}, T) \equiv c_f/c_{\text{eff}}(\mathbf{X}, T)$; use it for refractive-delay language so n remains reserved for density.
The clock-law derivation imports the transverse causal budget lemma: primitive branch tests may use c_f, but observer-level clock comparison uses the declared dressed speed $c_\star$, usually $c_\star = c_{\text{eff}}(\mathbf{X}, T)$ in a local Noether sea cell.

Conceptual Setup

Absolute Time vs Derived Clock Time

- **Absolute time** T
  - Fundamental evolution parameter for the complete architrino dynamics.
  - Global, universal, non-dynamical; used by the $\mathbb{U}_{\text{now}}$ universe-state perspective (simulation clock).
  - All worldlines are parametrized directly by T.
- **Derived clock time** τ (standard bridge term: proper time)
  - Time read by a **physical clock**: a bound Noether braid assembly, such as an atomic transition or binary oscillation, interacting with the Noether sea.
  - Encodes how many internal oscillation cycles occur per unit dT before projection into an observer chart.
  - The word `proper` does not mean substrate-level, privileged, or exemplary; it names the inherited relativity comparison target for a clock-carried record.

The fundamental claim is:

> Time dilation is not a change in the rate of T; it is a change in how fast internal dynamics of assemblies proceed **relative to** T, and then how that clock readout projects into t_{eff}, due to motion and medium coupling.

Clocks as Dynamical Systems

A clock is any assembly with a **stable, countable internal cycle**. The native picture is not time itself slowing; the countable assembly cycle is what changes cadence:

- Minimal model: a Noether braid with one declared clock-channel index $a_{\text{clk}} \in \{1, 2, 3\}$ whose cycle is counted. The clock-channel role is extracted from the record and is not assigned by radius order.
- Base frequency ω_0 (or period $T_0 = 2\pi/\omega_0$) is defined for:
  - Clock **at rest** in the absolute frame.
  - In a region of homogeneous Noether sea density $n = 1$ and negligible external gradients.

Derived clock time is then defined operationally as:

$$d\tau = \frac{\omega(\text{state})}{\omega_0}\, dT$$

where $\omega(\text{state})$ is the instantaneous internal oscillation frequency in the actual kinematic and environmental state.

The central problem is to compute $\omega(\mathbf{w}, n, \chi_{\text{sea}}, \Phi_{\text{eff}})$ from the master dynamics rather than assigning the clock-rate factor by analogy with relativity.

Moving-Branch Clock Retuning Target

The homogeneous moving-clock extraction is independent from weak-field PPN matching. Primitive branch calculations solve causal roots with c_f:

$$\|\mathbf{X}_o(T) - \mathbf{X}_j(T_0)\| = c_f(T - T_0)$$

The dressed observer-channel speed $c_\star$ is declared only after the clock/ruler channel is chosen: $c_\star = c_f$ for a primitive branch scan and usually $c_\star = c_{\text{eff}}(\mathbf{X}, T)$ for a Noether sea dressed clock comparison. Thus

$$\mathbf{w} = \mathbf{V}_{\text{cm}} - \mathbf{u}_{\text{sea}}, \qquad \beta_\star = \frac{\|\mathbf{w}\|}{c_\star}, \qquad \gamma_\star(\mathbf{w}) = \frac{1}{\sqrt{1 - \beta_\star^2}}$$

where $\mathbf{w}$ is the clock assembly drift through the local Noether sea.

The locally measured speed of light is therefore a co-calibrated observer readout, not a primitive identity among all speed symbols. In a weak homogeneous calibration cell W_0, a Physical Observer obtains the empirical value by comparing photon-channel round-trip transport against its own ruler and derived clock phase:

$$c_0 = \frac{2L_{\text{obs}}(W_0)}{\Delta\tau_{\gamma,\text{rt}}(W_0)}.$$

The numerator is a ruler response, the denominator is a clock readout, and the photon path samples the photon-channel speed c_γ. The closure burden is to derive why c_f, c_{eff}, c_γ, and c_0 collapse to one weak-homogeneous measured limit within the preferred-frame leakage budget; the equality cannot be supplied by notation alone.

The simple clock-budget target is that the declared channel speed splits into center-of-mass drift and transverse closure:

$$c_\star^2 = \|\mathbf{w}\|^2 + c_\perp^2$$

so

$$c_\perp = c_\star \sqrt{1 - \frac{\|\mathbf{w}\|^2}{c_\star^2}} = \frac{c_\star}{\gamma_\star(\mathbf{w})}$$

An accepted clock branch must then extract

$$\frac{d\tau}{dt_{\text{eff}}} = \frac{c_\perp}{c_\star} = \frac{1}{\gamma_\star(\mathbf{w})}$$

from its internal phase dynamics, rather than assign the factor independently.

For an admitted moving Noether braid branch q on a drift band $0 \le \|\mathbf{w}\|/c_f \le \beta_{\max} < 1$, choose one clock phase $\theta_{\text{clk},q}$ from the same causal-root ledger used for the branch's geometry. The extracted period is

$$T_q(\mathbf{w}) = \frac{2\pi}{\langle \dot{\theta}_{\text{clk},q} \rangle_{\text{cyc}}}, \qquad T_0 = T_q(\mathbf{0})$$

and the clock residual is

$$R_T^{(q)}(\mathbf{w}) \equiv \frac{T_q(\mathbf{w})}{T_0} - \gamma_\star(\mathbf{w})$$

The moving-clock theorem target is

$$\left| R_T^{(q)}(\mathbf{w}) \right| \le C_T \epsilon_{\text{LV}} \beta_\star^2$$

uniformly on the drift band, with any surviving preferred-frame sideband reported as a branch-sourced leakage term. This packet fails if the clock phase and ruler geometry come from different branch ledgers, if the residual is suppressed only by fitting a PPN coefficient after the fact, or if c_f is silently identified with $c_\star$ without a dressing map.

This moving-clock row is one leg of the structural-integrity common-limit closure in Lorentz Kinematics. It is not enough for the clock branch to approximate $\gamma_\star^{-1}$ in isolation. The same causal-root ledger must also produce the moving ruler deformation, photon synchronization row, and weak-field gravity-channel speed row used by Lorentz closure; otherwise the clock result is a branch-split fit rather than clock-map closure.

Noether Sea Braid Cadence

For redshift and cosmology work, the local Noether sea braid cadence can serve as the immediate clock reference before any separate detector clock is introduced. Let $\Omega_N(\mathbf{X}, T)$ be a representative cadence extracted from the local Noether sea braid population, with $T_N(\mathbf{X}, T) = 2\pi/\Omega_N(\mathbf{X}, T)$. Relative to the weak homogeneous reference cadence, define

$$\Gamma_N(\mathbf{X}, T) \equiv \frac{T_N(\mathbf{X}, T)}{T_{N0}} = \frac{\Omega_{N0}}{\Omega_N(\mathbf{X}, T)}$$

The quantity Γ_N records local cadence stretching of the Noether sea itself. It is therefore a substrate-facing clock diagnostic: $\Gamma_N = 1$ marks the weak homogeneous reference, while $\Gamma_N > 1$ marks a locally slowed or stretched Noether sea cadence. In the homogeneous moving Noether braid branch, the Lorentz-closure target is to derive the appropriate limit $\Gamma_N \to \gamma_\star$ or, equivalently, $\Omega_N/\Omega_{N0} \to 1/\gamma_\star$ for the declared clock channel. In a gravitational or cosmological Noether sea state comparison, Γ_N must instead be extracted from $n(\mathbf{X}, T)$, $\chi_{\rm sea}(\mathbf{X}, T)$, $\Phi_{\rm eff}$, and clock geometry.

This diagnostic does not replace the clock readout. Native clock-map derivations use $d\tau/dT$, while observer-coordinate comparisons use $d\tau/dt_{\rm eff}$. Γ_N supplies a more primitive Noether sea cadence factor from which clock-rate comparisons, gravitational redshift, and the redshift factorization in Expansion Mechanism can be built. The ordinary local clock-rate factor is the inverse:

$$C_N(\mathbf{X}, T) \equiv \frac{\Omega_N(\mathbf{X}, T)}{\Omega_{N0}} = \Gamma_N^{-1}(\mathbf{X}, T)$$

Using C_N as the emitting or receiving matter-clock factor requires a same-cell identification that must be tested rather than assumed. For a declared clock assembly $\mathcal{A}$, define

$$\Delta_{\text{clk-sea},\mathcal{A}} \equiv \ln\left[\frac{\Omega_{\mathcal{A}}(\mathbf{X}, T)}{\Omega_{\mathcal{A}}^{(0)}}\right] - \ln C_N(\mathbf{X}, T).$$

The endpoint redshift factorization may use Γ_N directly as the source/detector clock conversion only on a branch where $\Delta_{\text{clk-sea},\mathcal{A}} = 0$ within tolerance for both endpoint clock records. Otherwise the two mismatch terms remain explicit; they cannot be absorbed into the launch factor or path-history propagation row.

In the homogeneous moving Noether braid branch, the geometry-to-clock closure target is $C_N \to \xi \to 1/\gamma_\star$, so the corresponding cadence-stretch target is $\Gamma_N \to 1/\xi \to \gamma_\star$.

In the weak-field endpoint limit, the required recovery condition is

$$\frac{\Omega_N(\mathbf{X}, T)}{\Omega_{N0}} \approx 1 + \frac{\Phi_N(\mathbf{X}, T)}{c_0^2}, \qquad \Gamma_N(\mathbf{X}, T) \approx 1 - \frac{\Phi_N(\mathbf{X}, T)}{c_0^2}$$

to first order in Φ_N/c_0^2. Since $\Phi_N < 0$ in a deeper potential, this gives $\Gamma_N > 1$ there: the local Noether sea braid cadence is stretched relative to the weak homogeneous reference. For two endpoint cells E and R with no source-branch, launch, or path-history correction, the redshift recovery condition is therefore

$$\ln(1+z) \approx \ln \Gamma_{N,E} - \ln \Gamma_{N,R} \approx \frac{\Phi_N(R) - \Phi_N(E)}{c_0^2}$$

This is the clock-channel version of the weak gravitational-redshift benchmark. The derivation burden is to obtain the first equation from Noether sea constitutive response rather than impose it as an imported metric fact.

GR Proper-Time Functional Benchmark

The same clock map must also reproduce the observer-level proper-time functional that GR uses for timelike records. This is a bridge benchmark, not a substrate definition of time. For a candidate effective metric recovered from the Noether sea record,

$$d\tau = \frac{1}{c_0}\sqrt{-g_{\mu\nu}^{\rm eff} dx^\mu dx^\nu}$$

with the weak-field static endpoint limit above and the moving-clock limit

$$g_{\mu\nu}^{\rm eff} \frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau} = -c_0^2$$

This equation is not a claim that the Euclidean void is a four-dimensional curved substrate. It is the observer-level action benchmark: physical clocks should extremize the same effective interval that the signal, ruler, and orbital modules use when they project the Noether sea state into GR comparison language. If a branch recovers endpoint redshift but fails the integrated clock functional along accelerated or orbital records, the clock map has not closed.

Gamma-N Geometry Extraction Target

The equations above define the endpoint benchmark, but they do not yet derive the Noether sea cadence factor from Noether braid geometry. A first-order extraction scaffold should start from the local variables that already appear in the clock and transport programs: normalized Noether braid density n, Noether sea delay factor $\chi_{\rm sea}$, envelope scale λ, envelope shape ratio ξ, and a representative Noether braid scale $R_{\rm braid}$. Around the weak homogeneous reference, collect the logarithmic deformation record

$$\mathbf{g}_N = \left(\ln n,\, \ln \chi_{\rm sea},\, \ln \lambda,\, -\ln \xi,\, \ln \frac{R_{\rm braid}}{R_{\rm braid,0}}\right)^T$$

The candidate extraction law is

$$\ln \Gamma_N = \mathbf{b}_N \cdot \mathbf{g}_N + \mathcal{R}_\Gamma$$

where $\mathbf{b}_N$ is a constitutive coefficient row and $\mathcal{R}_\Gamma$ contains higher-order and branch-specific corrections. Write the row as

$$\mathbf{b}_N = (b_n,\, b_\chi,\, b_\lambda,\, b_\xi,\, b_R)$$

The sign convention places $-\ln \xi$ in the deformation record because the homogeneous Lorentz-closure branch requires $\Gamma_N \to 1/\xi$ when the clock readout is controlled only by oblate moving Noether braid geometry. In that branch

$$\mathbf{g}_N^{\mathrm{mov}} = (0,\, 0,\, 0,\, \ln \gamma_\star,\, 0)^T + O(\epsilon_{\mathrm{LV}})$$

so the moving Noether braid constraint fixes

$$b_\xi = 1$$

up to preferred-frame leakage. The first-order admissible row is therefore

$$\mathbf{b}_N = (b_n,\, b_\chi,\, b_\lambda,\, 1,\, b_R)$$

with the remaining coefficients belonging to the isotropic Noether sea constitutive response rather than to Lorentz geometry.

This is also the convention bridge to the effective metric subclass. If the local metric clock-rate factor is written as an isotropic factor times the envelope shape ratio,

$$C_N^{\mathrm{met}} = \Omega_{\mathrm{clk}}(n, \chi_{\mathrm{sea}}, \lambda, R_{\mathrm{braid}})\, \xi$$

then the cadence-stretch factor is

$$\Gamma_N^{\mathrm{met}} = (\Omega_{\mathrm{clk}}\xi)^{-1}$$

Writing

$$\ln \Omega_{\mathrm{clk}} = \omega_n \ln n + \omega_\chi \ln \chi_{\mathrm{sea}} + \omega_\lambda \ln \lambda + \omega_R \ln \frac{R_{\mathrm{braid}}}{R_{\mathrm{braid},0}} + \mathcal{R}_\Omega$$

therefore gives the coefficient identification

$$b_n = -\omega_n, \qquad b_\chi = -\omega_\chi, \qquad b_\lambda = -\omega_\lambda, \qquad b_R = -\omega_R, \qquad b_\xi = 1$$

The weak-field recovery condition then becomes a constraint on the same coefficient row:

$$\ln \Gamma_N(\mathbf{X}, T) = -\frac{\Phi_N(\mathbf{X}, T)}{c_0^2} + O\left(\frac{\Phi_N^2}{c_0^4}\right)$$

or, locally,

$$\mathbf{b}_N \cdot \nabla \mathbf{g}_N = -\frac{\nabla \Phi_N}{c_0^2} + O\left(\frac{\Phi_N \nabla \Phi_N}{c_0^4}\right)$$

Equivalently, let $U \equiv -\Phi_N > 0$ and define the static weak-potential response coefficients by

$$\ln n = a_n \frac{U}{c_0^2}, \qquad \ln \chi_{\mathrm{sea}} = a_\chi \frac{U}{c_0^2}, \qquad \ln \lambda = a_\lambda \frac{U}{c_0^2}, \qquad \ln \frac{R_{\mathrm{braid}}}{R_{\mathrm{braid},0}} = a_R \frac{U}{c_0^2}$$

to first order, with $-\ln \xi = 0 + O(U^2/c_0^4)$ in an isotropic static endpoint cell. Then weak gravitational redshift fixes only the scalar combination

$$b_n a_n + b_\chi a_\chi + b_\lambda a_\lambda + b_R a_R = 1$$

In clock-rate language this is the equivalent condition

$$\omega_n a_n + \omega_\chi a_\chi + \omega_\lambda a_\lambda + \omega_R a_R = -1$$

This is the first useful reduction of the proof burden. The Lorentz branch fixes the shape coefficient b_ξ, while static weak-field redshift fixes one isotropic coefficient combination. Individual values of b_n, b_χ, b_λ, and b_R, or equivalently of the ω row, require a constitutive calculation or simulation that extracts how a mass source changes n, χ_{sea}, λ, and R_{braid} in the same Noether sea cell.

Existing weak-field signal tests constrain one neighboring component of this vector. The PPN Shapiro-delay map uses the observer-normalized delay factor

$$\bar{\chi}_{\rm sea} = \frac{c_0}{c_{\rm eff}} = 1 + (1+\gamma_{\rm eff})\frac{U}{c_0^2} + O\left(\frac{U^2}{c_0^4}\right)$$

so its logarithmic response is

$$\delta \ln \bar{\chi}_{\rm sea} = (1+\gamma_{\rm eff})\frac{U}{c_0^2} + O\left(\frac{U^2}{c_0^4}\right)$$

This fixes a signal-delay response coefficient $a_\chi^{\rm sig} = 1 + \gamma_{\rm eff}$, giving $a_\chi^{\rm sig} \approx 2$ in the GR-matching solar-system branch. It becomes the clock-row coefficient a_χ only if the clock cadence and signal-propagation channel share the same scalar delay response in the tested branch. If they do not, the difference is not fit freedom; it is a channel-splitting residual that must be carried into PPN, redshift, and pressure-response comparisons.

Shared Clock/Signal Delay Closure

The equality between the clock coefficient and the Shapiro-delay coefficient is therefore a closure condition:

$$\Delta_\chi^{\rm clk\text{-}sig} \equiv a_\chi - a_\chi^{\rm sig} = a_\chi - (1+\gamma_{\rm eff}), \qquad \Delta_\chi^{\rm clk\text{-}sig} = 0$$

A branch may impose this condition only when the same first-order Noether sea delay factor retimes assembly clocks and signal propagation, the photon or signal channel has no separate χ_γ response at $O(U/c_0^2)$, the asymptotic normalization c_0/c_f is spatially constant in the comparison, and the weak cell is isotropic enough that first-order birefringent or stress-anisotropic delay terms are absent.

Under this shared-delay closure, the static endpoint constraint becomes

$$b_n a_n + b_\chi(1+\gamma_{\rm eff}) + b_\lambda a_\lambda + b_R a_R = 1$$

or, equivalently in clock-rate-row language,

$$\omega_n a_n + \omega_\chi(1+\gamma_{\rm eff}) + \omega_\lambda a_\lambda + \omega_R a_R = -1$$

In the GR-matching weak solar-system branch, $\gamma_{\rm eff} = 1$ makes the delay contribution $2b_\chi$ in the cadence-stretch row and $2\omega_\chi$ in the clock-rate row. If $\Delta_\chi^{\rm clk\text{-}sig} \neq 0$, the branch has not failed by definition, but it must carry $\Delta_\chi^{\rm clk\text{-}sig}$ as a measured residual across clock redshift, Shapiro delay, pressure-response, and cosmological redshift comparisons rather than absorbing it into a fitted coefficient.

The first admissible static packet is the minimal shared-delay specialization of this row. Let

$$A_\chi \equiv 1 + \gamma_{\rm eff}$$

If the weak static endpoint cadence is assigned entirely to the shared scalar delay response at first order, then

$$(a_n,\, a_\chi,\, a_\lambda,\, a_R) = (0,\, A_\chi,\, 0,\, 0)$$

and the cadence-stretch row is

$$(b_n,\, b_\chi,\, b_\lambda,\, b_R) = \left(0,\, A_\chi^{-1},\, 0,\, 0\right)$$

The inverse clock-rate row is therefore

$$(\omega_n,\, \omega_\chi,\, \omega_\lambda,\, \omega_R) = \left(0,\, -A_\chi^{-1},\, 0,\, 0\right)$$

so

$$\mathbf{b}_N \cdot \mathbf{a} = 1, \qquad \boldsymbol{\omega} \cdot \mathbf{a} = -1, \qquad b_i + \omega_i = 0$$

For the GR-matching weak branch, $A_\chi = 2$, giving $a_\chi = 2$, $b_\chi = 1/2$, and $\omega_\chi = -1/2$. This is a minimal endpoint packet, not a proof that density, envelope scale, or core-radius responses are physically absent. A compensated static family remains admissible:

$$a_\chi = A_\chi, \qquad b_\chi = \frac{1 - b_n a_n - b_\lambda a_\lambda - b_R a_R}{A_\chi}, \qquad \omega_i = -b_i$$

Compensated Static-Family Validation Packet

The compensated family is a constrained endpoint row, not an additional redshift fit. Under shared clock/signal delay, define the non-$\chi_{\rm sea}$ static response vector and coefficient row by

$$\mathbf{u}^G = (a_n,\, a_\lambda,\, a_R)^T, \qquad \mathbf{c} = (b_n,\, b_\lambda,\, b_R)^T$$

The weak static endpoint condition is then

$$S_G \equiv \mathbf{c} \cdot \mathbf{u}^G + b_\chi A_\chi = 1$$

A finite-height clock comparison samples the spatial derivative of the same scalar. For a small upward separation L near Earth, with $U(z+L) - U(z) \approx -gL$, the clock-rate ratio obeys

$$\frac{\Delta\nu}{\nu} = -\Delta \ln \Gamma_N = S_G \frac{gL}{c_0^2} + O(L^2) + O\left(\frac{U^2}{c_0^4}\right)$$

Thus finite-height redshift fixes $S_G = 1$ to the experimental tolerance. It does not distinguish the minimal row $\mathbf{c} = \mathbf{0}$ from a compensated row with $\mathbf{c} \cdot \mathbf{u}^G \neq 0$ and adjusted b_χ, provided the same coefficients are used across the sample.

Hydrogen spectral conversion adds a record-difference test rather than another endpoint normalization. For two admissible hydrogen records ℓ and ℓ' whose line-inferred cadence stretch agrees after the envelope-gap residual is removed, the same spectral row must satisfy

$$\mathbf{b}_N^{\text{spec}} \cdot \left(\mathbf{g}_{N,\text{H}}^{(\ell)} - \mathbf{g}_{N,\text{H}}^{(\ell')}\right) = 0$$

The minimal shared-delay row passes only if the record difference has no uncompensated χ_{sea} component after the fixed $-\ln\xi$ term is included. The hydrogen toy scan now demonstrates the discriminant: the clean shared-delay row passes a clean χ_{sea}-only packet, while the density/scale-compensated row passes the split-record scaffold. This does not yet prove that the gravitational static endpoint has nonzero a_n, a_λ, or a_R; it demonstrates within the scaffold that any atom-local record with persistent density, scale, or core-radius splits must use one shared compensated row instead of per-line clock factors; the universal statement remains a conjectured consistency requirement.

Pressure-response replay supplies the independent shared-row test. Let

$$\mathbf{a}^G = (a_n,\, A_\chi,\, a_\lambda,\, a_R)^T, \qquad \mathbf{a}^{P\to\Gamma} = \frac{\delta \mathbf{g}^{P,\text{iso}}}{\delta \ln \Gamma_N^{P,\text{iso}}}$$

A single isotropic cadence row can serve both the gravitational endpoint and the pressure-normalized replay only if

$$\begin{pmatrix} (\mathbf{a}^G)^T \\ (\mathbf{a}^{P\to\Gamma})^T \end{pmatrix} \mathbf{b} = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \qquad \omega_i = -b_i$$

The current Fe/Cr toy pressure projection has $\mathbf{a}^{P\to\Gamma} = (0, 0.6, 0, 0)^T$ (toy-replay value; no linked packet), while the GR-matching shared-delay endpoint has $A_\chi = 2$. Therefore the χ_{sea}-only shared row is falsified for that toy pressure replay. A broader compensated row remains conditional: it requires branch-derived non-χ_{sea} pressure response in n, λ, or R_{braid}, and it must still preserve $S_G = 1$ for finite-height and endpoint redshift.

The current validation result is therefore:

Coefficient	Status
a_n	Optional in the weak static endpoint; conditionally required only if a branch-derived density response is needed to keep hydrogen or pressure records on one shared row.
a_λ	Optional in the weak static endpoint; conditionally required only if the envelope-scale branch supplies the compensating record.
a_R	Optional in the weak static endpoint; conditionally required only after a declared R_{braid} readout ties the pressure or spectral record to the same row.

Unconstrained nonzero values of a_n, a_λ, or a_R are disfavored (toy-scoped). They may be promoted only as branch-derived compensated response, not as adjustable redshift coefficients.

This gives the derivation a concrete target. The same Γ_N extraction map must recover $\Gamma_N = 1$ in the weak homogeneous reference, $\Gamma_N \to 1/\xi$ in the homogeneous moving Noether braid Lorentz branch, and $\Gamma_N \approx 1 - \Phi_N/c_0^2$ in the weak gravitational endpoint branch. It must also remain separate from the launch factor D_v and the path-history propagation factor Y_X, so the endpoint contribution to redshift is only

$$\ln(1+z)_{\text{endpoint}} = \ln \Gamma_{N,E} - \ln \Gamma_{N,R}$$

The full candidate redshift comparison keeps that endpoint clock term separate from source, launch, and path-history terms:

$$\ln(1+z_X) = \ln \Gamma_{N,E} - \ln \Gamma_{N,R} - \ln D_v + Y_{X,E\to R} - \ln B_X(E)$$

Here $B_X(E)$ is the source-branch factor, D_v is the launch or relative-motion phase-compression factor, and $Y_{X,E\to R} = \ln \mathcal{P}_{E\to R,X}$ is the path-history propagation integral through the Noether sea. This chapter owns the coefficient-row extraction of Γ_N and $C_N = \Gamma_N^{-1}$; Noether sea owns the absolute-record transport map and its path-history factors. Those transport factors must not be folded into Γ_N unless a derivation proves the reduction in a declared limit.

Hydrogen Spectral Clock-Rate Conversion Target

Hydrogen spectra give the first atom-local use of the Γ_N extraction map. The cadence-stretch factor is not the frequency multiplier itself. In the sign convention above, $\Gamma_N > 1$ means the local Noether sea cadence is stretched, so the corresponding local clock-rate factor is

$$C_N(\mathbf{X}, T) = \Gamma_N^{-1}(\mathbf{X}, T)$$

For the hydrogen spectral channel at resolution ℓ, extract the clock-facing deformation record from the same response map used by the spectral scan:

$$\mathbf{g}_{N,\mathrm{H}}^{(\ell)} = \left(\ln n_{\mathrm{H}}^{(\ell)},\, \ln \chi_{\mathrm{sea,H}}^{(\ell)},\, \ln \lambda_{\mathrm{H}}^{(\ell)},\, -\ln \xi_{\mathrm{H}}^{(\ell)},\, \ln \frac{R_{\mathrm{braid,H}}^{(\ell)}}{R_{\mathrm{braid},0}} \right)^T$$

The hydrogen clock/rate conversion target is then

$$\ln \Gamma_{N,\mathrm{H}}^{(\ell)} = \mathbf{b}_N^{\mathrm{spec}} \cdot \mathbf{g}_{N,\mathrm{H}}^{(\ell)} + \mathcal{R}_{\Gamma,\mathrm{H}}^{\mathrm{spec},(\ell)}, \qquad C_{N,\mathrm{H}}^{(\ell)} = \left(\Gamma_{N,\mathrm{H}}^{(\ell)} \right)^{-1}$$

The row $\mathbf{b}_N^{\mathrm{spec}}$ is not a per-line fit. It is the spectral-channel instance of the same clock-row program above, with $b_\xi = 1$ inherited from the homogeneous Lorentz branch and the weak-field scalar combination constrained by gravitational redshift. The residual $\mathcal{R}_{\Gamma,\mathrm{H}}^{\mathrm{spec},(\ell)}$ carries higher-order branch effects such as recoil, hyperfine structure, medium anisotropy, or unresolved source-branch corrections; it must not absorb the basic distinction between n, χ_{sea}, and clock cadence.

For a hydrogen transition $a \to b$, the clock-converted spectral readout is therefore

$$\nu_{a\to b}^{\mathrm{obs},(\ell)} = C_{N,\mathrm{H}}^{(\ell)} \frac{E_{\mathrm{env}}^{(\ell)}(a) - E_{\mathrm{env}}^{(\ell)}(b)}{h} + \nu_{a\to b}^{\mathrm{res},(\ell)}$$

Equivalently, an isolated line with bounded event residual gives a line-inferred cadence stretch,

$$\widehat{\Gamma}_{N,\mathrm{H}}^{(\ell)}(a,b) = \frac{E_{\mathrm{env}}^{(\ell)}(a) - E_{\mathrm{env}}^{(\ell)}(b)}{h\nu_{a\to b}^{\mathrm{obs},(\ell)}}$$

The first pass condition is that one $\Gamma_{N,\mathrm{H}}^{(\ell)}$ from the local Noether sea response controls the chosen line set:

$$\max_{(a,b)\in\mathcal{L}_{\mathrm{H}}^0} \frac{\left| \ln \widehat{\Gamma}_{N,\mathrm{H}}^{(\ell)}(a,b) - \ln \Gamma_{N,\mathrm{H}}^{(\ell)} \right|}{\left| \ln \Gamma_{N,\mathrm{H}}^{(\ell)} \right| + \varepsilon_\Gamma} \le \Delta_\Gamma^{\mathrm{tol}}$$

This target fails if Γ_N is multiplied directly into the line frequency after being defined as cadence stretch, if each transition requires its own clock coefficient row, if n or χ_{sea} is used as a substitute for Γ_N, if recoil or photon-channel propagation is hidden inside Γ_N, or if the hydrogen spectral map uses a different Noether sea response record than the clock, Shapiro-delay, or endpoint-redshift comparisons.

The first proof/simulation packet for this row is the Hydrogen Γ_N Spectral Coefficient Row Toy Scan. It treats $\mathbf{b}_N^{\mathrm{spec}}$ as a constrained clock-row instance: $b_\xi = 1$ is fixed by the homogeneous Lorentz branch, the weak static endpoint row must satisfy $b_n a_n + b_\chi a_\chi + b_\lambda a_\lambda + b_R a_R = 1$, and the observer frequency uses $C_N = \Gamma_N^{-1}$. The packet passes only if a shared row controls the chosen hydrogen line set across admissible refinement; it fails when the scan needs a transition-specific row, a direct Γ_N frequency multiplier, a collapsed density/delay variable, or a residual budget that hides recoil, hyperfine structure, photon-channel propagation, or unresolved source-branch effects.

The first executable scaffold keeps the clock proof burden visible. Its accepted spectral row is inherited from the density/scale-compensated static-response packet, not fitted from hydrogen lines alone. Its hydrogen records also keep n, χ_{sea}, λ, ξ, and R_{braid} as separate entries in $\mathbf{g}_{N,\mathrm{H}}^{(\ell)}$, so a row that matches one line or one record can still fail when the component split changes under admissible refinement. The executable derives the scaffold line factors, observer frequencies, and replay envelope gaps from recovered principal labels plus one shared line-inferred $\ln \Gamma_N$. A completed theory-bearing record must therefore supply the same four inputs together from one declared hydrogen spectral channel ledger and the same Noether sea cell: the hydrogen $\mathbf{g}_{N,\mathrm{H}}^{(\ell)}$ record, envelope gaps, observer frequencies, and static response vector.

Mechanisms for Time Dilation

Two coupled mechanisms change the internal frequency of a Noether braid clock. The prescribed B1 candidate — one common midpoint, one coincident binary axis, one common frequency, and one common circulation sense, with independent per-binary radii, axial half-separations, transverse orbit radii, and phases — supplies mechanism intuition for a highly coordinated clock. The executable clock record below instead uses a prescribed A1 chart so orientation and per-binary frequency dependence remain independently falsifiable. The two charts are alternative clock candidates, not one clock ontology silently changing family.

Kinematic Effect (Velocity Dependence)

When the clock has center-of-mass velocity $\mathbf{V}_{\mathrm{cm}}$ relative to a local Noether sea drift $\mathbf{u}_{\mathrm{sea}}$, its material drift is $\mathbf{w} = \mathbf{V}_{\mathrm{cm}} - \mathbf{u}_{\mathrm{sea}}$:

1. **Path-length elongation:**
   Internal architrinos must traverse longer spatial paths per cycle because the clock's center of mass is in motion. Even in the clock's own rest frame, the underlying wake interactions are evaluated in the absolute frame where the worldline is slanted through absolute timespace.

2. **Finite causal speed:**
   Primitive self-hit and partner-hit roots are mediated by delayed, radial path-history interactions at speed c_f. When those roots are dressed into an observer-level clock law, the transverse budget must be formed with the declared channel speed $c_\star$: $c_\star = c_f$ for a primitive branch test and $c_\star = c_{\text{eff}}(\mathbf{X}, T)$ for a Noether sea dressed clock comparison.

3. **Shape deformation (Lorentz-link hypothesis):**
   Under the Family-A Lorentz-link hypothesis, increased $\|\mathbf{w}\|$ makes the complete braid's **oblate spheroidal exclusion envelope** flatten along the direction of motion:

- At low $\|\mathbf{w}\|$, the oblate spheroidal exclusion envelope is nearly spherical.
- As $\|\mathbf{w}\| \to c_\star$, that envelope contracts along $\hat{\mathbf{w}}$ while maintaining transverse dimensions, yielding semiaxes $(R_\perp, R_\perp, R_\parallel)$ and $R_\parallel < R_\perp$.
- This geometric dilation changes internal path lengths and curvature, lowering ω.

Geometry terminology follows Braid Envelope Geometry: the envelope shape ratio is $\xi = R_\parallel / R_\perp$. The derived clock-time factor is not defined to be ξ; it is the extracted clock observable $\omega_{\text{clk}}/\omega_0 = d\tau/dt_{\text{eff}}$ after an effective observer chart is declared. In the homogeneous Lorentz-closure target, the theory must derive $\omega_{\text{clk}}/\omega_0 \to \xi \to 1/\gamma_\star$.

Kinematic hypothesis:

$$c_\perp = c_\star \sqrt{1 - \frac{\|\mathbf{w}\|^2}{c_\star^2}}, \qquad \omega(\mathbf{w}, n = 1) \approx \omega_0 \frac{c_\perp}{c_\star} \quad \Rightarrow \quad \left.\frac{d\tau}{dt_{\text{eff}}}\right|_{\text{kin}} \approx \sqrt{1 - \frac{\|\mathbf{w}\|^2}{c_\star^2}}$$

in the regime where the clock's motion does not significantly disturb the local Noether sea. For SI comparison in the weak homogeneous comparison, the observer branch sets $c_\star$ to the measured low-gradient clock/signal speed $c_0 = c_{\text{eff}}(\infty)$; this is a declared branch status, not an independent replacement for the primitive wake speed c_f.

Muon Lifetime Benchmark

Cosmic-ray muons supply a compact observer-level benchmark for the moving-clock row. In the standard account, muons formed high in the atmosphere have a rest-frame mean lifetime near $2.2\,\mu\text{s}$ and travel at a large fraction of c_0. Without time dilation, a particle moving near c_0 for only a few microseconds would cross less than a kilometer before the exponential survival law suppresses the population. Yet high-altitude and sea-level counts, such as the Frisch-Smith Mount Washington comparison, retain far more muons than the undilated lifetime permits.

The benchmark is a clock-law test, not a new substrate-time claim. In the weak homogeneous observer branch, let N_{high} be the counted muon rate at the high detector, N_{low} the counted rate at the lower detector, Δh the height separation, $\tau_{\mu,0}$ the rest-lifetime comparison value, and $\|\mathbf{w}_\mu\|$ the muon drift speed through the local Noether sea. The observer-level survival target is

$$N_{\text{low}} \approx N_{\text{high}} \exp\left[-\frac{\Delta h / \|\mathbf{w}_\mu\|}{\gamma_\mu \tau_{\mu,0}}\right], \qquad \gamma_\mu = \frac{1}{\sqrt{1 - \|\mathbf{w}_\mu\|^2 / c_0^2}}.$$

The same event can be described in the muon's effective rest chart as length contraction of the atmospheric path. In $\mathbb{AAA}$ both descriptions are downstream exports of one moving-assembly response: the external observer sees a slowed internal reaction clock, while the muon-channel description compresses the traversed distance. The native burden is to derive the same γ_μ from the assembly and Noether sea record that also supports clocks, rulers, photon synchronization, and bounded preferred-frame leakage.

Gravitational Effect (Medium Dependence)

Massive assemblies polarize and densify the surrounding Noether sea. A clock deeper in this polarized region experiences:

1. **Higher local Noether density $n(\mathbf{X}, T)$ (equivalently higher ρ_{NS}):**
   Interaction delays with the Noether sea (and between internal architrinos through the Noether sea) increase. This raises the **Noether sea delay factor** χ_{sea} for internal processes.

2. **Effective field speed reduction $c_{\text{eff}}(\mathbf{X}, T) < c_f$:**

- The propagation of wake influences is slowed in dense regions (more frequent encounters with Noether braids).
- From the clock's perspective, each internal wake contribution is delayed in the declared clock map.

3. **Tidal distortion of Noether braid geometry:**
   Gradients in n and the effective potential Φ_{eff} compress the braid differently along radial vs tangential directions. This modifies binary radii and thus frequencies.

Gravitational hypothesis:
To first order in the Newtonian potential $\Phi_N(\mathbf{X},T)$,

$$\omega(\Phi_N) \approx \omega_0 \left(1 + \frac{\Phi_N}{c_0^2}\right) \quad \Rightarrow \quad \left.\frac{d\tau}{dt_{\text{eff}}}\right|_{\text{grav}} \approx 1 + \frac{\Phi_N}{c_0^2}$$

with the sign convention chosen so that $\Phi_N < 0$ (deeper potential) yields **slower** clocks ($d\tau/dt_{\text{eff}} < 1$), consistent with GR.

Finite-Height Clock Benchmark

Modern optical-clock comparisons turn gravitational time dilation into a finite-sample constraint, not only a satellite-scale or tower-scale effect. Near Earth's surface, two static clock elements separated by height L should show

$$\frac{\Delta\nu}{\nu} \approx \frac{\Delta\Phi_N}{c_0^2} \approx \frac{gL}{c_0^2}$$

Thus $L = 1\,\text{mm}$ corresponds to $\Delta\nu/\nu \approx 1.1 \times 10^{-19}$, while $L = 33\,\text{cm}$ corresponds to $\Delta\nu/\nu \approx 3.6 \times 10^{-17}$. These numbers are direct weak-field acceptance tests for the extracted clock map: the same Noether sea constitutive response that slows separated clocks must also describe an extended clock sample whose lower and upper portions accumulate different derived clock phases.

For independent atoms this can be corrected pointwise, as in ordinary redshift compensation. For entangled or collective clock states, however, assigning the entire apparatus the derived clock time at the trap center is only an approximation. The $\mathbb{AAA}$ closure target is to derive the measured clock time from collective phase evolution across the sample, with the center-time prescription emerging only when the gradient-induced phase spread is below the experiment's uncertainty.

Guided/free-fall atom interferometers sharpen this target because one branch is held in the laboratory frame while the other follows a free-fall trajectory. After subtracting controlled laser, magnetic, and preparation phases, the branch comparison should expose a cubic-time phase coefficient:

$$\Delta\phi_{\text{gf}}(T) = \widehat{\beta}_{T^3} T^3 + \Delta\phi_{\text{ctrl}}(T) + O(T^4)$$

This coefficient must be derived from the same weak-field clock and phase map that produces the finite-height redshift benchmark. A fit to $\widehat{\beta}_{T^3}$ cannot be allowed to use one effective potential record while the redshift, Shapiro-delay, lensing, PPN, or gravitational-wave-speed channels use another.

Quantum Clock-Interference Benchmark

Matter-wave interferometers separate two evidential levels. A branch phase shift induced by a gravitational potential can be retained as an effective-potential or gravitational Aharonov-Bohm comparison; by itself it is a phase recovery target, not proof that a portable clock record accumulated different derived times along the branches. Neutron COW-style phase experiments therefore belong on the phase-only side unless the internal degree of freedom itself functions as a clock.

The stronger benchmark appears when an internal degree of freedom is prepared as a clock and remains correlated with the path history. Let the two branch histories γ_1 and γ_2 export internal clock states $|\tau_1\rangle$ and $|\tau_2\rangle$ at recombination. The clock part of the visibility target is

$$\mathcal{V}_{\text{clk}} = |\langle\tau_1|\tau_2\rangle|, \qquad \mathcal{D}_{\text{clk}} = \sqrt{1 - \mathcal{V}_{\text{clk}}^2}.$$

The interference loss is then a record-formation question: visibility falls only to the extent that the internal clock states become distinguishable enough to supply which-path information. In $\mathbb{AAA}$, this does not promote branch-dependent time to substrate ontology. It says that a Noether braid clock can export branch-dependent clock records, and that the same clock map that recovers $d\tau/dt_{\text{eff}}$ in homogeneous moving-clock and weak-field limits must also predict the internal-state overlap for neutron, atom, or optical-ion clock interferometers.

Combined Dilation

In a region with potential $\Phi_N(\mathbf{X},T)$ and clock drift $\mathbf{w}$ relative to the Noether sea, we conjecture the observer-chart comparison

$$\frac{d\tau}{dt_{\text{eff}}} = \frac{\omega(\mathbf{w},\Phi_N,n)}{\omega_0} \approx \sqrt{1 + \frac{2\Phi_N}{c_0^2} - \frac{\|\mathbf{w}\|^2}{c_0^2}}$$

in the weak-field, low-velocity observer limit, with higher-order corrections ($\|\mathbf{w}\|^4/c_0^4$, Φ_N^2/c_0^4, cross-terms) determined by the detailed Noether braid response. Primitive simulations may still use c_f inside the root equation; the PPN comparison uses the dressed asymptotic speed c_0.

Outside that limit, the native clock map F will in general deviate from the GR expression and define the theory's distinctive strong-field / high-velocity predictions.

Effective Energy-Momentum Closure Test

In the same weak-field regime where the clock law is expected to be Lorentz-like, the center-of-mass kinematics should satisfy the effective mass-shell closure

$$E_{\mathrm{CM}}^2 = p_{\mathrm{CM}}^2 c_{\mathrm{eff}}^2 + M_0^2 c_{\mathrm{eff}}^4$$

with $d\tau/dt_{\mathrm{eff}} = \gamma_\star^{-1}$ and

$$E_{\mathrm{CM}} = \gamma_\star M_0 c_{\mathrm{eff}}^2, \qquad p_{\mathrm{CM}} = \gamma_\star M_0 v.$$

Here $\gamma_\star$ is the kinematic Lorentz-response factor for the declared speed channel. It is distinct from the scalar PPN spatial-compliance parameter γ_{eff} and from the index-bearing spatial metric $\gamma_{\mathrm{eff}}^{ij}$.
This is a cross-check on the emergent clock model, not an independent axiom at the architrino substrate level.
For definitions and interpretation, see Effective Energy-Momentum Closure.

Strong-Field / Horizon Alignment Note

For strong-field interpretation, use the canonical event-horizon alignment condition from singularity-resolution.
In this chapter, Planck-scale references inherit that same alignment definition.

Clock Model and Equations of Motion

To close the derivation gap, fix an explicit clock model and an explicit observable-extraction map.

Concrete A1 Clock State

Use one A1 record with six constituent architrinos grouped into three persistently indexed neutral binaries:

$$\mathcal{A} = \{1_+, 1_-, 2_+, 2_-, 3_+, 3_-\}$$

with intrinsic polarities $q_a = \pm\epsilon$, $\epsilon = |e|/6$, and trajectories $\mathbf{X}_a(T)$. No per-constituent inertial mass is assigned at the substrate level.

Define pair-separation vectors

$$\mathbf{r}_a = \mathbf{X}_{a+} - \mathbf{X}_{a-}, \qquad a \in \{1,2,3\}$$

with radii $R_a = \|\mathbf{r}_a\|$. The three radii are independently assignable and do not order or relabel the binaries.

For this state to carry the A1 label, its three binary axes must also be mutually orthogonal at the Family-A near-rest endpoint and converge toward the group-translation direction along the prescribed flattening coordinate λ_A. The frequencies f_a remain independently assignable, and the axial half-separations h_a, transverse orbit radii ρ_a, phases ϕ_a, and circulation rows remain explicit binary coordinates. This prescribed chart does not establish that the clock is retained or stable under EOM-solver evolution; failure to preserve the declared coordinate relations on the same evolved record would falsify the A1 clock assignment.

Microscopic Evolution Equation (Regularized)

For each $a \in \mathcal{A}$ evolve by the acceleration-first substrate law

$$\frac{d^2\mathbf{X}_a}{dT^2}(T) = \sum_{b\in\mathcal{A}} \kappa\, \sigma_{ab} |q_a q_b| \int_{T-h}^{T} dT_0\, \frac{\hat{\mathbf{r}}_{ab}(T;T_0)}{r_{ab}^2(T;T_0) + \epsilon_c^2}\, \delta_\eta\big(r_{ab}(T;T_0) - c_f(T-T_0)\big)$$

$$r_{ab}(T;T_0) = \|\mathbf{X}_a(T) - \mathbf{X}_b(T_0)\|, \qquad \hat{\mathbf{r}}_{ab} = \frac{\mathbf{X}_a(T) - \mathbf{X}_b(T_0)}{r_{ab}(T;T_0)}$$

This is the dual-mollified finite-memory certification form used in the dynamical chapters. The memory depth $h < \infty$ bounds the retained causal history, $\eta > 0$ thickens the causal wake surface, and $\epsilon_c > 0$ caps the near-collision inverse-square amplitude. Exploratory scans may use a simpler δ_η causal-surface mollifier only when they label the run as a non-certification approximation.

Clock Observable and Clock Map

Declare $a_{\mathrm{clk}} \in \{1,2,3\}$ as the clock channel on the source record. Let $\mathbf{e}_1, \mathbf{e}_2$ be an orthonormal basis of the mean orbital plane of $\mathbf{r}_{a_{\mathrm{clk}}}$, and define phase

$$\theta_{\mathrm{clk}}(T) = \operatorname{atan2}\big(\mathbf{r}_{a_{\mathrm{clk}}}\cdot\mathbf{e}_2, \mathbf{r}_{a_{\mathrm{clk}}}\cdot\mathbf{e}_1\big)$$

On a window $[T_1, T_2]$, define measured frequency

$$\omega_{\mathrm{clk}} = \frac{\theta_{\mathrm{clk}}(T_2) - \theta_{\mathrm{clk}}(T_1)}{T_2 - T_1}$$

For the reference run $(v = 0, \Phi_N = 0)$, set $\omega_0 = \omega_{\mathrm{clk}}^{\mathrm{ref}}$ and define

$$\frac{d\tau}{dT} \equiv \frac{\omega_{\mathrm{clk}}}{\omega_0}$$

This native observable is the benchmark preserved by the clock projector in Braid Envelope Geometry. For a branch record $\mathcal{B}_{\mathbf{X}j}^{(T_0)}$, the clock-facing projection keeps only the entries that can change the extracted phase or cadence:

$$\Pi_{\mathrm{clock}}\mathcal{B}_{\mathbf{X}j}^{(T_0)} = \left(\delta\theta_{\mathrm{clk}}^{(j)},\, \delta\omega_{\mathrm{clk}}^{(j)},\, \delta\chi_{\mathrm{sea}}^{(\ell,j)},\, J_{\mathbf{X}j},\, \Lambda_j,\, \mathcal{L}_j^{\mathrm{wake}}\big|_{\mathrm{phase}}\right)$$

Thus a boundary contribution may affect clock coupling only by changing the same phase increment, measured frequency, Noether sea delay factor, or phase-retained wake ledger used to compute $\omega_{\mathrm{clk}}/\omega_0$. A separate clock fit that bypasses this projection would split the clock benchmark from the assembly/Noether sea interface diagnostic.

Controlled Perturbation Family

Run the same A1 clock record under controlled backgrounds:

1. Uniform center-of-mass drift speed $v = \|\mathbf{V}_{\mathrm{CM}}\|$ through homogeneous medium.
2. Weak static potential background $\Phi_N(\mathbf{X}, T)$ (or $U \equiv -\Phi_N > 0$).
3. Weak-field regime constraints: $v^2/c_\star^2 \ll 1$ and $|U|/c_0^2 \ll 1$.

Use $c_\star = c_f$ for primitive kernel-only scans and $c_\star = c_0$ for observer-level PPN coefficient fits. This keeps the root-solver speed and the clock-comparison speed explicit instead of silently identifying them.

For each run j, record

$$(U_j,\ v_j,\ \omega_j)\,, \qquad y_j \equiv \frac{\omega_j}{\omega_0} - 1$$

Derivation Interface and Coefficient Map

This chapter keeps only the symbolic/numeric coefficient interface needed to bridge clock microdynamics to PPN observables.

Perturbative Expansion (Weak-field, Low-velocity)

For the coefficient map in this section, observer-level PPN fits use the low-gradient comparison speed $c_\star = c_0$; primitive kernel-only scans must state separately when they keep $c_\star = c_f$.

Linearize each trajectory as $\mathbf{X}_a(T) = \mathbf{X}_a^{(0)}(T) + \delta\mathbf{X}_a(T)$ around the periodic rest solution — conditional on a certified rest attractor supplying $\mathbf{X}_a^{(0)}$, which the retention disclaimer above records as not yet established — and expand the extracted clock ratio in

$$\epsilon_U \equiv U/c_0^2, \qquad \epsilon_v \equiv v^2/c_\star^2$$

Use the regression model

$$\frac{\omega}{\omega_0} = 1 - A_U\,\epsilon_U - A_v\,\epsilon_v + C_2\,\epsilon_U^2 + C_{Uv}\,\epsilon_U\epsilon_v + C_{v4}\,\epsilon_v^2 + \mathcal{O}(\epsilon^3)$$

Coefficient extraction from simulation ensemble $\{(U_j, v_j, \omega_j)\}_{j=1}^N$:

$$\mathbf{y} = X\mathbf{c} + \boldsymbol{\varepsilon}, \qquad \hat{\mathbf{c}} = (X^\top W X)^{-1} X^\top W \mathbf{y}$$

with

$$\mathbf{c} = (A_U, A_v, C_2, C_{Uv}, C_{v4})^\top, \quad y_j = \frac{\omega_j}{\omega_0} - 1$$

and design row

$$X_j = \left(-\epsilon_{U,j},\, -\epsilon_{v,j},\, \epsilon_{U,j}^2,\, \epsilon_{U,j}\epsilon_{v,j},\, \epsilon_{v,j}^2\right)$$

Estimated covariance:

$$\mathrm{Cov}(\hat{\mathbf{c}}) = \hat{s}^2 (X^\top W X)^{-1}, \qquad \hat{s}^2 = \frac{\sum_j w_j (y_j - (X\hat{\mathbf{c}})_j)^2}{N - 5}$$

Coefficient Targets and PPN Map

In the GR-matching weak-field observer limit, first-order targets are

$$A_U^\star = 1, \qquad A_v^\star = \frac{1}{2}$$

For the static branch ($v = 0$),

$$\frac{\omega}{\omega_0} = 1 - \frac{U}{c_0^2} + C_2\frac{U^2}{c_0^4} + \cdots$$

and the PPN map used in PPN Parameters is

$$\beta_{\text{eff}} = \frac{1 + 2C_2}{2}$$

So the GR target $\beta_{\text{eff}} = 1$ implies

$$C_2^\star = \frac{1}{2}$$

The mixed coefficient C_{Uv} is treated as a leakage diagnostic at this order.

Execution protocols, benchmark catalogs, and numeric pass/fail thresholds are routed through:

1. Validation Protocols
2. Simulation Run Protocols
3. Constraint Ledger
4. Closure Scorecard

Failure Conditions and Red Flags

This program fails, and the emergent-metric project is likely untenable, if any of the following hold:

1. **Incorrect velocity dependence:**

- If $T_q(\mathbf{w})$ cannot be made to fit $\propto \gamma_\star(\mathbf{w})$ without fine-tuning internal clock geometry or Noether sea parameters.

2. **Wrong sign or magnitude of gravitational dilation:**

- Clocks deeper in a potential must tick slower. Any prediction of faster ticks, or gross magnitude mismatch, is fatal.

3. **Directional anisotropy:**

- If $T_q(\mathbf{w})$ depends measurably on direction in the absolute frame, violating isotropy bounds ($< 10^{-16}$ sidereal modulation), the theory contradicts precision Lorentz tests.

4. **Clock-dependence:**

- If different reasonable clock designs (different internal assemblies) yield different $d\tau/dt_{\text{eff}}$ at the same (v, Φ_N) beyond experimental bounds, the emergent Equivalence Principle fails.

5. **Parameter bloat:**

- If matching these effects requires introducing many independent medium parameters (n profiles, ad hoc transport coefficients), the theory's naturalness score collapses; see Parameter Ledger.

Chapter target:
A concrete definition of **how** to compute $\omega(\mathbf{w}, \Phi_{\text{eff}}, n)$ for a Noether braid clock, and a clear native expression for $d\tau/dT$ plus its observer-chart projection $d\tau/dt_{\text{eff}}$ in terms of those quantities.

Closure Program Interface (clock-to-PPN bridge)

This chapter supplies the fitted coefficient bridge between microscopic clock dynamics and PPN observables.

The clock-to-PPN closure checklist is:

1. Define a reference clock assembly and extraction window for ω_0.
2. Run controlled perturbations over (U_j, v_j) in the weak-field, low-velocity regime.
3. Fit $(A_U, A_v, C_2, C_{Uv}, C_{v4})$ from the extracted clock ratios.

4. Forward $\hat{\beta}_{\text{eff}}$ and the leakage coefficient $\hat{C}_{Uv}$ to PPN Parameters.
5. Record pass/fail status in Closure Scorecard against Constraint Ledger bounds.

Given extracted coefficients

$$\hat{\mathbf{c}} = (\hat{A}_U, \hat{A}_v, \hat{C}_2, \hat{C}_{Uv}, \hat{C}_{v4})$$

map to

$$\hat{\beta}_{\text{eff}} = \frac{1 + 2\hat{C}_2}{2}$$

and forward to the PPN decision vector in spacetime/ppn-parameters.md.

A compact closure statistic is:

$$\chi^2_{\text{closure}} = (\hat{\mathbf{q}} - \mathbf{q}_\star)^\top \Sigma_q^{-1} (\hat{\mathbf{q}} - \mathbf{q}_\star)$$

with

$$\hat{\mathbf{q}} = (\hat{A}_U, \hat{A}_v, \hat{\beta}_{\text{eff}}, \hat{C}_{Uv}), \qquad \mathbf{q}_\star = (1, \tfrac{1}{2}, 1, 0)$$

Low χ^2_{closure} with no preferred-direction leakage is the acceptance condition for the clock-law sector.

Lorentz Kinematics

This chapter is the focused program statement for deriving operational Lorentz behavior from delayed substrate dynamics. The substrate has absolute time, a Euclidean void, and finite wake speed. Physical Observers nevertheless recover Lorentz-like clocks, rulers, and signal timing in tested regimes. The purpose of this chapter is to make that required compensation law explicit, distinguish the closure target from any already-proved result, and organize the derivation path from microdynamics to measurable clock-and-ruler behavior.

The opening abstract states the target; the later sections move through the governing delayed dynamics, the anisotropy mechanism, and the conditions under which assembly-built observers could recover standard Lorentz kinematics.

The reader should keep four moving pieces distinct. The substrate has a preferred rest frame. A moving assembly can deform and retune. Physical Observers synchronize clocks and rulers using assemblies and signals. Precision experiments see only the exported observer record. Lorentz recovery succeeds only if the same retained branch hides the first piece from the fourth by controlling the middle two.

For the theory-bridge version that maps special-relativistic terms directly to the deformable Noether braid story, see the special-relativity bridge. For the reader-facing synthesis of the branch-quantized Lorentz milestone, see Return-Cycle Lorentz Quantization. For the interactive geometry surface, open A1 Lorentz Geometry App.

Coordinate Layers

This chapter uses two coordinate layers, and they must not be collapsed. Native substrate equations use the absolute frame: T is absolute time, $\mathbf{X} = (X^1, X^2, X^3)$ is position in the Euclidean void, and worldlines are written as $\mathbf{X}_i(T)$ with native velocity $\mathbf{V}_i = d\mathbf{X}_i/dT$. Causal roots, wake intersections, branch histories, and assembly trajectories are first stated in this layer.

The Lorentz or GR-comparison layer uses the effective observer chart. Its coordinates are t_{eff} and x^i_{eff}, with metric rows such as $g^{\text{eff}}_{\mu\nu}$. These coordinates are not a second substrate and not hidden names for T and $\mathbf{X}$. They are the chart reconstructed by Physical Observers from physical clocks, rulers, signal timing, Noether sea state, and retained records. Proper time τ is a derived clock readout in this observer layer, so $d\tau/dt_{\text{eff}}$ is an observer-coordinate clock-rate comparison, not a derivative with respect to absolute time.

The bridge between layers is therefore a constitutive closure map:

$$(t_{\text{eff}}, x^i_{\text{eff}}) = \chi_{\text{eff}}(T, \mathbf{X}, \mathcal{N}_{\text{sea}}, \text{observer record}).$$

Unless a local derivation supplies the needed row, χ_{eff} remains an obligation. A Lorentz formula counts in this chapter only when the same retained branch record supplies the map from absolute substrate quantities to effective observer records and keeps preferred-frame leakage inside the declared bounds. Bare symbols such as t, $\mathbf{x}$, dt, and dx^i are therefore avoided as working notation because they hide which side of the map is being used.

Abstract

This document develops a first-principles program for deriving effective Lorentz kinematics inside $\mathbb{AAA}$ from delayed architrino dynamics in a Euclidean void with absolute time. The central claim is not postulated covariance, but dynamical compensation: moving assemblies deform and

retune their internal frequencies so that assembly-built observers recover Lorentz-consistent clock and ruler behavior. The objective is an exact or asymptotically controlled derivation of

$$L_{\parallel}(v) = \frac{L_0}{\gamma_\star(v)} \qquad T(v) = \gamma_\star(v)\,T_0 \qquad \gamma_\star(v) = \frac{1}{\sqrt{1 - v^2/c_\star^2}}$$

with bounded preferred-frame leakage in measurable observables.

This is an exact-substrate-asymmetry to bounded-emergent-symmetry theorem target. Absolute time, the Euclidean void, and finite c_f are not observer-level Lorentz symmetry. The substrate symmetry group is $E(3) \times \mathbb{R}_T$, not a boost-invariant Lorentz or Poincare group, so Lorentz invariance cannot be counted as a substrate-exact invariant. It is admissible only if the source-to-effective map suppresses every observer-accessible preferred-frame current below the declared ϵ_{LV} bounds while preserving the clock, ruler, and photon-channel successes of special relativity.

Stated plainly, the chapter asks how an asymmetric substrate can export a symmetric measurement world. The answer cannot be “because coordinates say so”; it has to come from assembly deformation, clock retuning, synchronization, and a shared Noether sea dressing map.

Here ϵ_{LV} is a residual budget, not one binary tolerance. It contains distinct rows for Michelson-Morley two-way optical isotropy, Kennedy-Thorndike boost dependence, Ives-Stilwell clock-dilation behavior, slow-clock-transport synchronization and closed transported-clock loops, Hughes-Drever and clock-comparison matter-sector isotropy, sidereal modulation, closed-loop Sagnac response, photon-sector dispersion/birefringence/time-of-flight leakage, weak-field preferred-frame terms, and gravitational-wave-versus-photon speed matching. Each row must declare its expansion order in the appropriate drift parameter, such as $\beta_\oplus \equiv v_\oplus/c_{\mathrm{eff}}$ for terrestrial null tests, its validity regime, and its experimental tolerance before Lorentz recovery can be counted as bounded.

The common-mode requirement is therefore multi-sector. Matter-sector clocks, photon-channel propagation, and the effective gravitational channel cannot be tuned independently. A branch that nulls Michelson-Morley-type two-way optical anisotropy but leaves orientation-dependent clock energy levels, sidereal leakage, photon birefringence, or a separated effective gravitational-wave speed is not a Lorentz recovery branch.

This makes Lorentz recovery the prototype invariant-provenance problem. The invariant interval is not accepted as primitive substrate geometry; it is the observer-level invariant to be exported by one retained branch record. The derivation must say which substrate quantities are exact, which observer quantities are emergent, and which residual currents remain as preferred-frame leakage diagnostics.

Speed convention: primitive delayed-root equations are solved with c_f. The declared speed $c_\star$ enters only after the channel has been named: set $c_\star = c_f$ for a primitive wake branch chart, $c_\star = c_{\mathrm{eff}}(\mathbf{X}, T)$ for Noether sea dressed clocks and rulers, and $c_\star = c_\gamma(\mathbf{X}, T)$ for photon synchronization. The low-gradient Lorentz limit may identify the measured channel speed with $c_0 = c_{\mathrm{eff}}(\infty)$ only after the dressing map is declared.

Notation guardrail: $\chi_{\mathrm{sea}} = c_f/c_{\mathrm{eff}}$ is the Noether sea delay factor, not the Lorentz clock-rate factor. The velocity-sector target is $d\tau/dt_{\mathrm{eff}} \to \sqrt{1-\beta_{\mathrm{eff}}^2}$ only after the clock projection f_τ is extracted from the same Noether sea and assembly record and projected into an effective observer chart. A derivation that writes $\chi_{\mathrm{sea}} \to \sqrt{1-\beta_{\mathrm{eff}}^2}$ has changed notation; the corpus-level target is the map from $(n, \chi_{\mathrm{sea}}, \Phi_{\mathrm{eff}}, \mathrm{assembly\ state})$ into f_τ with $R_{\tau v} \to 0$.

A stronger prediction is also available. The Lorentz formulas should not be imported as an independent observer-level rule and then copied onto assemblies. They should be recovered from the same causal-root progression that gives stable assemblies their discrete branch ledgers. In that sense the Lorentz factor is a closure target for the quantum-facing branch structure of the dynamics: the root ledger must generate the contraction, clock-retuning, and residual-leakage coefficients rather than merely coexist with them.

Problem Statement

Kinematic closure target

In $\mathbb{AAA}$, the substrate ontology is:

1. Euclidean 3-space represented by a chosen absolute-frame coordinate scaffold.
2. Global absolute time T.
3. Finite propagation speed c_f for potential transfer through the Noether sea.

To match modern precision constraints, operational observers made from bound assemblies must infer effective Lorentz kinematics even though the substrate itself is not Minkowskian at the fundamental level. We call this required dynamical compensation the Lorentzian conspiracy.

Michelson-Morley-type null experiments make this a quantitative acceptance condition, not a philosophical preference. The framework may keep a Euclidean-void rest frame only if the two-way signal residual later written as $\Delta_{\mathrm{tw}}(\beta_\star, \theta)$ is generated by the same branch record that retunes material arms and clocks, and remains $O(\epsilon_{\mathrm{LV}})$ across the tested orientations. A cancellation achieved by separately fitting photon speed, clock rate, and ruler length would be a fit, not Lorentz closure.

The closure target is two-way operational isotropy, not one-way substrate isotropy. A primitive photon-channel speed may remain anisotropic relative to the absolute frame, because one-way speed is inseparable from clock synchronization for embedded observers. The required theorem is that the assembly-clock synchronization map absorbs the residual one-way anisotropy while the measurable round-trip diagnostic $\Delta_{\rm tw}$ and the boost-dependent and clock-isotropy rows remain below their declared leakage bounds.

This makes synchronization reabsorption a dynamical export, not a convention chosen after the fact. Let $\mathcal{S}_{\rm asm}$ denote the synchronization convention physically realized by assembly clocks, rulers, and signal channels. A successful Lorentz export must drive $\mathcal{S}_{\rm asm}$ to operational Einstein synchrony inside the tested regime while any Reichenbach-style one-way freedom remains inaccessible to embedded observers. If an apparatus can extract the absolute-frame anisotropy by comparing assembly clocks, signal timing, or calibration loops, the preferred-frame leakage wall has failed even if a two-way Michelson-Morley row is small.

The clock channel has to be written as its own substrate-to-observer map:

$$\frac{d\tau}{dt_{\rm eff}} = f_\tau(\beta_{\rm eff},\, n(\mathbf{X},T),\, \chi_{\rm sea}(\mathbf{X},T),\, \Phi_{\rm eff}(\mathbf{X},T),\, \text{assembly state})\,, \qquad \beta_{\rm eff} \equiv \frac{v}{c_{\rm eff}}.$$

The velocity-sector residual is

$$R_{\tau v}(\beta_{\rm eff}) \equiv \left.\frac{d\tau}{dt_{\rm eff}}\right|_{\nabla n=0,\, \nabla\Phi_{\rm eff}=0} - \sqrt{1-\beta_{\rm eff}^2},$$

and must be bounded by time-dilation tests such as Ives-Stilwell and storage-ring clock comparisons. The weak-field potential-sector residual is

$$R_{\tau\Phi} \equiv \left.\frac{d\tau}{dt_{\rm eff}}\right|_{\beta_{\rm eff}=0} - \left(1+\frac{\Phi_{\rm eff}}{c_{\rm eff}^2}+O\left(\frac{\Phi_{\rm eff}^2}{c_{\rm eff}^4}\right)\right),$$

with the $\Phi_{\rm eff}$ sign convention declared, and must recover gravitational-redshift and PPN clock/curvature constraints. Equivalence-principle recovery requires $R_{\tau v}$ and $R_{\tau\Phi}$ to come from the same Noether sea response and assembly-clock map.

The absolute velocity used by the substrate solver cannot remain an observer-accessible quantity. In the accepted export, any dependence on absolute v must be absorbed into nonseparable combinations of assembly-clock synchronization, ruler response, and signal-channel calibration, so Physical Observers recover Lorentz-invariant records rather than a direct preferred-frame speed meter.

Mathematical objective

Given a translating bound assembly, first for one binary and then for the prescribed A1 chart, derive:

Here `A1` means one complete Family-A braid with persistent binary indices $a \in \{1,2,3\}$, independently assignable positive radii R_a and frequencies f_a, mutually orthogonal binary axes at $\lambda_A = 0$, and axes converging toward the group-translation direction as $\lambda_A \to 1$. Axial half-separations, transverse orbit radii, phases, and circulation remain explicit binary coordinates. The label supplies no Lorentz law, retained branch, hierarchy, particle assignment, or stability result; those are the theorem targets below, falsified if same-record evolution fails the coordinate or observer-residual gates.

1. The velocity-dependent equilibrium shape tensor $Q(v)$ and its anisotropy.
2. The velocity-dependent internal period $T(v)$.
3. Conditions under which $(Q(v), T(v))$ produce effective Lorentz ruler and clock laws.
4. Residual non-Lorentz terms and their scaling.

Governing Microdynamics

Causal path-history interaction form

For architrino labels $i, j \in \{1, \ldots, N\}$ with positions $\mathbf{X}_i(T)$, write the reduced branch equation in acceleration-first form:

$$\frac{d^2\mathbf{X}_i}{dT^2} = \sum_{j\neq i} \mathbf{A}_{i\leftarrow j}(\mathbf{X}_i(T), \mathbf{X}_j(T-\Delta_{ij}(T)), \mathbf{V}_j(T-\Delta_{ij}(T))) + \mathbf{A}_i^{\rm self}(T).$$

with causal delay

$$\Delta_{ij}(T) = \frac{\|\mathbf{X}_i(T) - \mathbf{X}_j(T-\Delta_{ij}(T))\|}{c_f}$$

The self-hit acceleration contribution $\mathbf{A}_i^{\rm self}$ captures history-dependent wake re-intersections and is the non-Markovian origin of branch-sensitive corrections.

No architrino-specific inertial weights enter this substrate equation. When quadratic energy or momentum bookkeeping is needed below, the single universal conversion constant $\mu_{\rm arch}$ may be used; it does not alter the acceleration law or assign primitive mass to an architrino.

Co-moving decomposition

For an assembly center trajectory $\mathbf{X}_c(T)$ with mean velocity $\mathbf{V}$, write

$$\mathbf{X}_i(T) = \mathbf{X}_c(T) + \mathbf{r}_i(T), \qquad \mathbf{X}_c(T) = \frac{1}{N}\sum_i \mathbf{X}_i(T), \qquad \sum_i \mathbf{r}_i(T) = \mathbf{0}.$$

The closure task is to solve for bounded relative motion $\mathbf{r}_i(T)$ under translation $\|\mathbf{V}\| < c_f$ and extract period and geometry renormalization.

Dimensionless drift-delay form and variational closure

Fix a rest-attractor length scale a_0 and period T_0, and define

$$\beta_f \equiv \frac{v}{c_f} \qquad s \equiv \frac{T}{T_0} \qquad \boldsymbol{\rho}_i(s) \equiv \frac{\mathbf{r}_i(T)}{a_0} \qquad \chi_{\mathrm{dd}} \equiv \frac{c_f T_0}{a_0}$$

Then delay closure in co-moving coordinates is

$$\hat{\tau}_{ij}(s) = \frac{1}{\chi_{\mathrm{dd}}}\left\|\boldsymbol{\rho}_i(s) - \boldsymbol{\rho}_j(s - \hat{\tau}_{ij}(s)) + \chi_{\mathrm{dd}}\beta_f\,\hat{\mathbf{e}}_{\|}\hat{\tau}_{ij}(s)\right\|$$

with $\hat{\tau}_{ij} \equiv \tau_{ij}/T_0$.
The dd subscript marks this as a local drift-delay scale, not the Noether sea delay factor χ_{sea} or the effective coordinate map χ_{eff}.

Let $\boldsymbol{\rho}^{\star}(s;\beta_f)$ be a $P(\beta_f)$-periodic translating attractor. Linearization gives a delay-Floquet system

$$\delta\dot{\mathbf{y}}(s) = A_0(s;\beta_f)\,\delta\mathbf{y}(s) + \sum_{n=1}^{N_d} A_n(s;\beta_f)\,\delta\mathbf{y}(s - \hat{\tau}_n^{\star})$$

where $\mathbf{y}$ stacks positions and velocities in relative coordinates. Kinematic closure requires:

1. Existence of $\boldsymbol{\rho}^{\star}(s;\beta_f)$ for $\beta_f \in [0, \beta_{\max})$.
2. Spectral stability of the monodromy operator (all nontrivial Floquet multipliers inside the unit disk).
3. Smooth coefficient maps for axis and period renormalization extracted from $\boldsymbol{\rho}^{\star}$.

Translating binary benchmark

The first hard Lorentz-closure calculation is the moving version of the declared reference rest two-body branch (certificate packet pending; see the closure-packet contract in Binary Dynamics). Let $\sigma \in \{+1, -1\}$ label the two opposite-polarity architrinos and choose the drift direction $\hat{\mathbf{e}}$. A translating binary branch has the substrate ansatz

$$\mathbf{X}_\sigma(T) = uT\,\hat{\mathbf{e}} + \sigma\,\boldsymbol{\rho}_u(\theta(T)), \qquad \theta(T + T_u) = \theta(T) + 2\pi$$

with $\boldsymbol{\rho}_u$ periodic on the retained branch chart. This is not a Lorentz boost of coordinates. It is a direct absolute-time branch ansatz inserted into the delayed root equation.

For a root emitted by constituent σ' and received by constituent σ, the delay $\tau > 0$ must solve

$$G_{\sigma\sigma'}(\tau;\theta,u) \equiv \|u\tau\,\hat{\mathbf{e}} + \sigma\,\boldsymbol{\rho}_u(\theta) - \sigma'\,\boldsymbol{\rho}_u(\theta - \Omega_u\tau)\| - c_f\tau = 0, \qquad \Omega_u \equiv \frac{2\pi}{T_u}$$

The branch Jacobian is

$$J_{\sigma\sigma'}(\tau;\theta,u) = 1 - \frac{(u\hat{\mathbf{e}} + \sigma'\Omega_u\boldsymbol{\rho}_u'(\theta - \Omega_u\tau))\cdot\hat{\mathbf{r}}_{\sigma\sigma'}}{c_f}$$

where $\hat{\mathbf{r}}_{\sigma\sigma'}$ is the unit vector from the transmitter emission point to the receiver-now point. This is structurally the same transmitter-side factor that appears in Lienard-Wiechert delay geometry. The analogy is useful only at the level of causal-root flux: the canonical Master EOM has the radial inverse-square line of action and transmitter-side acceleration weight $W^{\mathrm{acc}} = c_f/|D_t|$, but not the full electrodynamic velocity-field and acceleration-field terms. The Lorentz answer therefore cannot be imported from classical electrodynamics; it must be computed on this branch.

The leading/trailing asymmetry in this translating ledger is already visible in the pure drift part of the same Jacobian. For a uniformly moving transmitter with drift ratio $\beta_f = u/c_f$ and θ the angle between the drift direction and the transmitter-to-receiver line of action, the simple-root wake-density factor is

$$\mathcal{D}_{\mathrm{wake}}(\theta;\beta_f) = \frac{1}{1 - \beta_f\cos\theta}$$

before the internal orbital velocity, branch multiplicity, and finite-window energy rows are added. Thus the translating binary calculation is not asking whether anisotropy exists; it is asking whether the full deformed branch ledger converts this microscopic wake-density anisotropy into

Lorentzian contraction, clock dilation, and bounded residual leakage.

The primitive Lorentz test for this binary is the residual triple

$$\mathcal{R}_{\rm bin}(u) = \left(R_T^{\rm bin}(u), R_\xi^{\rm bin}(u), R_{\rm shape}^{\rm bin}(u)\right), \qquad \gamma_f(u) \equiv \left(1 - \frac{u^2}{c_f^2}\right)^{-1/2}$$

with

$$R_T^{\rm bin}(u) \equiv \frac{T_u}{T_0} - \gamma_f(u), \qquad R_\xi^{\rm bin}(u) \equiv \frac{L_\parallel(u)}{L_\perp(u)} - \frac{1}{\gamma_f(u)}$$

Here $L_\parallel$ and $L_\perp$ are extracted from the same periodic solution by projecting the relative orbit along and transverse to $\hat{\mathbf{e}}$. The shape residual measures the remaining branch-chart difference from the Lorentz-deformed rest solution,

$$R_{\rm shape}^{\rm bin}(u) \equiv \inf_\varphi \frac{\|\boldsymbol{\rho}_u(\theta) - \boldsymbol{\rho}_L(\theta+\varphi; u)\|_{\rm cyc}}{R_0}, \qquad \boldsymbol{\rho}_L(\theta; u) = R_0\left(\gamma_f^{-1}\cos\theta\,\hat{\mathbf{e}} + \sin\theta\,\hat{\mathbf{e}}_\perp\right)$$

in the planar orientation where the drift direction lies in the binary plane. A clean primitive result has $\mathcal{R}_{\rm bin} = 0$ or a controlled residual traceable to named branch-ledger features. A nonzero residual is not a rhetorical failure; it is the first foundation-level pressure on the Lorentz-closure program, because the binary is the first available internal clock and ruler.

Exact substrate symmetries and delay currents

At action level, use a causal path-history functional

$$S = \int dT \left[\sum_i \frac{1}{2}\mu_{\rm arch}\left\|\frac{d\mathbf{X}_i}{dT}\right\|^2 - \frac{1}{2}\sum_{i\neq j}\int_{\Sigma_{ij}} d^2\sigma\,\mathcal{L}_{\rm int}(\mathbf{X}_i(T), \mathbf{X}_j(T-\Delta))\right]$$

The exact substrate symmetry group is

$$G_{\rm fund} = E(3)\times\mathbb{R}_T$$

and the associated delayed-Noether proof target is that conserved totals close only after wake and medium channels are included:

$$\mathbf{P}_{\rm tot} = \sum_i \mu_{\rm arch}\frac{d\mathbf{X}_i}{dT} + \mathbf{P}_{\rm wake} \qquad E_{\rm tot} = \sum_i \frac{1}{2}\mu_{\rm arch}\left\|\frac{d\mathbf{X}_i}{dT}\right\|^2 + E_{\rm wake}.$$

These are universal-weight bookkeeping proxies for the delayed-Noether closure target, not primitive momentum or mass assignments. Only after the architrino-plus-wake-plus-medium ledger closes does an isolated translating assembly admit a co-moving reduction to a bounded periodic or quasi-periodic branch $\boldsymbol{\rho}^\star(s;\beta_f)$ with fixed mean drift extracted from the same record.

Emergent Kinematics from Delay Anisotropy

Directional delay asymmetry

For a primitive benchmark drifting binary with instantaneous separation vector $\mathbf{r} = r\,\hat{\mathbf{n}}$ and center drift $\mathbf{V} = v\,\hat{\mathbf{e}}_\parallel$, causal-delay closure satisfies

$$\Delta = \frac{\|\mathbf{r} + \mathbf{V}\Delta\|}{c_f}$$

This subsection is deliberately a c_f branch-chart calculation. For operational clock, ruler, or photon tests, repeat the same budget with the declared $c_\star$ after Noether sea dressing. With $\mu \equiv \hat{\mathbf{n}}\cdot\hat{\mathbf{e}}_\parallel$ and $\beta_f = v/c_f$, the two directional roots are

$$\tau_\pm(r,\mu;\beta_f) = \frac{r}{c_f}\,\frac{\sqrt{1-\beta_f^2(1-\mu^2)} \pm \beta_f\mu}{1-\beta_f^2}$$

Special orientations recover standard forms:

$$\mu = 1: \quad \tau_+ = \frac{r}{c_f - v} \qquad \tau_- = \frac{r}{c_f + v}$$

$$\mu = 0: \quad \tau_+ = \tau_- = \frac{r}{\sqrt{c_f^2 - v^2}}$$

The symmetric delay channel and associated causal-rate proxy are

$$\bar{\tau}(\mu;\beta_f) \equiv \frac{\tau_+ + \tau_-}{2} = \frac{r}{c_f}\,\frac{\sqrt{1-\beta_f^2(1-\mu^2)}}{1-\beta_f^2}$$

$$\nu(\mu;\beta_f) \equiv \frac{1}{\bar{\tau}(\mu;\beta_f)}$$

Since $\bar{\tau}$ depends on μ, interaction response is anisotropic and induces

$$K_\parallel(v) \neq K_\perp(v)$$

Weak-velocity expansion to $O(\beta_f^4)$

Direct expansion of the symmetric lag gives

$$\bar{\tau}(\mu;\beta_f) = \frac{r}{c_f}\left[1 + \frac{1+\mu^2}{2}\beta_f^2 + \frac{3+6\mu^2-\mu^4}{8}\beta_f^4 + O(\beta_f^6)\right]$$

and thus

$$\nu(\mu;\beta_f) = \frac{c_f}{r}\left[1 - \frac{1+\mu^2}{2}\beta_f^2 + \frac{-1-2\mu^2+3\mu^4}{8}\beta_f^4 + O(\beta_f^6)\right]$$

Two anchor limits are:

$$\mu = 1:\ \bar{\tau} = \frac{r}{c_f}\gamma_f^2,\ \nu = \frac{c_f}{r}(1-\beta_f^2) \qquad \mu = 0:\ \bar{\tau} = \frac{r}{c_f}\gamma_f,\ \nu = \frac{c_f}{r}\frac{1}{\gamma_f}$$

Closed-return derivation of the Lorentz axis ratio

The one-way roots above expose the preferred branch chart. They are not yet an observer-facing Lorentz law, because a physical clock or ruler is not made from a single one-way leg. A stable material branch is admitted only when the relevant causal wake returns to a compatible phase. The primitive Lorentz-geometry object is therefore a closed return cycle.

Use the declared channel speed $c_\star$ for the closure problem under consideration, with

$$\beta_\star \equiv \frac{v}{c_\star} \qquad \gamma_\star \equiv \frac{1}{\sqrt{1-\beta_\star^2}}$$

In a homogeneous Noether sea cell, take $R_\parallel$ to be the semiaxis along drift and $R_\perp$ to be a transverse semiaxis. A longitudinal return cycle has unequal forward and rear legs,

$$t_+ = \frac{R_\parallel}{c_\star - v} \qquad t_- = \frac{R_\parallel}{c_\star + v}$$

so its closed return time is

$$T_\parallel = t_+ + t_- = \frac{R_\parallel}{c_\star - v} + \frac{R_\parallel}{c_\star + v} = \frac{2R_\parallel c_\star}{c_\star^2 - v^2} = \frac{2R_\parallel}{c_\star}\gamma_\star^2$$

A transverse return cycle uses part of the causal budget to keep pace with the translated receiver. The remaining transverse closure speed is

$$c_\perp = c_\star\sqrt{1-\frac{v^2}{c_\star^2}} = \frac{c_\star}{\gamma_\star}$$

and therefore

$$T_\perp = \frac{2R_\perp}{c_\perp} = \frac{2R_\perp}{c_\star}\gamma_\star$$

The closure condition for a Lorentz-admissible branch is that the same material return cycle closes with one period in the longitudinal and transverse channels:

$$T_\parallel = T_\perp + O(\epsilon_{\mathrm{LV}} T_0)$$

In the zero-leakage homogeneous limit this gives

$$\frac{2R_\parallel}{c_\star}\gamma_\star^2 = \frac{2R_\perp}{c_\star}\gamma_\star$$

hence

$$\xi(v) \equiv \frac{R_\parallel(v)}{R_\perp(v)} = \frac{1}{\gamma_\star(v)}$$

This is the direct map from Lorentz kinematics to Noether braid geometry. The oblate spheroidal envelope for an admitted branch q can be written

$$\frac{x_{\perp,1}^2 + x_{\perp,2}^2}{R_{\perp,q}^2} + \frac{x_\parallel^2}{R_{\parallel,q}^2} = 1 \qquad R_{\parallel,q} = \frac{R_{\perp,q}}{\gamma_\star} + O(\epsilon_{\mathrm{LV}} R_{\perp,q})$$

Equivalently, the realized ruler factor is the inverse shape ratio:

$$\gamma_{\mathrm{rul}}^{(q)}(v) \equiv \frac{R_{\perp,q}(v)}{R_{\parallel,q}(v)} = \frac{1}{\xi_q(v)} = \gamma_\star(v) + O(\epsilon_{\mathrm{LV}})$$

The same closure has a useful selection form. Let a rest-frame separation at angle θ_0 to the drift direction deform by an unknown axial factor $g(\beta_\star)$:

$$R_\parallel = R_0 \cos\theta_0 \, g(\beta_\star), \qquad R_\perp = R_0 \sin\theta_0$$

For a closed return through a channel with speed $c_\star$, the orientation-sensitive bracket in the round-trip delay is proportional to

$$B(\theta_0) = c_\star^2 R_0^2 \left[g^2 \cos^2\theta_0 + (1-\beta_\star^2)\sin^2\theta_0\right]$$

An orientation-independent material clock requires this equality for every θ_0 simultaneously, so the coefficients of $\cos^2\theta_0$ and $\sin^2\theta_0$ must agree, hence

$$g(\beta_\star) = \sqrt{1-\beta_\star^2}$$

in the zero-leakage homogeneous limit. This selects the Lorentz contraction law as the unique axial deformation that removes matter-sector orientation leakage for this closed-return benchmark. It is still not a stability theorem: the delayed acceleration law must also show that the contracted branch is an attracting solution of the boosted delay dynamics.

The same equations give a direct geometry dictionary for the oblate spheroidal envelope. In the no-extra-scale channel, take $R_\perp = R_0$ and $R_\parallel = R_0/\gamma_\star$. Then

$$\xi \equiv \frac{R_\parallel}{R_\perp} = \frac{1}{\gamma_\star} = \sqrt{1-\beta_\star^2} \qquad \gamma_\star = \frac{R_\perp}{R_\parallel}$$

and therefore

$$\beta_\star = \sqrt{1-\xi^2} = \sqrt{1-\frac{R_\parallel^2}{R_\perp^2}}$$

Thus the velocity fraction is encoded as the eccentricity of the oblate spheroidal envelope, while $\gamma_\star$ is encoded as its transverse-to-longitudinal aspect ratio. This is only a statement about the shape channel: a separate scale channel λ may change the absolute size without changing the dimensionless ratios ξ, $\gamma_\star$, and $\beta_\star$.

The clock law belongs to the return-cycle period, not to the absolute size of the oblate spheroidal envelope. If a rest branch has period T_0, the observer-sector target is

$$T_q(v) = \gamma_\star(v) T_0 + O(\epsilon_{\mathrm{LV}} T_0)$$

For the simple return-cycle benchmark above, substituting $R_\parallel = R_\perp/\gamma_\star$ gives

$$T_\parallel = \frac{2R_\perp}{c_\star}\gamma_\star$$

so the period dilation is the same $\gamma_\star$ that appears as the inverse axis ratio. This remains true even when the oblate spheroidal envelope becomes very thin. As $\beta_\star \to 1$, the forward leg is

$$t_+ = \frac{R_\parallel}{c_\star - v} = \frac{R_\perp}{c_\star}\sqrt{\frac{1+\beta_\star}{1-\beta_\star}} \longrightarrow \infty$$

while the rear leg satisfies

$$t_- = \frac{R_\parallel}{c_\star + v} = \frac{R_\perp}{c_\star}\sqrt{\frac{1-\beta_\star}{1+\beta_\star}} \longrightarrow 0$$

The divergent clock factor is therefore not caused by a large object. It is caused by the vanishing forward catch-up margin $c_\star - v$ in the closed return cycle. The contraction of $R_\parallel$ and the divergence of $T_q(v)$ are two coupled readouts of the same closure condition.

In this precise theorem-target sense, Lorentz response is branch-indexed in the framework. The smooth function $\gamma_\star(v)$ remains the observer-level envelope, but a physical material branch can realize that envelope only through a discrete admissible closure class q. The quantized object is not the algebraic curve by itself; it is the branch-indexed realization

$$q \longmapsto \left(\xi_q(v), \gamma_{\mathrm{rul}}^{(q)}(v), \gamma_{\mathrm{clk}}^{(q)}(v), \mathcal{L}_{\mathrm{root}}^{(q)}(v)\right)$$

with admissibility requiring the same causal-root ledger to close the oblate spheroidal envelope geometry, clock period, and preferred-frame leakage bounds. Thus a continuous Lorentz formula would be recovered as the common envelope of discrete Noether braid return-cycle classes only after those branch-admissibility conditions close.

Confirmation status: the ruler law has no confirmation from evolved dynamics at any drift speed. The prescribed translating-family prediction — that the moving branch's shape ratio $\xi(u)/\xi(0)$ should approach $1/\gamma_f(u)$ — remains a closure target of the delayed acceleration law, not a measured result. The actual branch may deform internally, and confirmation requires evolving it directly under the master equation and measuring the relative-periodic envelope it settles to. Whether the contracted branch is an attracting solution of the moving delay dynamics is the same open question stated above; it is not answered here.

To keep this closure target testable, the branch should report a single Lorentz residual record rather than separate narrative successes. For a declared channel speed $c_\star$ and branch q, write

$$\mathcal{R}_{\mathrm{Lor},q}(\beta_\star) = \left(R_T^{(q)}, R_\xi^{(q)}, R_u^{(q)}, R_{E\mathbf{p}}^{(q)}, R_\gamma^{(q)}, \epsilon_{\mathrm{LV}}^{(q)}\right)$$

where

$$R_T^{(q)}(v) \equiv \frac{T_q(v)}{T_0} - \gamma_\star(v) \qquad R_\xi^{(q)}(v) \equiv \xi_q(v) - \frac{1}{\gamma_\star(v)}$$

For a one-dimensional velocity-composition test in the same declared channel,

$$R_u^{(q)} \equiv u_{\mathrm{eff}} - \frac{u' + v}{1 + u'v/c_\star^2}$$

For the effective mass-shell and photon-channel tests, use

$$R_{E\mathbf{p}}^{(q)} \equiv E_q^2 - \left(\|\mathbf{p}_q\|^2 c_\star^2 + m_q^2 c_\star^4\right) \qquad R_\gamma^{(q)} \equiv E_\gamma - c_\gamma \|\mathbf{p}_\gamma\|$$

Here m_q is the observer-sector inertial response assigned to the admitted branch, and $R_\gamma^{(q)}$ is evaluated only after the photon channel has been declared. The same causal-root ledger, medium dressing map, and branch state must feed all components. A branch that fits clock slowing with one ledger, ruler contraction with another, and photon propagation with an independent channel has not closed Lorentz behavior; it has only matched isolated formulas.

This derivation is stronger than assigning an oblate spheroidal envelope after the fact. The one-way longitudinal legs remain asymmetric; the Lorentz geometry appears only when the closed return cycle is allowed to choose the semiaxes that make longitudinal and transverse closure periods agree. In $\mathbb{AAA}$ terms, the envelope is the visible projection of a branch that has solved its return-cycle ledger.

Effective shape law

Fix a drift band $0 \le \beta_f \le \beta_{\max} < 1$, with $\beta_f = v/c_f$, and choose one admitted translating branch q. The primitive root ledger on that band is still solved at c_f; $\beta_\star = v/c_\star$ is introduced only for the declared primitive or dressed observer channel being tested.

Define the cycle-averaged shape tensor on the translating attractor:

$$Q_{ab}^{(q)}(v) \equiv \frac{1}{N_q}\left\langle \sum_{i=1}^{N_q} r_{i,a} r_{i,b} \right\rangle_{\mathrm{cyc},q}$$

This equal-weight geometric convention is fixed before closure. It prevents the extracted shape residual from changing when an observer-level inertial-response convention is later assigned to the admitted assembly branch.
Let $q_\parallel(v), q_{\perp,1}(v), q_{\perp,2}(v)$ be principal-frame eigenvalues of $Q^{(q)}(v)$, with principal axis chosen along drift for $q_\parallel$. Define extracted semiaxes

$$a_{\parallel,q}(v) \equiv \sqrt{q_\parallel(v)} \qquad a_{\perp,q}(v) \equiv \sqrt{\frac{q_{\perp,1}(v) + q_{\perp,2}(v)}{2}}$$

The moving-assembly contraction residual is

$$R_\xi^{(q)}(v) \equiv \frac{a_{\parallel,q}(v)}{a_{\perp,q}(v)} - \frac{1}{\gamma_\star(v)}$$

and the theorem target is the leakage bound

$$\left|R_\xi^{(q)}(v)\right| \le C_\parallel \epsilon_{\rm LV} \beta_\star^2$$

uniformly on the declared drift band. This is a moving-assembly extraction condition. Weak-field PPN tests can later falsify the dressed medium response, but they are not inputs to this semiaxis extraction.

Quadratic closure and coefficient constraints

On the attracting manifold, use principal-frame quadratic closure

$$U_{\rm eff} = \frac{1}{2}K_\parallel(v)\, r_\parallel^2 + \frac{1}{2}K_\perp(v)\left(r_{\perp,1}^2 + r_{\perp,2}^2\right)$$

Notation guardrail: in this chapter, $U_{\rm eff}$ denotes the cycle-averaged mechanical potential on the translating attractor; it is distinct from the positive weak-field PPN variables U and U_Φ used in spacetime/ppn-parameters.md.
For fixed action shell, semiaxes scale as $a_i \propto K_i^{-1/2}$, hence

$$\frac{a_\parallel}{a_\perp} = \sqrt{\frac{K_\perp}{K_\parallel}}$$

Write

$$\frac{K_\parallel}{K_0} = 1 + k_2\beta_f^2 + k_4\beta_f^4 + O(\beta_f^6) + \Delta_\parallel^{\rm LV}$$

$$\frac{K_\perp}{K_0} = 1 + \ell_2\beta_f^2 + \ell_4\beta_f^4 + O(\beta_f^6) + \Delta_\perp^{\rm LV}$$

with $|\Delta_i^{\rm LV}| \le C_i\epsilon_{\rm LV}$. Then

$$\frac{a_\parallel}{a_\perp} = 1 + \frac{\ell_2 - k_2}{2}\beta_f^2 + \left[\frac{\ell_4 - k_4}{2} + \frac{3k_2^2}{8} - \frac{k_2\ell_2}{4} - \frac{\ell_2^2}{8}\right]\beta_f^4 + O(\beta_f^6) + O(\epsilon_{\rm LV})$$

Matching to

$$\frac{1}{\gamma_f} = 1 - \frac{1}{2}\beta_f^2 - \frac{1}{8}\beta_f^4 + O(\beta_f^6)$$

imposes

$$\ell_2 - k_2 = -1$$

$$4(\ell_4 - k_4) + 3k_2^2 - 2k_2\ell_2 - \ell_2^2 = -1$$

Stiffness tensor from causal-wake surface integrals

To anchor coefficient matching in the microdynamics, define the pairwise causal-wake potential on a translating attractor $\boldsymbol{\rho}^\star(s;\beta_f)$:

$$\mathcal{U}_{ij}(T;\beta_f) \equiv \int_{\Sigma_{ij}^{\rm wake}(T)} \frac{\kappa\,\epsilon^2}{\|\mathbf{X}_i(T) - \mathbf{X}_j(T-\Delta)\|^2}\, W_{ij}(T,\sigma;\eta)\, d^2\sigma$$

where W_{ij} is the regularized causal kernel weight and $\eta > 0$ is the regularization scale.
Set

$$U_{\rm eff}(T;\beta_f) \equiv \sum_{i<j} \mathcal{U}_{ij}(T;\beta_f) \qquad K_{ab}(\beta_f) \equiv \left\langle \frac{\partial^2 U_{\rm eff}}{\partial r_a \partial r_b} \right\rangle_{\rm cyc}$$

with cycle average $\langle\cdot\rangle_{\rm cyc}$ taken on $\boldsymbol{\rho}^\star$.
Project to principal channels:

$$K_\parallel = \hat{e}_\parallel^a K_{ab} \hat{e}_\parallel^b \qquad K_\perp = \frac{1}{2}(\delta^{ab} - \hat{e}_\parallel^a \hat{e}_\parallel^b) K_{ab}$$

Dimensionless factorization exposes Category A coupling:

$$K_i(\beta_f) = \frac{\kappa\,\epsilon^2}{a_0^3}\,\mathcal{I}_i(\beta_f, \chi_{\rm dd}, \eta, \dots) \qquad i \in \{\parallel, \perp\}$$

Hence

$$k_2 = \frac{\partial^2_{\beta_f}\mathcal{I}_\parallel\big|_{\beta_f=0}}{2\,\mathcal{I}_\parallel(0)} \qquad \ell_2 = \frac{\partial^2_{\beta_f}\mathcal{I}_\perp\big|_{\beta_f=0}}{2\,\mathcal{I}_\perp(0)}$$

$$k_4 = \frac{\partial^4_{\beta_f}\mathcal{I}_\parallel\big|_{\beta_f=0}}{24\,\mathcal{I}_\parallel(0)} \qquad \ell_4 = \frac{\partial^4_{\beta_f}\mathcal{I}_\perp\big|_{\beta_f=0}}{24\,\mathcal{I}_\perp(0)}$$

Therefore the Lorentz-matching constraints in Quadratic Closure and Coefficient Constraints and Clock-Channel Expansion and Minimal Closure Solution become explicit derivative identities on $\mathcal{I}_\parallel, \mathcal{I}_\perp$ evaluated on the delay-Floquet attractor.

Period renormalization

Let $T_q(v)$ be the fundamental oscillation period of the assembly attractor in absolute time, extracted from the declared clock phase on the same branch ledger as the semiaxes. The clock retuning residual is

$$R_T^{(q)}(v) \equiv \frac{T_q(v)}{T_0} - \gamma_\star(v)$$

Operational proper-time behavior requires the theorem-target bound

$$\left|R_T^{(q)}(v)\right| \le C_T \epsilon_{\rm LV} \beta_\star^2$$

Exact closure is the limit $\epsilon_{\rm LV} \to 0$.

Clock-channel expansion and minimal closure solution

Use a symmetric clock-frequency aggregator

$$\omega_{\rm clk}(v) \equiv \omega_0 \left(\frac{K_\parallel K_\perp^2}{K_0^3}\right)^{1/6} \qquad \frac{T(v)}{T_0} = \frac{\omega_0}{\omega_{\rm clk}(v)}$$

Then

$$\frac{T(v)}{T_0} = 1 - \frac{k_2 + 2\ell_2}{6}\beta_f^2 + \left[\frac{7}{72}(k_2 + 2\ell_2)^2 - \frac{k_4 + \ell_2^2 + 2\ell_4 + 2k_2\ell_2}{6}\right]\beta_f^4 + O(\beta_f^6) + O(\epsilon_{\rm LV})$$

Matching to

$$\gamma_f = 1 + \frac{1}{2}\beta_f^2 + \frac{3}{8}\beta_f^4 + O(\beta_f^6)$$

gives the clock constraints

$$k_2 + 2\ell_2 = -3$$

$$\frac{7}{72}(k_2 + 2\ell_2)^2 - \frac{k_4 + \ell_2^2 + 2\ell_4 + 2k_2\ell_2}{6} = \frac{3}{8}$$

Combining with shape closure yields a minimal matched coefficient set

$$k_2 = -\frac{1}{3} \qquad \ell_2 = -\frac{4}{3}$$

and, at $O(\beta_f^4)$,

$$k_4 = -\frac{1}{9} \qquad \ell_4 = \frac{2}{9}$$

before leakage terms are added. This coefficient vector is conditional on the two declared ansatzes: the fixed-action harmonic-shell scaling $a_i \propto K_i^{-1/2}$ used in shape closure and the $1/6$-power geometric-mean clock aggregator above; neither is yet derived from primitives.

binary-3 transduction hypothesis (working)

Assume binary 3 is the dominant transducer for energy exchange with passerby assemblies (non-locally coupled encounters). Under this source-record hypothesis, the leading kinematic response is boundary-driven at binary 3, then propagated through binaries 2 and 1. The indices are persistent identities, not a radius or energy ordering.

For locally coupled assemblies (strong axial coupling), interaction pathways are distinct and should be modeled as a separate regime, not merged with passerby-transfer fits.

State update map for single-quantum uptake

For an assembly state

$$\mathcal{S} = \{v_{\mathrm{tr}}, f_1, f_2, f_3, \mathbf{A}, \mathcal{E}_{\mathrm{excl}}, \tau_{\mathrm{op}}\}$$

let one absorbed quantum ΔE_q induce

$$\mathcal{S} \mapsto \mathcal{S}' = \mathcal{S} + \Delta\mathcal{S}(\Delta E_q)$$

with the following structured components:

1. Translational architrino speed increase: $\Delta v_{\mathrm{tr}} > 0$.
2. Discrete frequency retuning of binaries $1, 2, 3$: $\Delta f_k = n_k\, \delta f_k$, with $n_k \in \mathbb{Z}$ and $k \in \{1, 2, 3\}$.
3. A1 axis realignment: $\Delta\mathbf{A} \neq 0$ (precession/tilt of principal axes).
4. Exclusion-zone geometry shift: $\Delta\mathcal{E}_{\mathrm{excl}} \neq 0$ (shape and orientation update).
5. Operational time response shift: $\Delta\tau_{\mathrm{op}} \neq 0$.

Open mapping: observer-level time dilation in $\mathbb{AAA}$

The observer-level clock-dilation channel is not yet fully mapped in substrate variables. The working interpretation in this document is:

$$\tau_{\mathrm{op}} = \tau_{\mathrm{op}}(f_1, f_2, f_3, \mathbf{A}, \mathcal{E}_{\mathrm{excl}}, v_{\mathrm{tr}})$$

where τ_{op} is an emergent clock functional of assembly internal frequencies, axis geometry, exclusion-zone shape, and translation state.

The immediate task is to identify which subset dominates $\partial\tau_{\mathrm{op}}/\partial E$ in the passerby-transfer regime, with the default prior that binary-3-mediated updates are first-order.

Evolving scenario: exclusion-volume driven effective spacetime

Working assumption:

1. In the working source record, binary 3 defines the effective exclusion-volume boundary; see Braid Envelope Geometry. This is a provisional branch role, not a taxonomy identity.
2. Each A1 binary $(1, 2, 3)$ has its own circulation axis.
3. Total angular and translational momentum are conserved at assembly level (up to modeled exchange channels with environment).

Proposed mechanism chain under applied force (acceleration of a Noether braid-based assembly):

1. External forcing increases translational state.
2. Axis coupling drives partial alignment of the three persistently indexed circulation axes.
3. Alignment is accompanied by binary radius contraction across layers (with layer-dependent sensitivity).
4. The exclusion volume changes shape and orientation because the working source record assigns its boundary to precessing binary 3.
5. Neighboring assemblies then see changed path-history geometry and interaction timing.
6. At coarse scale, this appears as a modified effective kinematic/geometric background, i.e. an emergent spacetime response.

This can be treated as a coupled state map:

$$(\mathbf{V}, \mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3, R_1, R_2, R_3, \mathcal{E}_{\mathrm{excl}}) \xrightarrow{\Delta\mathbf{p}} (\mathbf{V}', \mathbf{A}_1', \mathbf{A}_2', \mathbf{A}_3', R_1', R_2', R_3', \mathcal{E}_{\mathrm{excl}}')$$

Initial directional hypothesis for acceleration response:

$$\|\mathbf{A}_1 - \mathbf{A}_3\|,\ \|\mathbf{A}_2 - \mathbf{A}_3\| \downarrow \qquad R_1, R_2, R_3 \downarrow$$

with the strongest transduction provisionally assigned to binary 3.

Interpretive thesis:

Einstein-like spacetime behavior may be recovered as the continuum limit of moving, deforming exclusion volumes of Noether braids under translation and local volume variation, rather than from fundamental geometric curvature at substrate level.

Consistency checks required for this scenario:

1. Contraction and alignment must satisfy conservation laws and admissible torque channels.
2. The induced clock/ruler renormalization must reproduce Lorentz-like scaling to required accuracy.
3. Residual anisotropy harmonics must remain below empirical bounds after observer construction.
4. Local axial-coupling encounters must be modeled separately from passerby-transfer events.

Status: scenario is a structured hypothesis, not yet a proved derivation. Its proof burden is to recover the theorem targets and simulation residuals below from the same branch ledger.

Two-channel deformation: shape plus scale

Relevant to Lorentzian closure, the Noether braid deformation is not only axis-ratio change. A working two-channel model is:

1. Shape channel (oblateness): longitudinal compression relative to transverse radius.
2. Scale channel (radius rescaling): transverse radius changes with energy state.

Use the declared observer-channel speed for this closure step:

$$R_{\parallel} = \frac{R_{\perp}}{\gamma_\star} \qquad \gamma_\star = \frac{1}{\sqrt{1-\beta_\star^2}} \qquad \beta_\star = \frac{v_{\mathrm{tr}}}{c_\star}$$

with $c_\star = c_{\mathrm{eff}}$ for Noether sea dressed clock/ruler closure and $c_\star = c_f$ only for a primitive branch-chart calculation. For the scale channel, use

$$R_{\perp} = R_{\perp}(E) \qquad \frac{dR_{\perp}}{dE} < 0$$

as a working prior in energized regimes; a certified energized-branch record exhibiting $dR_{\perp}/dE \geq 0$ is the observable that would flip this sign choice.

The corresponding exclusion volume model is

$$V(\beta_\star, E) = \frac{4\pi}{3} R_{\perp}(E)^2 R_{\parallel}(E, \beta_\star) = \frac{4\pi}{3} R_{\perp}(E)^3 \sqrt{1-\beta_\star^2}$$

This gives a direct state-space channel from energy and translation into local Noether sea geometry:

$$(\beta_\star, E) \longmapsto (R_{\parallel}, R_{\perp}, V)$$

Local deformation fields and effective geometry handoff

For coarse-grained modeling, define local fields

$$\xi(x) = \frac{R_{\parallel}}{R_{\perp}} \qquad \lambda(x) = \frac{R_{\perp}(x)}{R_{\perp,0}}$$

with $\xi \in (0,1]$ as shape and λ as scale. The Lorentz-closure target is $\xi(x) \to 1/\gamma_\star(x)$ in the homogeneous drift regime.

Terminology guardrail: ξ is the Noether braid envelope shape ratio, inherited from Braid Envelope Geometry. It is not defined as the clock-rate factor. In the homogeneous Lorentz-closure regime the proof target is

$$\frac{\omega_{\mathrm{clk}}}{\omega_0} = \frac{d\tau}{dt_{\mathrm{eff}}} \to \xi \to \frac{1}{\gamma_\star}$$

so clock slowing is a derived readout of the geometry-to-clock map.

Together with local assembly density $n(x)$ (with $\rho_{\mathrm{NS}}(x) = \rho_{\mathrm{NS},0} n(x)$) and preferred-frame flow/orientation $\hat{u}(x)$, these define a minimal handoff tuple

$$(\xi, \lambda, n, \hat{u})_x$$

for constructing effective kinematic and metric responses. The kinematic closure requirement is that observer-built rods/clocks from this Noether sea recover Lorentz-consistent operational laws to bounded leakage.

Algebraic effective metric map from the handoff tuple

To make Stage D constructive, introduce an observer-sector pseudo-Riemannian template

$$\eta^{\mu\nu} = \mathrm{diag}(-1, 1, 1, 1)$$

used only as an operational constitutive object (not as substrate ontology). Let $\hat{u}^\mu$ be the unit medium-flow 4-field with

$$\eta_{\mu\nu} \hat{u}^\mu \hat{u}^\nu = -1$$

Define the disformal covariant metric

$$g_{\mu\nu}^{\text{eff}}(x) = \Omega^2(n,\lambda)\left[\eta_{\mu\nu} + \left(1-\xi^2(x)\right)\hat{u}_\mu\hat{u}_\nu\right]$$

Its inverse form is

$$g_{\text{eff}}^{\mu\nu}(x) = \Omega^{-2}(n,\lambda)\left[\eta^{\mu\nu} + \left(1-\xi^{-2}(x)\right)\hat{u}^\mu\hat{u}^\nu\right]$$

Hence microscopic shape closure, when it yields $\xi \to 1/\gamma_\star$, is injected directly into $g_{\mu\nu}^{\text{eff}}$.

In the local Noether sea rest frame ($\hat{u}^\mu = (1,0,0,0)$), with observer-sector coordinate $x_{\text{eff}}^0 = c_0 t_{\text{eff}}$:

$$ds_{\text{eff}}^2 = g_{\mu\nu}^{\text{eff}}dx_{\text{eff}}^\mu dx_{\text{eff}}^\nu = -\Omega^2\xi^2(dx_{\text{eff}}^0)^2 + \gamma_{ij}^{\text{eff}}dx_{\text{eff}}^i dx_{\text{eff}}^j$$

Therefore the stationary ideal clock-rate factor extracted from the metric subclass is $\Omega\xi$, while the spatial ruler scale is governed by Ω. This preserves the geometry-first interpretation: ξ remains the oblate-envelope shape ratio, and the clock rate agrees with ξ only after the geometry-to-clock closure is proved.

Observer Construction and Operational Invariance

Assembly clocks and rods

Physical observers are built from the same bound-state class that obeys the above deformation and period laws. Therefore, measurement devices inherit velocity-dependent retuning.

Two-way signal speed criterion

For ruler and clock systems made of translated assemblies, two-way signal experiments must satisfy

$$c_{2w}(\theta,v) = c_{\text{iso}} + O(\epsilon_{\text{LV}})$$

uniformly in orientation θ. This is the operational statement that maps substrate anisotropy into effective Lorentz symmetry at observer scale.

For clock-and-ruler synchronization, c_{iso} is the dressed local assembly signal speed. For photon synchronization, it is the local photon-channel speed c_γ; photon Gate A must show when the photon branch shares the same homogeneous-cell limit as c_{eff}.

Conditional synchronization-reabsorption lemma

The synchronization claim has a compact conditional form. In a weak homogeneous cell, suppose the same moving-assembly response supplies the photon-channel clock and ruler laws

$$L_\parallel(v) = \frac{L_0}{\gamma_\gamma}, \qquad \frac{d\tau}{dt_{\text{eff}}} = \frac{1}{\gamma_\gamma}, \qquad \gamma_\gamma = \frac{1}{\sqrt{1-v^2/c_\gamma^2}},$$

with v measured relative to the Euclidean-void rest frame. These equations are not assumed as completed dynamics; they are the response form the branch must derive from one Noether sea and assembly record.

In the absolute frame, the one-way photon legs along a longitudinal arm are unequal:

$$t_\rightarrow = \frac{L_\parallel}{c_\gamma - v}, \qquad t_\leftarrow = \frac{L_\parallel}{c_\gamma + v}.$$

The one-way anisotropy is therefore real at the substrate level. The round-trip absolute time is

$$t_{\text{rt}} = t_\rightarrow + t_\leftarrow = \frac{2L_\parallel c_\gamma}{c_\gamma^2 - v^2} = \frac{2L_0\gamma_\gamma}{c_\gamma}.$$

The moving assembly clock records

$$\tau_{\text{rt}} = \frac{t_{\text{rt}}}{\gamma_\gamma} = \frac{2L_0}{c_\gamma}.$$

Thus the measurable two-way photon-channel speed is c_γ even though the two one-way legs were asymmetric in absolute time. Einstein synchronization assigns the remote-clock reading by splitting this round trip; a Reichenbach-style one-way freedom remains, but embedded observers cannot extract the absolute anisotropy unless the clock, ruler, or signal-channel response leaves a residual in the preferred-frame leakage budget.

Slow clock transport supplies an independent synchronization route. A clock carried adiabatically between two endpoints must agree with the Einstein-synchronized endpoint clock in the zero-transport-speed limit, with any surviving $O(\beta_\star)$ discrepancy retained as a clock-law leakage row. Agreement is not guaranteed by two-way optical isotropy alone because the transported clock samples the moving-assembly cadence throughout its path.

The conditional lemma applies to a contractible out-and-back path in one synchronization patch. It does not set a rotating closed loop to zero. For a loop with area vector $\mathbf{A}_{\text{loop}}$ and angular velocity $\mathbf{\Omega}_{\text{rot}}$, the observer-level Sagnac comparison has the nonzero leading target

$$\Delta t_{\text{Sag}} = \frac{4\mathbf{\Omega}_{\text{rot}} \cdot \mathbf{A}_{\text{loop}}}{c_\gamma^2} + \mathcal{R}_{\text{Sag}}.$$

The same clock, ruler, and photon record must recover this loop residual while keeping the contractible two-way anisotropy row small. Treating synchronization reabsorption as a global cancellation around rotating loops would therefore fail the observer map.

This lemma proves only a conditional reabsorption statement: if one branch supplies the square-root ruler law and the square-root clock law, then the two-way optical row self-nulls. It does not prove that the Noether sea response yields those laws. Any deviation in $L_\parallel$, $d\tau/dt_{\text{eff}}$, or c_γ becomes one of the leakage residuals below.

The same caution applies to speed identification. Let c_{clk} denote the limiting speed that appears in the moving-assembly clock law and let c_γ denote the photon-channel speed used for synchronization. The conditional reabsorption above requires $\gamma_{\text{clk}} = \gamma_\gamma$ in the tested homogeneous branch. If a primitive calculation supplies $\gamma_f(v)$ using c_f while the photon row uses $\gamma_\gamma(v)$ with a different speed, the mismatch appears as an $O(\beta_\star^2)$ two-way residual rather than as Lorentz closure. The accepted target is therefore common-mode dressing: the observer-facing clock, ruler, photon, and effective gravitational channels must share the same homogeneous limiting speed after the Noether sea response is declared. It is not legitimate to collapse c_f, c_γ, c_{eff}, and $c_{\text{GW}}^{\text{eff}}$ by notation before that derivation is supplied.

The same criterion has a long-baseline photon consequence. If the photon branch uses a frequency-dependent delay factor, then a distant transient comparison accumulates

$$\Delta t_\gamma^{\text{model}}(\omega_a, \omega_b; z) = \int_{\Gamma_z} \frac{\chi_\gamma(\omega_a, \mathbf{X}, T) - \chi_\gamma(\omega_b, \mathbf{X}, T)}{c_0}\, d\ell$$

Operational Lorentz closure therefore requires this residual to vanish, or remain below the declared timing bound, in the same weak homogeneous branch that supplies $c_{2w}(\theta, v) = c_{\text{iso}} + O(\epsilon_{\text{LV}})$. It is not enough to recover local two-way isotropy while leaving cosmological photon timing to a separately tuned channel record.

Round-trip anisotropy cancellation through $O(\beta_\star^4)$

Let arm lengths in the preferred frame be written using the declared two-way signal channel speed, with $\beta_\star = v/c_\star$:

$$\frac{L_\parallel}{L_0} = 1 + \alpha_2\beta_\star^2 + \alpha_4\beta_\star^4 + O(\beta_\star^6) \qquad \frac{L_\perp}{L_0} = 1 + b_2\beta_\star^2 + b_4\beta_\star^4 + O(\beta_\star^6)$$

Round-trip absolute times are

$$t_\parallel = \frac{2L_\parallel c_\star}{c_\star^2 - v^2} = \frac{2L_0}{c_\star}\left[1 + (1+\alpha_2)\beta_\star^2 + (1+\alpha_2+\alpha_4)\beta_\star^4 + O(\beta_\star^6)\right]$$

$$t_\perp = \frac{2L_\perp}{\sqrt{c_\star^2 - v^2}} = \frac{2L_0}{c_\star}\left[1 + \left(b_2 + \frac{1}{2}\right)\beta_\star^2 + \left(b_4 + \frac{b_2}{2} + \frac{3}{8}\right)\beta_\star^4 + O(\beta_\star^6)\right]$$

Define the normalized anisotropy mismatch

$$\Delta_{\text{tw}}(\beta_\star) \equiv \frac{t_\parallel - t_\perp}{2L_0/c_\star} = A_2\beta_\star^2 + A_4\beta_\star^4 + O(\beta_\star^6)$$

with

$$A_2 = \alpha_2 - b_2 + \frac{1}{2} \qquad A_4 = \alpha_4 - b_4 + \alpha_2 - \frac{b_2}{2} + \frac{5}{8}$$

Operational isotropy through $O(\beta_\star^4)$ requires

$$A_2 = 0 \qquad A_4 = 0$$

In the transverse-gauge choice $b_2 = b_4 = 0$, this yields

$$\alpha_2 = -\frac{1}{2} \qquad \alpha_4 = -\frac{1}{8}$$

which is precisely $L_\parallel = L_0/\gamma_\star + O(\beta_\star^6)$.

Derivation Program

Stage A: binary analytic benchmark

Start with a single causal path-history binary under constant drift $\mathbf{V}$. Derive:

1. Existence and stability of periodic or quasi-periodic attractors.
2. Closed-form or asymptotic estimates for $(a_\parallel/a_\perp)(\beta_f)$.
3. First nonzero leakage coefficients in the β_f expansion.

Stage B: A1 full closure

Promote to an A1 with coupled circulation scales. Establish:

1. Persistence of aligned attractor family under drift.
2. Factorization or controlled coupling of 1/2/3 period shifts.
3. Emergent universal γ_f-law independent of axial-structure details, within a defined class.

Stage C: continuum handoff

Derive coarse-grained kinematic constitutive relations used by effective metric models:

$$\mathcal{K}_{\text{micro}} \Longrightarrow \mathcal{K}_{\text{eff}}(v, n, \nabla n, \dots)$$

so local assembly kinematics and macroscopic refractive geometry are mathematically linked.

Stage D: effective-medium and weak-field closure sequence

To connect the two-channel deformation model to observables, use the following sequence:

1. Single-braid constitutive closure: derive or fit-test $R_\perp(E)$ and induced $\xi(E, \beta_\star)$ from causal path-history A1 dynamics.
2. Effective-medium propagation law: construct $n_{\text{eff}}(\xi, \lambda, n)$ for signal transport through deformed Noether braid populations.
3. Effective metric extraction: build $g^{\text{eff}}_{\mu\nu}$ from medium variables and preferred-frame structure.
4. Weak-field consistency checks: verify Newtonian limit and required post-Newtonian behavior in the operational observer sector.
5. Strong-field/cosmology consistency checks: test horizon-adjacent and expansion-regime implications of the same constitutive channels.

Effective connection and geodesic emergence

Given $g^{\text{eff}}_{\mu\nu}$ from Algebraic Effective Metric Map from the Handoff Tuple, define

$$\Gamma^\lambda_{\mu\nu} = \frac{1}{2} g^{\lambda\rho}_{\text{eff}} \left(\partial_\mu g^{\text{eff}}_{\rho\nu} + \partial_\nu g^{\text{eff}}_{\rho\mu} - \partial_\rho g^{\text{eff}}_{\mu\nu}\right)$$

Geodesic flow in the observer sector is

$$\frac{d^2 x^\lambda_{\text{eff}}}{d\tau^2} + \Gamma^\lambda_{\mu\nu} \frac{dx^\mu_{\text{eff}}}{d\tau} \frac{dx^\nu_{\text{eff}}}{d\tau} = 0$$

For weak drift, slowly varying Noether sea flow, and quasi-static fields in a local Noether sea rest frame, define

$$\Phi_{\text{eff}}(x^i_{\text{eff}}) \equiv c_0^2 \ln\big(\Omega(n, \lambda)\, \xi\big)$$

The c_0^2 prefactor marks this as an observer-sector potential calibration: c_0 is the declared observer-sector speed, and the $c_f \to c_0$ normalization is an obligation of the dressing map, not an input identity. Any residual c_f-vs-c_0 mismatch in this branch is bounded by the same ϵ_{LV} budget that the structural-integrity closure target must drive below the experimental rows above; it is not assumed small here.
Then the nonrelativistic geodesic limit becomes

$$\frac{d^2 x^i_{\text{eff}}}{dt^2_{\text{eff}}} = -\xi^2 \gamma^{ij}_{\text{eff}} \partial_{x^j_{\text{eff}}} \Phi_{\text{eff}} + O\!\left(\frac{\|\mathbf{V}\|^2}{c_0^2}, \epsilon_{\text{LV}}\right) = -\gamma^{ij}_{\text{eff}} \partial_{x^j_{\text{eff}}} \Phi_{\text{eff}} + O\!\left(\left|1 - \xi^2\right| \, |\nabla \Phi_{\text{eff}}| \, , \frac{\|\mathbf{V}\|^2}{c_0^2}, \epsilon_{\text{LV}}\right)$$

with explicit source channels

$$\nabla \Phi_{\text{eff}} = c_0^2 \left[\partial_{\ln n} \ln \Omega \; \nabla \ln n + \partial_{\ln \lambda} \ln \Omega \; \nabla \ln \lambda + \nabla \ln \xi\right]$$

Thus gradients of n and λ (and kinematic ξ gradients) enter the affine structure as the apparent-gravity source terms.

The eikonal/least-time handoff is then:

$$\delta \int_\Gamma n_{\text{eff}}(x)\, ds = 0 \quad \Longleftrightarrow \quad \nabla_{\dot{x}} \dot{x} = 0 \text{ under } g^{\text{eff}}_{\mu\nu}$$

in the weak-field refractive regime.

Coefficient-extraction and closure estimators

For each simulated drift speed, keep the channel label explicit. Primitive branch calculations use $\beta_f = v/c_f$; dressed observer-channel fits use $\beta_\star = v/c_\star$ after the dressing map is declared. Extract from long-window attractor statistics:

$$\hat{\alpha}_j \equiv \frac{a_{\parallel,q}(\beta_j)}{a_{\perp,q}(\beta_j)} \qquad \hat{\tau}_j \equiv \frac{T_q(\beta_j)}{T_0}$$

Fit even-power truncations

$$\hat{\alpha}(\beta_f) = 1 + \hat{\alpha}_2\beta_f^2 + \hat{\alpha}_4\beta_f^4 \qquad \hat{\tau}(\beta_f) = 1 + \hat{\tau}_2\beta_f^2 + \hat{\tau}_4\beta_f^4$$

Lorentz closure at this order requires

$$\hat{\alpha}_2 = -\frac{1}{2} \quad \hat{\alpha}_4 = -\frac{1}{8} \qquad \hat{\tau}_2 = \frac{1}{2} \quad \hat{\tau}_4 = \frac{3}{8}$$

Define closure residuals on a primitive calibration band $0 \le \beta_f \le \beta_{\max}$, or on the dressed band after replacing β_f by $\beta_\star$ and γ_f by $\gamma_\star$:

$$R_\xi^{(q)}(\beta_f) \equiv \hat{\alpha}(\beta_f) - \frac{1}{\gamma_f(\beta_f)}$$

$$R_T^{(q)}(\beta_f) \equiv \hat{\tau}(\beta_f) - \gamma_f(\beta_f)$$

The reported leakage scores are

$$\mathcal{E}_{\text{shape}} \equiv \sup_{0\le\beta_f\le\beta_{\max}} \left|R_\xi^{(q)}(\beta_f)\right|$$

$$\mathcal{E}_{\text{clock}} \equiv \sup_{0\le\beta_f\le\beta_{\max}} \left|R_T^{(q)}(\beta_f)\right|$$

For two-way anisotropy, fit

$$\Delta_{\text{tw}}(\beta_f, \theta) = \sum_{m\ge1} \mathcal{A}_{2m}(\beta_f)\cos(2m\theta)$$

and enforce

$$\sup_{0\le\beta_f\le\beta_{\max}} |\mathcal{A}_{2m}(\beta_f)| \le C_m\epsilon_{\text{LV}}$$

Analytic derivation of kinematic closure coefficients

On the circular benchmark branch, take the rest-frame attractor $\boldsymbol{\rho}^\star(s;0)$ as a stable planar orbit of radius r_0 and frequency ω_0. The cycle carries emergent phase symmetry $\phi \mapsto \phi + \text{const}$ with adiabatic invariant

$$J = \oint \mathbf{p}_{\text{eff}} \cdot d\mathbf{r}$$

For each principal oscillator channel, $J_i \propto \sqrt{K_i}\,A_i^2$, so adiabatic drift retuning implies

$$A_i(\beta_f) = A_i(0)\left(\frac{K_i(0)}{K_i(\beta_f)}\right)^{1/4}$$

This provides the fixed-action retuning route from stiffness expansion to the coefficient extraction in Stiffness Tensor from Causal-Wake Surface Integrals.

The simplest scalar kernel is useful mainly because it fails in a controlled way. For translation $\mathbf{V} = v\hat{\mathbf{e}}_\parallel$ with primitive $\beta_f = v/c_f$, suppose one tries the causal-delay potential form

$$\mathcal{U}_{\text{eff}}(\mathbf{r};\beta_f) = \frac{\kappa\,\epsilon^2}{r_{\text{cd}}\left(1 - \boldsymbol{\beta}_f \cdot \hat{\mathbf{n}}_{\text{cd}}\right)} \qquad \boldsymbol{\beta}_f \equiv \frac{\mathbf{V}}{c_f}$$

Define stiffness by cycle-averaged Hessian evaluation on $\boldsymbol{\rho}^\star(s;\beta_f)$:

$$K_{ab}(\beta_f) = \left\langle \frac{\partial^2 \mathcal{U}_{\text{eff}}}{\partial r_a \partial r_b} \right\rangle_{\text{cyc}}$$

Naively expanding the causal-delay closure

$$\Delta = \frac{\|\mathbf{r} + \mathbf{V}\Delta\|}{c_f}$$

and projecting longitudinal/transverse channels would suggest integrals of the form

$$\mathcal{I}_{\parallel}(\beta_f) = \mathcal{I}_0 \int_0^{2\pi} \frac{d\theta}{2\pi} \frac{\cos^2\theta}{(1-\beta_f\cos\theta)^3}$$

$$\mathcal{I}_{\perp}(\beta_f) = \mathcal{I}_0 \int_0^{2\pi} \frac{d\theta}{2\pi} \frac{\sin^2\theta}{(1-\beta_f\cos\theta)^3}$$

This naive block is not a derivation of the Lorentz-matching vector. With the displayed normalization it gives positive normalized stiffness growth rather than the required negative coefficient pattern, and any sign reversal would require an additional channel normalization that is not present in the scalar kernel. The block is therefore a failure diagnostic: the target vector must come from the completed action kernel on the same causal-root ledger, with branch phase closure and fixed-action retuning included before the stiffness derivatives are taken.

The valid theorem target keeps the Stiffness Tensor from Causal-Wake Surface Integrals extraction rules,

$$k_2 = \frac{\partial^2_{\beta_f}\mathcal{I}_{\parallel}\big|_{\beta_f=0}}{2\,\mathcal{I}_{\parallel}(0)} \quad \ell_2 = \frac{\partial^2_{\beta_f}\mathcal{I}_{\perp}\big|_{\beta_f=0}}{2\,\mathcal{I}_{\perp}(0)}$$

$$k_4 = \frac{\partial^4_{\beta_f}\mathcal{I}_{\parallel}\big|_{\beta_f=0}}{24\,\mathcal{I}_{\parallel}(0)} \quad \ell_4 = \frac{\partial^4_{\beta_f}\mathcal{I}_{\perp}\big|_{\beta_f=0}}{24\,\mathcal{I}_{\perp}(0)}$$

but now requires the branch-action integrals $\mathcal{I}_{\parallel}, \mathcal{I}_{\perp}$ to be computed from the completed delayed action and the admitted moving branch chart. The Lorentz-matching closure condition (ansatz-conditional) remains

$$(k_2, \ell_2, k_4, \ell_4) = \left(-\frac{1}{3}, -\frac{4}{3}, -\frac{1}{9}, \frac{2}{9}\right)$$

The target vector is not a fit parameter, but this section no longer claims that the displayed scalar kernel derives it. A valid derivation must show that the completed action kernel, the causal-root ledger, branch phase closure, and fixed-action retuning together yield the derivative identities above on the same branch.

Causal-root ledger progression as a Lorentz prediction

The coefficient calculation above suggests a sharper interpretation of the Lorentz closure problem. In standard observer physics, the Lorentz formulas are usually treated as kinematic consequences of invariant signal speed and the relativity principle. In this chapter they are instead treated as emergent observer-level consequences of a delayed assembly dynamics. The additional $\mathbb{AAA}$ prediction is that the Lorentz coefficients are not merely smooth deformation coefficients. They should be generated by the same branch-chart structure that later appears, after coarse-graining, as discrete quantum behavior.

The ordinary version is this: a clock or ruler does not obey Lorentz behavior because a formula has been assigned to it. It is a physical assembly with delayed causal roots, stable branch records, and Noether sea coupling. If Lorentz behavior is real in this architecture, the measured smooth law must be the exported average of those retained branch records, not a coordinate rule pasted onto the substrate afterward.

Stated more strongly, the novel claim is a branch-quantized Lorentz response. This does not mean that the algebraic function

$$\gamma_\star(v) = \frac{1}{\sqrt{1 - v^2/c_\star^2}}$$

is replaced everywhere by a step function. It means that a physical clock or ruler can realize Lorentz behavior only through stable branch charts whose causal-root ledgers are integer objects. For a stable branch class q, define the realized clock and ruler Lorentz factors by

$$\gamma_{\rm clk}^{(q)}(\beta_\star) \equiv \frac{T_q(\beta_\star)}{T_0} \qquad \gamma_{\rm rul}^{(q)}(\beta_\star) \equiv \frac{R_{\perp,q}(\beta_\star)}{R_{\parallel,q}(\beta_\star)}$$

The branch-quantization claim is that the admissible material responses at fixed background conditions form the ledger-indexed set

$$\Gamma_{\rm adm}(\beta_\star) = \left\{ \left(\gamma_{\rm clk}^{(q)}(\beta_\star), \gamma_{\rm rul}^{(q)}(\beta_\star)\right) : q \in \mathcal{Q}_{\rm stable}(\beta_\star) \right\}$$

where $\mathcal{Q}_{\rm stable}(\beta_\star)$ is the set of stable causal-root ledger classes. The observer-level Lorentz factor is recovered only when the active branch family, hierarchy averaging, and Noether sea dressing collapse this set to a universal effective value:

$$\gamma_{\rm clk}^{(q)}(\beta_\star) = \gamma_{\rm rul}^{(q)}(\beta_\star) = \gamma_\star(\beta_\star) + O(\epsilon_{\rm LV})$$

for all admitted clock/ruler assemblies in the tested homogeneous regime. Thus $\gamma_\star$ remains the continuous effective envelope measured by Physical Observers, while the substrate implementation is quantized by admissible causal-root ledgers. If this is correct, residual deviations from exact Lorentz closure should carry branch-spectrum signatures rather than arbitrary smooth phenomenological drift.

In this chapter, the native formulation of this idea is the progression of the causal-root ledger. This progression is the ordered change, under a control parameter such as drift speed β_f, of the active causal-root ledger

$$\mathcal{L}_{\text{root}}(\beta_f) = \left\{(a, b, m, T, T_{t,m}, J_{ab}^{(m)}, \sigma_{ab}^{(m)}) : m \in \mathcal{R}_{ab}^{\text{act}}(\beta_f)\right\}$$

Here a is the receiver, b is the source, m labels an active delayed branch, $T_{t,m}$ is the emission time, $J_{ab}^{(m)}$ is the causal Jacobian, and $\sigma_{ab}^{(m)}$ records the interaction sign or channel orientation used by the local branch chart. The ledger is quantum-facing because stable assembly states depend on integer branch counts, separator events, and admissible self-hit / partner-hit histories. It is Lorentz-facing because the same roots determine the cycle-averaged stiffness tensor and clock period.

The local prediction can be stated as a closure condition. There must exist one admissible branch-chart class $\mathfrak{B}_{\text{mov}}(\beta_f)$ on a drift band $0 \leq \beta_f \leq \beta_{\max}$ such that

$$K_{ab}(\beta_f) = \left\langle \sum_{(a,b,m)\in\mathcal{L}_{\text{root}}(\beta_f)} \partial_a \partial_b \mathcal{U}_{ab}^{(m)}(T; \beta_f, \eta) \right\rangle_{\text{cyc}}$$

and the extracted coefficient vector

$$\mathbf{c}_{\text{L}}(\mathfrak{B}_{\text{mov}}) \equiv (k_2, \ell_2, k_4, \ell_4)$$

satisfies the ansatz-conditional target

$$\mathbf{c}_{\text{L}}(\mathfrak{B}_{\text{mov}}) = \left(-\frac{1}{3}, -\frac{4}{3}, -\frac{1}{9}, \frac{2}{9}\right) + O(\epsilon_{\text{br}} + \epsilon_{\text{hier}} + \epsilon_{\text{reg}})$$

The error terms have distinct jobs. ϵ_{br} measures branch-chart incompleteness or missed active roots, ϵ_{hier} measures A1 hierarchy leakage away from the binary benchmark, and ϵ_{reg} measures finite-η regularization error. This condition is stronger than fitting $L_\parallel = L_0/\gamma_f$ and $T(v) = \gamma_f T_0$. It says the fitted coefficients must be traceable to active causal roots with no independent Lorentz postulate and no per-observable retuning.

This gives a possible prediction of the framework. If Lorentz behavior is rooted in causal-root progression, then the first nonzero deviations from exact Lorentz closure should not be arbitrary smooth functions of speed. They should inherit the structure of branch charts: smooth even-power drift terms inside a fixed chart, plus localized or resonant leakage near separator events, small-divisor interlayer resonances, or changes in admissible root multiplicity. In a nonresonant chart the leakage should obey

$$\left\| \mathbf{c}_{\text{L}}(\beta_f) - \left(-\frac{1}{3}, -\frac{4}{3}, -\frac{1}{9}, \frac{2}{9}\right) \right\|_W \leq C_{\text{br}}\epsilon_{\text{br}} + C_{\text{hier}}\epsilon_{\text{hier}} + C_{\text{reg}}\epsilon_{\text{reg}}$$

while near a chart-changing event the two-way anisotropy diagnostic should decompose into the ordinary Lorentz-canceling part plus a branch-sourced residual:

$$\Delta_{\text{tw}}(\beta_f, \theta) = \Delta_{\text{tw}}^{\text{smooth}}(\beta_f, \theta) + \sum_{r\in\mathcal{R}_{\text{res}}} B_r \, \mathcal{W}_r(\beta_f) \cos(2m_r\theta + \varphi_r)$$

Here each residual label r must correspond to a named branch-chart feature: a separator approach, a small-divisor relation between layer frequencies, a finite-memory cutoff, a Jacobian-floor loss, or a root-ledger transition. A residual with no branch-chart source is not a successful prediction; it is either ordinary fitting error or an incomplete closure model.

The technology-facing status is therefore conditional. The immediate test is not necessarily a laboratory Lorentz-violation search. The first test is mathematical and computational: solve a controlled translating branch chart, extract $\mathcal{L}_{\text{root}}(\beta_f)$, compute $K_\parallel$, $K_\perp$, $T(v)$, and Δ_{tw}, and verify that the same ledger produces the Lorentz coefficients and any residual sidebands. Only after a nonzero residual survives branch completion, hierarchy averaging, and $\eta \to 0$ control does the question become an experimental one. If the predicted residual amplitude lies below existing clock, resonator, matter-interferometer, or photon-channel sensitivity, the theory remains constrained but not yet technology-testable. If a branch-sourced residual survives at an accessible scale, its signature should be more specific than a generic Lorentz-violation coefficient: it should carry the speed, orientation, material-channel, or medium-density dependence of the responsible branch-chart feature.

This also prevents overclaiming. This chapter does not prove that quantum mechanics causes special relativity. It states a narrower closure target: in $\mathbb{AAA}$, the discrete causal-root progression that supports quantum-facing assembly behavior must also generate the Lorentz formulas in the homogeneous weak-field observer limit. If the branch ledger produces quantum-like discreteness but fails to produce the Lorentz coefficient vector, then the proposed common mechanism fails. If it produces the Lorentz vector only by tuning a separate clock law, ruler law, or photon speed for each observable, the Lorentz bridge also fails.

A1 adiabatic decoupling bound

Conditional lemma target: this bound assumes the Theorem A translating attractor exists and the nonresonance condition holds; the averaging computation below is an open obligation, not a completed proof.

Let

$$\mathbf{c}^{(2)} \equiv (k_2, \ell_2, k_4, \ell_4)_{\text{binary}} \qquad \mathbf{c}^{(3)} \equiv (k_2, \ell_2, k_4, \ell_4)_{\text{A1}}$$

and define

$$\mathcal{D}_{23} \equiv \left\| \mathbf{c}^{(3)} - \mathbf{c}^{(2)} \right\|_W \qquad \|x\|_W^2 \equiv x^\top W x,\ W \succ 0$$

For the source record's indexed rows $(1,2,3)$, decompose the binary-3 channel stiffness in the coupled A1 system into its isolated binary contribution plus cross-binary corrections:

$$K_{ab}^{(3),\text{A1}} = K_{ab}^{(3),\text{bin}} + \left\langle \frac{\partial^2 \mathcal{U}_{3\leftrightarrow 2}}{\partial r_a \partial r_b} \right\rangle_{\text{cyc}} + \left\langle \frac{\partial^2 \mathcal{U}_{3\leftrightarrow 1}}{\partial r_a \partial r_b} \right\rangle_{\text{cyc}}$$

Under hierarchical separation

$$\omega_1 \gg \omega_2 \gg \omega_3 \qquad r_1 \ll r_2 \ll r_3$$

apply Hamiltonian averaging (Lie-Deprit transform) to eliminate fast phases. The monopole part renormalizes $\mathcal{I}_0$ only; the dipole contribution vanishes in the binary-1 center-of-mass frame; the leading anisotropic correction is quadrupolar and scales as $(r_2/r_3)^2$. This hierarchy is a declared source-record ordering, not a meaning of the persistent indices. Therefore

$$\mathcal{D}_{23} \le C_Q \left(\frac{r_2}{r_3}\right)^2 + O\left(\left(\frac{r_1}{r_3}\right)^2\right)$$

A sufficient closure condition is

$$\left(\frac{r_2}{r_3}\right)^2 \le C_{23}\epsilon_{\text{LV}}$$

which yields

$$\mathcal{D}_{23} \le C_{23}\epsilon_{\text{LV}}$$

Spectral-decoupling vulnerability criterion

The A1 Adiabatic Decoupling Bound assumes Diophantine nonresonance:

$$|m\omega_3 - n\omega_2| \ge \frac{\gamma_D}{(|m| + |n|)^{\tau_D}} \quad \forall\, m, n \in \mathbb{Z} \setminus \{0\} \qquad \gamma_D > 0,\ \tau_D > 1$$

If this condition is violated so that

$$|m\omega_3 - n\omega_2| \lesssim \delta\omega_{\text{nl}}$$

for small integers (m, n) and nonlinear coupling width $\delta\omega_{\text{nl}}$, then small divisors invalidate the homological equations of the Lie transform. The resulting secular resonance destroys adiabatic decoupling, can break KAM tori, and drives $O(1)$ interlayer energy exchange. In that regime, coefficient drift can exceed the quadrupole estimate and local preferred-frame leakage can rise above $O(\epsilon_{\text{LV}})$ even when geometric hierarchy is large.

Theorem Targets

Theorem A0 (forward partner-root speed-limit lemma)

The primitive material speed-limit row has a kinematic upper-bound lemma before any detailed Noether braid deformation is solved. In a translating branch with center drift $u\hat{\mathbf{e}}$, a retained partner row whose receiver lies ahead of its source by positive co-moving separation $d_\parallel \ge d_{\min} > 0$ must satisfy

$$c_f \Delta = \left\| u\Delta\, \hat{\mathbf{e}} + \boldsymbol{\rho}_i(T) - \boldsymbol{\rho}_j(T - \Delta) \right\| \ge u\Delta + d_{\min}$$

and therefore

$$(c_f - u)\,\Delta \ge d_{\min}$$

No such forward partner root exists for $u \geq c_f$; for $u < c_f$ its required delay is at least $d_{\min}/(c_f - u)$. Thus a bound translating assembly whose structural closure requires leading-side partner rows cannot preserve its causal-root ledger at or above primitive field speed. This proves the upper-bound side

$$c_{\mathrm{mat}}^{\mathrm{lim}} \leq c_f$$

for that class of material branches. The remaining Lorentz program is the constructive side: proving that stable branch families exist for $u < c_f$, that their deformation and periods approach the common envelope, and that Noether sea dressing maps the primitive bound to the observer-channel speeds without an independent fit.

Theorem A1 (translating binary Lorentz residual)

The first constructive test of Theorem G is the translating maximum-curvature binary benchmark defined in Translating Binary Benchmark. Start from the declared reference rest binary (certificate packet pending; see the closure-packet contract in Binary Dynamics) with radius R_0, period T_0, active root ledger b_0, positive Jacobian floors, and bounded transmitter-side acceleration weights. For each $0 < u < c_f$, solve the absolute-time delayed root equations for

$$\mathbf{X}_\sigma(T) = uT\,\hat{\mathbf{e}} + \sigma\,\boldsymbol{\rho}_u(\theta(T))$$

on a retained deformed ledger b_u. The target is not merely existence. The branch must return the residual triple

$$\mathcal{R}_{\mathrm{bin}}(u) = \left(R_T^{\mathrm{bin}}(u), R_\xi^{\mathrm{bin}}(u), R_{\mathrm{shape}}^{\mathrm{bin}}(u)\right)$$

with either

$$\mathcal{R}_{\mathrm{bin}}(u) = 0$$

on the primitive branch, or a controlled residual whose source is a named causal-root feature: a branch transition, small Jacobian floor, finite-memory cutoff, shape-mode excitation, or Noether sea dressing row.

This calculation decides whether the first available internal clock and ruler obey primitive FitzGerald contraction and clock dilation:

$$\frac{L_\parallel(u)}{L_\perp(u)} = \frac{1}{\gamma_f(u)}, \qquad \frac{T_u}{T_0} = \gamma_f(u), \qquad \gamma_f(u) = \left(1 - \frac{u^2}{c_f^2}\right)^{-1/2}$$

If these equalities hold on the same branch ledger, the Lorentzian compensation has been derived for the two-body clock rather than asserted. If they fail, the residual is the earliest foundation-level falsification pressure: it marks exactly where the primitive kernel departs from Lorentzian matter behavior before Noether braid averaging or Noether sea dressing is allowed to repair anything.

Theorem A (attractor existence under drift)

Target (unproved). For admissible coupling and regularization parameters, there exists a bounded translating attractor family for binary and A1 systems for $\|\mathbf{V}\| < c_f$.

Theorem B (anisotropic deformation law)

Target (unproved). Let $\beta_\star = v/c_\star$ and $\gamma_\star = (1-\beta_\star^2)^{-1/2}$ for the declared observer channel.

On the attracting manifold, principal-axis deformation obeys

$$\frac{a_\parallel}{a_\perp} = 1 - \frac{1}{2}\beta_\star^2 - \frac{1}{8}\beta_\star^4 + R_1(\beta_\star) \qquad |R_1(\beta_\star)| \leq C_1 \epsilon_{\mathrm{LV}}\,\beta_\star^2$$

equivalently

$$\frac{a_\parallel}{a_\perp} = \frac{1}{\gamma_\star} + R_1(\beta_\star)$$

Theorem C (clock renormalization law)

Target (unproved). Fundamental period satisfies

$$\frac{T(v)}{T_0} = 1 + \frac{1}{2}\beta_\star^2 + \frac{3}{8}\beta_\star^4 + R_2(\beta_\star) \qquad |R_2(\beta_\star)| \leq C_2 \epsilon_{\mathrm{LV}}\,\beta_\star^2$$

equivalently

$$\frac{T(v)}{T_0} = \gamma_\star + R_2(\beta_\star)$$

Theorem D (operational Lorentz closure)

Target (unproved). For composite observers formed from this assembly class, two-way kinematic observables satisfy

$$\Delta_{\mathrm{tw}}(\beta_\star,\theta)=\sum_{m\ge 1}\mathcal{A}_{2m}(\beta_\star)\cos(2m\theta)\qquad |\mathcal{A}_{2m}(\beta_\star)|\le C_m\epsilon_{\mathrm{LV}}$$

uniformly on $0\le\beta_\star\le\beta_{\max}$.

Theorem E (coefficient identifiability from attractor statistics)

Given smooth attracting branches and nondegenerate Jacobian of the map

$$(k_2,\ell_2,k_4,\ell_4)\mapsto(\alpha_2,\alpha_4,\tau_2,\tau_4)$$

the drift-response coefficients are locally identifiable from $(a_\parallel/a_\perp, T/T_0)$ data up to the leakage scale $O(\epsilon_{\mathrm{LV}})$.

Theorem F (cross-regime universality of closure coefficients)

If binary and A1 attracting branches exist, are smooth in β_f, share the same coarse-grained causal kernel class, and satisfy nonresonant hierarchy

$$\omega_1\gg\omega_2\gg\omega_3\qquad |m\omega_3-n\omega_2|\ge\frac{\gamma_D}{(|m|+|n|)^{\tau_D}}\ \ \forall\, m,n\in\mathbb{Z}\setminus\{0\}\qquad \gamma_D>0,\ \tau_D>1$$

then their extracted closure vectors satisfy

$$\left\|\mathbf{c}^{(3)}-\mathbf{c}^{(2)}\right\|_W\le C_Q\left(\frac{r_2}{r_3}\right)^2+O\left(\left(\frac{r_1}{r_3}\right)^2\right)$$

In particular, if $(r_2/r_3)^2\le C_{23}\epsilon_{\mathrm{LV}}$, operational Lorentz closure is universal across these two micro-regimes up to preferred-frame leakage.

Theorem G (structural-integrity common-limit closure)

This theorem is the parent Lorentz-closure target for Theorems B-D, the photon synchronization row, and the weak-field gravitational-wave speed row. Theorem A0 supplies the primitive kinematic obstruction: a material branch that needs forward partner-hit closure cannot have a sustained translating ledger with $c_{\mathrm{mat}}^{\mathrm{lim}}>c_f$. Theorem A1 supplies the first constructive clock/ruler decision surface by asking whether the translating two-body branch returns $R_T^{\mathrm{bin}}=0$ and $R_\xi^{\mathrm{bin}}=0$ before Noether braid averaging or Noether sea dressing is invoked. In the weak homogeneous observer branch, a retained material assembly branch closes only if the matter-assembly limiting speed, the Noether sea dressed clock/ruler speed, the photon-channel speed, and the empirical calibration speed obey

$$c_{\mathrm{mat}}^{\mathrm{lim}}=c_{\mathrm{eff}}=c_\gamma=c_0+O(\epsilon_{\mathrm{LV}}c_0)$$

on the same causal-root ledger. The same branch record must then supply the longitudinal deformation $a_\parallel/a_\perp=\gamma_0^{-1}+O(\epsilon_{\mathrm{LV}})$, clock cadence $d\tau/dt_{\mathrm{eff}}=\gamma_0^{-1}+O(\epsilon_{\mathrm{LV}})$, two-way signal residual $\Delta_{\mathrm{tw}}=O(\epsilon_{\mathrm{LV}})$, and the gravitational-wave speed residual $|c_{\mathrm{GW}}/c_\gamma-1|\le\epsilon_{\mathrm{GW}}$ in the weak-field TT channel. Closure fails if the photon speed, gravitational-wave speed, material limiting speed, or deformation coefficients require independently fitted dressing records.

Observable Interface

Key outputs to pass into validation and simulation layers:

1. Predicted anisotropy harmonics for resonator-style tests.
2. Velocity-dependent clock shift coefficients beyond leading $\gamma_\star$ term.
3. Orientation-dependent residuals in two-way propagation observables.
4. Parameter surfaces where leakage remains below target bounds.
5. Branch-sourced residual labels linking any nonzero Δ_{tw} sideband, clock residual, or shape residual to a specific causal-root ledger feature rather than to a free phenomenological coefficient.

Failure Conditions

The Lorentzian conspiracy program fails if any of the following occur:

1. No stable translating attractor exists over physically relevant drift range.
2. Required contraction or period scaling appears only by fine tuning.
3. Residual anisotropy terms exceed accepted bounds after full observer construction.
4. Different assembly decorations produce incompatible kinematic laws that prevent universal operational closure.
5. The weak-field connection built from $g_{\mu\nu}^{\mathrm{eff}}$ fails to reproduce a Newtonian Poisson limit for Φ_{eff} in the operational observer sector.

6. Diophantine nonresonance fails (small-divisor regime), causing secular interbinary resonance and invalidating the adiabatic mismatch bound used in A1 Adiabatic Decoupling Bound.
7. The extracted Lorentz coefficients cannot be traced to the causal-root ledger on a completed branch chart, or the same ledger cannot generate clock, ruler, and two-way signal closure without separate per-observable tuning.

Position in the $\mathbb{AAA}$ Program

This priority is the first gate because it constrains all downstream bridges:

1. Without kinematic closure, emergent metric claims are underdetermined.
2. Without universal assembly clock behavior, phenomenological mapping to GR tests is unstable.
3. With kinematic closure established, metric constitutive derivations and PPN matching become sharply posed problems.

Emergent Metric

This chapter explains how metric language enters a theory whose substrate is not metric spacetime. The Euclidean void remains fixed. The Noether sea changes state inside it. The effective metric is the observer-level description extracted from clock, ruler, signal, and medium-response channels. This chapter says what that metric means, which medium variables are supposed to carry it, and what weak-field map has to be recovered before the spacetime branch can claim GR-level closure.

The opening fixes the ontological picture and the canonical symbols first. The later sections then move through equation-of-state support, refraction-versus-curvature language, weak-field constitutive maps, and closure interfaces.

The one-line map is: Noether sea record to clock, ruler, signal, and drift response; those responses to an effective metric; that effective metric to GR benchmark observables. Each arrow has to be earned. A metric that fits only one channel is not yet a spacetime recovery, because Physical Observers need one coherent effective geometry across clocks, photons, matter motion, and gravitational-wave channels.

Absolute Frame vs. Effective Geometry

The spacetime branch keeps two descriptions separate. The absolute frame is the fixed bookkeeping structure of absolute time and Euclidean position; it supplies the substrate coordinates in which architrino path histories and Noether sea state are recorded. Effective geometry is the observer-level metric reconstructed from clocks, rulers, signal propagation, and medium response.

The bridge is therefore constitutive rather than ontological. A successful metric map must explain how the same Noether sea record produces lapse, spatial-compliance, drift, and signal-delay channels without treating the Euclidean void itself as curved.

Ontological Picture

- **Substrate**: A fixed Euclidean 3D void with absolute time T. A chosen chart (X, Y, Z) represents fixed void locations; the labels never move or curve.
- **Noether sea**: The Noether sea, a pervasive population of coupled pro/anti Noether braids. The bridge term *spacetime medium* is used when translating toward effective spacetime language.
- $\mathbb{U}_{\mathrm{now}}$ **universe-state perspective**: Complete-state bookkeeping on the absolute-time slice, carrying:
  - The full architrino microstate $S(T)$,
  - The instantaneous state of the Noether sea (density $\rho_{\mathrm{NS}}(\mathbf{X}, T)$, alignment, stress),
  - The derivable effective potential field $\Phi_{\mathrm{eff}}(\mathbf{X}, T)$ and its gradients.

From this bookkeeping perspective, there is only:

- Flat Euclidean geometry $h_{ij} = \delta_{ij}$,
- A dynamic medium (Noether braids) moving and rearranging in that geometry.

The metric appears only after a Physical Observer record is assembled from those ingredients.

Canonical Symbols (Spacetime)

Use the following symbols consistently across spacetime chapters:

- $n(\mathbf{X}, T)$: normalized Noether braid density.
- $\rho_{\text{NS}}(\mathbf{X}, T) = \rho_{\text{NS},0}\, n(\mathbf{X}, T)$: physical Noether braid density.
- $\chi_{\text{sea}}(\mathbf{X}, T) = c_f / c_{\text{eff}}(\mathbf{X}, T)$: Noether sea delay factor.
- $c_0 \equiv c_{\text{eff}}(\infty)$: asymptotic homogeneous observer-channel speed used in weak-field metric comparisons.
- $\Phi_{\text{eff}}(\mathbf{X}, T)$: constitutive potential inferred from the clock channel.
- $\Phi_N(\mathbf{X}, T)$: Newtonian benchmark potential used for weak-field matching.
- $U \equiv -\Phi_N > 0$: positive weak-field PPN potential variable.
- $N(t_{\text{eff}}, x^i_{\text{eff}})$: observer-level lapse or clock-rate field reconstructed from Noether sea state.
- $u^i_{\text{sea,eff}}(t_{\text{eff}}, x^i_{\text{eff}})$: Noether sea drift field in the observer-level bookkeeping map.
- ${e^a}_i(t_{\text{eff}}, x^i_{\text{eff}})$: spatial frame field carrying Noether sea compliance and orientation response.
- $\gamma^{\text{eff}}_{ij}(t_{\text{eff}}, x^i_{\text{eff}}) = \delta_{ab}{e^a}_i{e^b}_j$: observer-level spatial compliance metric.

What “Metric” Means Here

- **Effective metric** $g^{\text{eff}}_{\mu\nu}(t_{\text{eff}}, x^i_{\text{eff}})$ is *not* a fundamental property of the void. It is a derived description of:
  - How assembly-based clocks tick,
  - How assembly-based rulers measure distances,
  - How photon-channel packets and gravitational-wave channels propagate through the Noether sea.

We define $g^{\text{eff}}_{\mu\nu}$ operationally:

> At each effective-chart point $(t_{\text{eff}}, x^i_{\text{eff}})$, choose an idealized Physical Observer (Noether braid clock + ruler), and infer a local metric from their measured time intervals and spatial separations.

The $\mathbb{U}_{\text{now}}$ universe-state perspective then maps substrate and medium data into observer-level ADM/Cartan fields:

$$\left(h_{ij}, n, \chi_{\text{sea}}, \Phi_{\text{eff}}, \nabla\Phi_{\text{eff}}, \text{stress}, \text{alignment}\right) \;\Rightarrow\; \left(N, u^i_{\text{sea,eff}}, {e^a}_i, \gamma^{\text{eff}}_{ij}\right) \;\Rightarrow\; g^{\text{eff}}_{\mu\nu}$$

The first arrow is the open constitutive problem. It carries the main closure burden: the Noether sea state must produce the clock, ruler, drift, and signal channels together. In observer-record language, this map is the Π_{ADM} projection consumed after it has been built from the shared record; listing Φ_{eff} and χ_{sea} on the first arrow marks intermediate constitutive fields, not independently fitted inputs. The second arrow is the observer-level metric assembly; it does not curve the Euclidean void.

Weak-Gravity Visibility Scale

For weak effective-metric recovery, the useful small parameter is not the material temperature measured against the Planck temperature. It is the dimensionless effective potential, together with the density-length scale that sources that potential. For a roughly uniform ordinary-matter body of characteristic size L and standard-matter density ρ_{mat}, the Newtonian comparison estimate is

$$\epsilon_\Phi \equiv \frac{|\Phi_{\text{eff}}|}{c_0^2} \sim \frac{4\pi G_{\text{eff}}\rho_{\text{mat}}L^2}{3c_0^2}$$

Thus ordinary density can be weakly visible to clocks and signal paths when it is integrated over planetary or stellar length scales, while meter-scale laboratory samples require much higher density or precision. The Earth core is thermally cold on a Planck-temperature comparison, but that fact is not the limiting variable for weak gravity. Its contribution to observer-level metric response comes from the rest-energy, pressure, stress, and exposed assembly ledger distributed over a large body, projected through the same Noether sea response map that supplies Φ_{eff}, Γ_N, and χ_{sea}.

A spherical-source sanity check keeps this point from collapsing into a temperature-gradient story. A hot or strongly excited medium region can have maximum scalar excitation near its center while the effective gravitational acceleration vanishes there by symmetry:

$$\mathbf{a}_{\text{eff}}(\mathbf{0}) = -\nabla\Phi_{\text{eff}}(\mathbf{0}) = \mathbf{0}.$$

The constitutive variable that sources Φ_{eff} may therefore be an energy, stress, or RMS excitation record, but the force-like observer readout still comes from the spatial gradient of the shared effective potential. A model that equates gravity directly with “more temperature” fails this center-gradient check even before PPN coefficients are tested.

Alternating-Flux Constitutive Candidate

One candidate route from assembly wakes to weak gravity is an RMS excitation law. If local causal-wake hits alternate in sign, direction, or branch provenance, the mean signed force can cancel while the quadratic excitation of the Noether sea remains:

$$\Phi_{\text{eff}}^{\theta}(\mathbf{X},T) \propto \mathcal{K}_{\text{sea}} \left\langle \left(\sum_s q_s A_s(\mathbf{X},T) \right)^2 \right\rangle_{\Delta T}^{1/2}.$$

Here θ labels the shared candidate record being tested, A_s denotes the branch-resolved wake amplitude from source segment s — defined on the same retained causal root as the branch law and carrying the same-record transmitter-side acceleration weight and inverse-square factor W_s^{acc}/r_s^2, not a bare $1/r$ or root-independent amplitude — and $\mathcal{K}_{\text{sea}}$ is a constitutive response coefficient to be derived, not fitted independently. The route is useful only if the same averaged excitation also supplies the lapse, spatial-compliance, lensing, Shapiro, and PPN rows.

Because the RMS factor is non-negative, the attractive weak-field branch requires a declared negative sign: $\mathcal{K}_{\text{sea}} < 0$ in the convention $\Phi_{\text{eff}} = c_0^2 \ln N < 0$ near an ordinary mass source. Increasing the shared RMS excitation must then make Φ_{eff} more negative monotonically on that branch. Without this sign and monotonicity condition, the candidate does not determine even the direction of the recovered weak-field acceleration.

ADM/Cartan Reconstruction Surface

This chapter owns the ADM/Cartan reconstruction surface consumed by the observer-record map in Observer Framework and by neighboring dynamics chapters. The observer-level line element target is

$$ds_{\text{eff}}^2 = -N^2 c_0^2 dt_{\text{eff}}^2 + \gamma_{ij}^{\text{eff}} \left(dx_{\text{eff}}^i - u_{\text{sea,eff}}^i dt_{\text{eff}}\right) \left(dx_{\text{eff}}^j - u_{\text{sea,eff}}^j dt_{\text{eff}}\right)$$

Here N is the clock-rate or lapse channel, $u_{\text{sea,eff}}^i$ is medium drift, and γ_{ij}^{eff} is the spatial compliance channel built from the frame field $e^a{}_i$. In the GR-matching regime the effective connection is the Levi-Civita connection of $g_{\mu\nu}^{\text{eff}}$; torsion, nonmetricity, birefringence, dispersion, and preferred-frame leakage are deviation observables rather than substrate ontology.

This form is the common handoff surface for clock redshift, Shapiro delay, lensing, geodesic motion, photon synchronization, and preferred-frame tests. A scalar speed map alone is therefore not enough for closure: it can support a first Shapiro-delay intuition, but the full PPN burden requires the lapse, drift, and spatial-compliance channels together.

The same handoff can be written as a local clock-and-signal quadratic form,

$$d\tau^2 = A^2(\mathcal{N}_{\text{sea}})\, dt_{\text{eff}}^2 - \frac{1}{c_0^2} B_{ij}(\mathcal{N}_{\text{sea}}) \left(dx_{\text{eff}}^i - u_{\text{sea,eff}}^i dt_{\text{eff}}\right) \left(dx_{\text{eff}}^j - u_{\text{sea,eff}}^j dt_{\text{eff}}\right)$$

with A, B_{ij}, and $u_{\text{sea,eff}}^i$ read from the same retained Noether sea state and Physical Observer record. In the local Noether sea rest frame, the photon-channel null condition $d\tau^2 = 0$ gives

$$c_\gamma(\hat{\mathbf{k}}, \mathcal{N}_{\text{sea}}) = \frac{c_0 A(\mathcal{N}_{\text{sea}})}{\sqrt{B_{ij}(\mathcal{N}_{\text{sea}}) \hat{k}^i \hat{k}^j}}$$

The weak homogeneous observer branch requires

$$A \to 1, \qquad B_{ij} \to \delta_{ij}, \qquad u_{\text{sea,eff}}^i \to 0$$

This is a constitutive equation, not a new fundamental four-dimensional metric on absolute timespace. Every weak-field expansion about this branch is additionally conditional on the homogeneous quiescent Noether sea being an equilibrium of the constitutive dynamics; that equilibrium predicate is an open closure item of the Noether sea program, and the expansions below inherit it rather than establish it.

As a form-level recovery, the same handoff already has the correct weak-field clock shape once the clock-channel potential has been matched to the Newtonian benchmark. In a weak, slow comparison window,

$$\frac{d\tau_A}{dt_{\text{eff}}} \approx 1 - \frac{U}{c_0^2} - \frac{\|\mathbf{w}\|^2}{2c_0^2},$$

where $U \geq 0$ is the positive Newtonian potential declared above and $\mathbf{w}$ is the clock drift through the local Noether sea. This reproduces the Newtonian-limit clock relation and the standard g_{00} first-order structure as a comparison form. It is not yet coefficient-level GR closure: $\Phi_{\text{eff}} = \Phi_N$, G_{eff}, and any Einstein-equation analogue must still be derived from the same Noether sea response record that supplies A, B_{ij}, c_{eff}, and the photon channel.

The retained weak-field coefficient map should therefore be expressed at the ADM/Cartan level before observable projections are evaluated. With

$$\delta n \equiv n - 1, \qquad \delta\chi \equiv \frac{\chi_{\text{sea}}}{\chi_{\text{sea}}(\infty)} - 1, \qquad \varphi \equiv \frac{\Phi_{\text{eff}}}{c_0^2}$$

and with $\Sigma_{\text{sea},ij}^{\text{tf}}$ the retained trace-free Noether sea stress projection, the minimal coefficient scaffold is

$$N = 1 + A_N^n \delta n + A_N^\chi \delta\chi + A_N^\Phi \varphi + Q_N(\delta n, \delta\chi, \varphi, \Sigma^{\rm tf}_{\rm sea}) + O(c_0^{-6}, \epsilon_{\rm LV})$$

$$\gamma^{\rm eff}_{ij} = h_{ij}\left(1 + A_\gamma^n \delta n + A_\gamma^\chi \delta\chi + A_\gamma^\Phi \varphi\right) + A_{\gamma,{\rm tf}} \Sigma^{\rm tf}_{{\rm sea},ij} + O(c_0^{-4}, \epsilon_{\rm LV})$$

$$u^i_{\rm sea,eff} = D^i{}_j w^j \frac{U}{c_0^2} + O(c_0^{-5}, \epsilon_{\rm LV}), \qquad \gamma^{\rm eff}_{ij} = \delta_{ab} e^a{}_i e^b{}_j$$

Here w^i is the Noether sea drift relative to the comparison frame, $D^i{}_j$ is the drift-response coefficient, and U is the positive PPN potential. These are not new substrate fields. They are coefficient rows for the observer-level reconstruction. Redshift, Shapiro delay, lensing, weak-field acceleration, and preferred-frame residuals must read from these rows as one shared constitutive record.

A practical consistency check is that those channels must be projections of one shared record of the Noether sea and the Physical Observer, not independently tuned descriptions. For an observation window W, let θ collect the retained Noether sea state, source assemblies, observer clock/ruler state, signal-channel record, apparatus calibration, and boundary wake data. Let

$$\Pi_{\rm clk}\theta, \qquad \Pi_{\rm rul}\theta, \qquad \Pi_{\rm sig}\theta$$

denote the clock, ruler, and signal projections of that same record. Let $\mathcal{B}_{\rm eff}$ be the benchmark bundle returned by the candidate effective-metric map from those projections, and let $\mathcal{B}^W_{\rm GR}$ denote the GR/PPN benchmark bundle on W for redshift, Shapiro delay, lensing, precession, two-way signal speed, and preferred-frame bounds. A compact metric-recovery residual is

$$\mathcal{R}_{\rm metric}(\theta; W) = \left\|\mathcal{B}_{\rm eff}\left(\Pi_{\rm clk}\theta, \Pi_{\rm rul}\theta, \Pi_{\rm sig}\theta\right) - \mathcal{B}^W_{\rm GR}\right\|_{\Sigma_W^{-1}} + \lambda_{\rm PF}\sum_{i=1}^{3}\alpha_i(\theta)^2 + \lambda_{\rm retune}\mathcal{S}_{\rm retune}(\theta)$$

Here Σ_W is the declared benchmark covariance, α_i are the preferred-frame parameters, and $\mathcal{S}_{\rm retune}(\theta)$ records whether separate parameter choices were used to pass different channels. The closure condition is

$$\mathcal{R}_{\rm metric}(\theta; W) \le \epsilon_{\rm metric}, \qquad \mathcal{S}_{\rm retune}(\theta) = 0$$

The point is not to add a new spacetime ontology. It is to require the effective metric to behave as one constitutive summary of the same Noether sea state and observer record across clocks, rulers, signal propagation, and weak-field gravitational tests.

Geodesic and Lensing Recovery Benchmarks

The effective metric map must also recover the two standard variational benchmarks consumed by orbital, clock, and light-propagation tests. For timelike records,

$$S_{\rm clk} = -m c_0^2 \int d\tau, \qquad d\tau = \frac{1}{c_0}\sqrt{-g^{\rm eff}_{\mu\nu} dx^\mu_{\rm eff} dx^\nu_{\rm eff}}$$

and extremizing this observer-level action must give the same weak-field acceleration contribution used in the PPN bundle,

$$\frac{d^2 x^i_{\rm eff}}{dt^2_{\rm eff}} = -\gamma^{ij}_{\rm eff}\partial_{x^j_{\rm eff}}\Phi_{\rm eff} + O(c_0^{-2})$$

For null signal records,

$$g^{\rm eff}_{\mu\nu} dx^\mu_{\rm eff} dx^\nu_{\rm eff} = 0$$

must match the eikonal path-time extremal of the Noether sea signal channel. In the point-mass weak-field limit, the recovered deflection target is

$$\Delta\theta = 2(1+\gamma_{\rm eff})\frac{GM}{b\,c_0^2} + O(c_0^{-4})$$

so the GR limit $\gamma_{\rm eff} = 1$ gives $\Delta\theta = 4GM/(b\,c_0^2)$. A lapse-only or scalar-delay-only map that supplies only $2GM/(b\,c_0^2)$ has recovered the Newtonian half-test, not the full effective metric. This is why the ADM/Cartan map must carry both the clock/lapse channel and the spatial-compliance channel.

Lensing-Dynamics Equality Constraint

Hybrid dark-sector comparisons sharpen the metric burden: a modified force law that changes baryonic dynamics must also give the correct lensing potential, or the inferred dynamical mass and lensing mass will disagree. In weak-field comparison language, write the effective metric potentials as

$$ds^2_{\rm eff} = -\left(1 + \frac{2\Phi_{\rm dyn}}{c_0^2}\right) c_0^2 dt^2_{\rm eff} + \left(1 - \frac{2\Psi_{\rm sp}}{c_0^2}\right)\gamma^{\rm eff}_{ij} dx^i_{\rm eff} dx^j_{\rm eff}$$

Massive slow probes read the dynamical potential $\Phi_{\rm dyn}$, while weak lensing reads the Weyl combination

$$\Phi_{\rm lens} = \frac{\Phi_{\rm dyn} + \Psi_{\rm sp}}{2}$$

The equality target is therefore

$$\Phi_{\rm lens} = \Phi_{\rm dyn} + O(\epsilon_{\rm lens}), \qquad \Psi_{\rm sp} - \Phi_{\rm dyn} = O(\epsilon_{\rm lens})$$

equivalently $\gamma_{\rm eff} \equiv \Psi_{\rm sp}/\Phi_{\rm dyn} \to 1$ in the weak-field lensing regime. A scalar force or medium-response correction that appears only in the clock/lapse channel accelerates matter but under-deflects light. A valid $\mathbb{AAA}$ response must project the same Noether sea state into the lapse and spatial-compliance channels so that rotation curves, hydrostatic mass, time delay, and lensing consume one effective metric.

For a window W, add the lensing-dynamics residual

$$\mathcal{R}_{\rm lens=dyn}(\theta; W) = \left\|\nabla\Phi^{\theta}_{\rm dyn} - \nabla\Phi^{\rm obs}_{\rm dyn}\right\|^2_{C^{-1}_{\rm dyn}} + \left\|\nabla\Phi^{\theta}_{\rm lens} - \nabla\Phi^{\rm obs}_{\rm lens}\right\|^2_{C^{-1}_{\rm lens}} + \lambda_\gamma \left\|\gamma^{\theta}_{\rm eff} - 1\right\|^2_W + \lambda_{\rm shared}\mathcal{S}_{\rm retune}(\theta)$$

This residual belongs to the effective-metric closure program, not to dark-sector ontology by itself. It is the condition that lets a medium-response explanation of galaxy or cluster dynamics remain compatible with the same lensing map.

Matter-Channel Compatibility Target

The same shared-record rule applies to the effective matter channels whose observations test the metric. The retained comparison lesson from matter-first gravity programs is not that their ontology should be imported, but that predictive matter dynamics and observer-level geometry cannot be chosen independently. In this framework, the matter channel, clock channel, ruler channel, and signal channel must remain projections of the same Noether sea record θ.

For the signal-carrying channels used in metric reconstruction, let $\mathrm{Char}_r(\theta)$ denote the observer-level characteristic surface family extracted from channel r, and let $\mathrm{Null}(g^{\rm eff}_{\mu\nu}(\theta))$ denote the null surface family of the reconstructed effective metric. A compact compatibility residual is

$$\mathcal{R}_{\rm char}(\theta) = \sup_{r\in\mathfrak{R}_{\rm sig}} \left[d_{\rm cone}\left(\mathrm{Char}_r(\theta), \mathrm{Null}(g^{\rm eff}_{\mu\nu}(\theta))\right) + \lambda_{\rm C}\mathcal{R}^{(r)}_{\rm Cauchy}(\theta)\right]$$

where $\mathcal{R}^{(r)}_{\rm Cauchy}$ records failure of the declared channel to share the predictive Cauchy evolution used by the same observer-level metric record. In the validated weak homogeneous photon regime, this residual includes the requirement that the two physical polarization branches share the same free-space characteristic cone up to the birefringence tolerance routed through Failure Criteria.

This remains a closure target rather than substrate ontology. If $\mathcal{R}_{\rm char}$ is small only because the photon, clock, ruler, or stress channels use different fitted records, the metric has not been recovered as a constitutive output of the Noether sea.

For fermion matter channels, the compatibility burden inherits the spinor ledger. The effective metric may summarize the matter channel only after the ordered-frame spinor target, the effective spin-operator record, and weak-coupling-triad exposure are supplied by the same branch record. In compact form,

$$\mathcal{R}^{\rm fermion}_{\rm metric}(\theta; W) = \mathcal{R}_{\rm metric}(\theta; W) + \lambda_{\rm s2m}\mathcal{R}_{\rm spin\to metric}(\theta; W)$$

with $\mathcal{R}_{\rm spin\to metric}$ defined in Angular Momentum and Spin. This does not add spinor ontology to the metric. It states when fermion matter records are mature enough to be consumed by the metric constitutive map without importing weak handedness or spin as unexplained effective labels.

The same-record condition is part of the metric claim. A fermion stress channel cannot pass metric compatibility by combining one branch for inertial response, another branch for spinor closure, and a third branch for weak exposure; the retained row that supplies the ordered-frame spinor label must also satisfy the row-local gauge-control and angular-momentum residuals consumed by $\mathcal{R}_{\rm spin\to metric}$.

In the shared pullback notation, the stress-side consumer is $\Pi_{\rm matter}\mathcal{L}_\star(\theta; W, r_\star)$. The fermion metric row therefore fails if spinor closure, weak exposure, and matter response are sourced from different retained rows, even when each reduced row is individually well fitted.

Noether Braid Deformation and Metric Language

At the assembly level, an individual Noether braid has an oblate, deformable exclusion envelope; see Braid Envelope Geometry. This chapter does not identify that individual Noether braid envelope with the metric. The metric bridge uses many deforming Noether braids in the Noether sea, whose coarse variables determine clock, ruler, and signal behavior.

When translating toward General Relativity, Einstein's field equations first appear as the standard comparison form

$$G_{\mu\nu} = \frac{8\pi G}{c^4}T_{\mu\nu}$$

not as substrate curvature of the Euclidean void. In the $\mathbb{AAA}$ weak-field translation, the speed slot is supplied by the recovered homogeneous observer-channel speed c_0, the right-hand side is interpreted through matter assemblies and Noether sea stress, and the left-hand side is the observer-level metric summary reconstructed from clock, ruler, and signal channels.

For axially symmetric or rotating sources, oblate spheroidal coordinates can be a useful effective chart. A representative line element has the form

$$ds^2 = -f(\zeta, \vartheta)c_0^2 dt_{\text{eff}}^2 + g_1(\zeta, \vartheta)d\zeta^2 + g_2(\zeta, \vartheta)d\vartheta^2 + g_3(\zeta, \vartheta)d\phi^2$$

where (ζ, ϑ, ϕ) are local effective-chart coordinates, and f, g_1, g_2, g_3 encode the observer-level response of clocks, rulers, and signal paths. The symbols ζ and ϑ do not rename the Noether braid envelope ratio ξ or the mollifier width η. These coefficients are not primitive geometry. They are closure targets to be derived from Noether sea density, strain, alignment, and deformation.

The useful GR analogy is therefore limited but important:

- oblate coordinates help describe rotating or deformed effective sources,
- interior and exterior effective solutions around oblate bodies remain useful comparison targets,
- perturbative methods can capture small departures from spherical symmetry,
- and standard predictions such as redshift, Shapiro delay, lensing, orbital precession, frame-dragging, and gravitational-wave emission from deformed sources must be recovered from one reusable constitutive map.

The assembly fact that a Noether braid is oblate belongs in Braid Envelope Geometry. The spacetime claim that a population of deformed Noether braids yields an effective metric belongs here and in PPN Parameters.

Jacobson-Type Support: Metric as Equation of State

This Noether sea-first picture is paralleled by the general Jacobson-style lesson: Einstein equations are plausibly an **equation of state** for an underlying microscopic system rather than substrate-level laws of the void itself.

That comparative point fits $\mathbb{AAA}$ cleanly:

- the Euclidean void and absolute time are fundamental background structure,
- the Noether sea is the relevant microstructure,
- and relativistic metric behavior is the long-wavelength thermodynamic closure of that microstructure.

On this reading, quantizing the effective metric directly is not the primary move. The primary move is to understand and simulate the microphysical medium well enough that GR-like geometry emerges as its coarse constitutive summary.

The spacetime-condensate comparison makes the same point in hydrodynamic language. If $g_{\mu\nu}^{\text{eff}}$ is a collective variable, then a long-wavelength quantized-metric calculation is analogous to quantizing a collective mode. The missing microscopic question is the coarse-graining map

$$\Pi_{\text{hydro}} : \left(S(T), \mathcal{H}_\Omega^W, \mathcal{N}_{\text{sea}}\right) \longrightarrow g_{\mu\nu}^{\text{eff}}$$

and the residual

$$\mathcal{R}_{\text{hydro}\to g}(\theta) = \frac{\left\| g_{\mu\nu}^{\text{eff}}(\theta) - \Pi_{\text{hydro}}[S(T), \mathcal{H}_\Omega^W, \mathcal{N}_{\text{sea}}] \right\|}{\epsilon_g}$$

This residual is not a new gate; it states the existing constitutive burden in a form that separates collective-mode recovery from microscopic derivation.

This does not license dismissing low-energy quantized-metric calculations. In the long-distance regime, the effective-field-theory treatment of GR separates unknown high-energy local terms from calculable infrared corrections. $\mathbb{AAA}$ should preserve that result as an observer-level recovery benchmark: the microscopic account may differ, but the weak-field constitutive record must reproduce the same long-distance quantum correction when its variables are coarse-grained into the effective metric description.

Relative-entropy gravity proposals add a useful comparison pressure here. They place a matter/geometry mismatch functional at the action level and then ask for Einstein behavior, dark-energy-like terms, and horizon-area behavior as consequences of one variational record. In this chapter that is a benchmark discipline, not a mechanism to import. Any entropy-based comparison must still project through the same Noether sea record that supplies $T_{\mu\nu}^{\text{eff}}$, $g_{\mu\nu}^{\text{eff}}$, horizon labels, and the effective dark-energy row; otherwise the entropy functional is only another fitted description.

This support is useful but limited. A Jacobson-style argument would explain why GR-like behavior is a natural equilibrium limit of many possible media, not why $\mathbb{AAA}$ is uniquely correct. The distinguishing burden therefore shifts to the departures from equilibrium, where the detailed Noether braid architecture should matter.

It also does not derive inertia by itself. A successful equation-of-state route can recover an effective Einstein equation while leaving open how a particular assembly acquires its inertial response, why accelerated and gradient-driven local records agree to equivalence-principle accuracy, and how the same Noether sea record fixes the mass-side response tensor. Those burdens remain with the mass, energy, Lorentz-closure, and Noether braid dynamics programs.

Local-Horizon Recovery Target

The Jacobson comparison gives this chapter a sharper recovery target than the general phrase “metric as equation of state.” In the standard argument, a local horizon patch is assigned a boost-energy flux dQ, an Unruh temperature T_U, and an entropy change dS proportional to horizon area. The $\mathbb{AAA}$ translation cannot assume those quantities as substrate facts. It must derive their observer-level analogues from one Noether sea record, using the same clock, signal, stress, and finite-boundary data that later recover weak-field GR.

For a Physical Observer O and a small effective-horizon patch $\partial\Omega$, let θ denote the shared Noether sea state and observer-channel record. Let $\mathcal{B}^{(O)}_{\partial\Omega}(\theta)$ be the observer-accessible boundary-wake label set induced by the finite-boundary data in Observer Framework. A compact thermodynamic comparison residual is

$$dS^{(O)}_{\partial\Omega}(\theta) = d\left(k_B \log\left|\mathcal{B}^{(O)}_{\partial\Omega}(\theta)\right|\right), \qquad dQ^{(O)}_{\partial\Omega}(\theta) = \int_{\partial\Omega} T^{\mathrm{eff}}_{\mu\nu}(\theta)\xi^\mu d\Sigma^\nu$$

and

$$\mathcal{R}_{\mathrm{thermo}}(\theta) = \sup_{O,\partial\Omega} \frac{\left|dQ^{(O)}_{\partial\Omega}(\theta) - T^{(O)}_U dS^{(O)}_{\partial\Omega}(\theta)\right|}{\left|dQ^{(O)}_{\partial\Omega}(\theta)\right| + T^{(O)}_U \left|dS^{(O)}_{\partial\Omega}(\theta)\right| + \varepsilon}$$

The local-horizon gate is $\mathcal{R}_{\mathrm{thermo}}(\theta) \le \epsilon_{\mathrm{thermo}}$ in the equilibrium weak-field comparison regime, with the same θ also passing the ADM/Cartan and PPN gates below. If the residual can be made small only by assigning independent entropy, temperature, and stress records to each patch, then the equation-of-state analogy has not become a native closure. If it can be made small for all local horizon patches while local observer-level conservation holds, the Jacobson route supplies a proof scaffold for recovering an effective Einstein equation without treating the Euclidean void as curved.

The first proof scaffold is to make the boundary count, temperature, and flux three projections of the same record rather than three fitted fields. For a finite analysis window W, the boundary label count should satisfy

$$\mathcal{N}^{(O)}_{\partial\Omega}(\theta; W) = \left|\mathcal{B}^{(O)}_{\partial\Omega}(\theta; W)\right|, \qquad S^{(O)}_{\partial\Omega}(\theta; W) = k_B \log \mathcal{N}^{(O)}_{\partial\Omega}(\theta; W)$$

The area-scaling target is not imposed as ontology. It is the recoverable limit

$$\frac{\partial S^{(O)}_{\partial\Omega}}{\partial A^{\mathrm{eff}}_{\partial\Omega}} \longrightarrow \frac{k_B}{4A_{\mathrm{align}}}$$

where $A^{\mathrm{eff}}_{\partial\Omega}$ is the observer-level patch area and A_{align} is the alignment-area scale used in the black-hole entropy target. The local temperature comparison is

$$T^{(O)}_U = \frac{\hbar a_O}{2\pi k_B c_0}, \qquad a_O^2 = \gamma^{\mathrm{eff}}_{ij} a^i_O a^j_O$$

with a^i_O extracted from the same observer-channel metric record. The flux projection must then agree with the effective stress-energy flux computed from that record, and the local conservation residual

$$\mathcal{R}^{(O)}_{E,\partial\Omega}(\theta; W) = \frac{\left|\Delta E^{(O)}_\Omega(\theta; W) + dQ^{(O)}_{\partial\Omega}(\theta; W)\right|}{\left|\Delta E^{(O)}_\Omega(\theta; W)\right| + \left|dQ^{(O)}_{\partial\Omega}(\theta; W)\right| + \varepsilon}$$

must be small on the same windows. Thus the local-horizon pass condition is not only $\mathcal{R}_{\mathrm{thermo}} \le \epsilon_{\mathrm{thermo}}$, but also $\mathcal{R}^{(O)}_{E,\partial\Omega} \le \epsilon_E$ and the weak-field ADM/Cartan gates for the same θ. A concrete simulation protocol for this target is Thermodynamic Residual.

Native Shared-Record Variation Target

The residual above becomes a derivation only after the comparison record is made explicit. For a region Ω, Physical Observer O, and finite analysis window W, use

$$\theta_{\Omega,O,W} = \left(\mathcal{H}^W_\Omega, \mathcal{B}^{(O)}_{\partial\Omega}(W), \mathcal{N}_{\mathrm{sea}}|_{\Omega,W}, O_W, \Pi_{\mathrm{eff}}, \mu_{\Omega,\theta}\right)$$

Here $\mathcal{H}^W_\Omega$ is the retained path-history data on the window, $\mathcal{B}^{(O)}_{\partial\Omega}(W)$ is the observer-accessible boundary-wake record, $\mathcal{N}_{\mathrm{sea}}|_{\Omega,W}$ is the locally resolved Noether sea state, O_W is the observer's clock, ruler, and readout state on the window, Π_{eff} is the projection to the observer-level fields $(N, u^i_{\mathrm{sea,eff}}, \gamma^{\mathrm{eff}}_{ij}, T^{\mathrm{eff}}_{\mu\nu})$, and $\mu_{\Omega,\theta}$ is the conditional measure over unresolved deterministic histories. This tuple is not a new substrate object. It only names the record that must supply entropy, temperature, flux, and effective metric data together.

Let δ_ℓ denote an admissible local-horizon perturbation that keeps the observer, window, projection map, and comparison regime fixed while varying the resolved Noether sea state and boundary flux through the patch. The native closure target is

$$\delta_\ell \log \left|\mathcal{B}^{(O)}_{\partial\Omega}(\theta_{\Omega,O,W})\right| = \frac{\delta_\ell A^{\mathrm{eff}}_{\partial\Omega}}{4A_{\mathrm{align}}} = \frac{\delta_\ell Q^{(O)}_{\partial\Omega}}{k_B T^{(O)}_U} + \mathcal{O}(\epsilon_{\mathrm{local}})$$

Equivalently, $\delta_\ell Q^{(O)}_{\partial\Omega} = T^{(O)}_U \delta_\ell S^{(O)}_{\partial\Omega} + \mathcal{O}(k_B T^{(O)}_U \epsilon_{\mathrm{local}})$, with $S^{(O)}_{\partial\Omega} = k_B \log|\mathcal{B}^{(O)}_{\partial\Omega}|$. The error term collects declared local-gradient, finite-window, and record-coarse-graining residuals; it may not hide a second entropy record, a second stress record, or a separately tuned temperature.

The first proof step is to show that the logarithmic boundary-label count admits an area density on the observer-level horizon patch:

$$\log \left|\mathcal{B}^{(O)}_{\partial\Omega}(\theta_{\Omega,O,W})\right| = \int_{\partial\Omega} \sigma_{\mathrm{bw}}(\theta_{\Omega,O,W}; x_{\mathrm{eff}})\, dA_{\mathrm{eff}}(x_{\mathrm{eff}}) + \mathcal{O}(\epsilon_{\mathrm{edge}}), \qquad \sigma_{\mathrm{bw}} \longrightarrow \frac{1}{4A_{\mathrm{align}}}$$

in the equilibrium weak-field limit. The proof fails if the distinguishable boundary-wake count scales with unresolved interior volume or arbitrary history length after the effective area is fixed, if $T^{(O)}_U$ is not extracted from the same observer-channel acceleration that defines $A^{\mathrm{eff}}_{\partial\Omega}$, if $dQ^{(O)}_{\partial\Omega}$ uses a stress tensor not projected from $\theta_{\Omega,O,W}$, or if the same record cannot also satisfy weak-field ADM/Cartan recovery.

A more explicit reduction is the boundary-factorization theorem target. Let $\mathcal{P}_{\partial\Omega}$ be a patch decomposition of the observer-level horizon surface with

$$A_{\mathrm{eff}}(P_a) = a_\theta A_{\mathrm{align}} + \mathcal{O}(\epsilon_A A_{\mathrm{align}}), \qquad P_a \in \mathcal{P}_{\partial\Omega}$$

where a_θ is the derived dimensionless patch-area normalization for the retained record. The coefficient cannot be interpreted as a literal independent one-patch count: $\log|\mathcal{L}_a| = 1/4$ would require $|\mathcal{L}_a| = e^{1/4}$, not the cardinality of a finite set. The coherent target is an area-normalized block entropy density. For a connected patch block $U \subseteq \mathcal{P}_{\partial\Omega}$, let $\mathcal{L}_U(\theta_{\Omega,O,W})$ be the joint retained boundary-wake label set on U after fixing the observer record and the edge data to the accuracy declared by $\epsilon_{\mathrm{local}}$. The local aligned-label density is

$$s_{\mathrm{align}}(\theta_{\Omega,O,W}) = \lim_{|U|\to\infty} \frac{1}{|U|} \log|\mathcal{L}_U(\theta_{\Omega,O,W})|$$

when the limit exists after boundary corrections. The locality part of the theorem target is

$$\log|\mathcal{L}_U(\theta_{\Omega,O,W})| = |U|\, s_{\mathrm{align}}(\theta_{\Omega,O,W}) + \mathcal{O}(|\partial U|\epsilon_{\mathrm{corr}})$$

where the correction records edge and finite-correlation effects between adjacent patches. The normalization part is then the aligned-label statement

$$\frac{s_{\mathrm{align}}(\theta_{\Omega,O,W})}{a_\theta} \longrightarrow \frac{1}{4}$$

Together with $\sum_{P_a \in \mathcal{P}_{\partial\Omega}} A_{\mathrm{eff}}(P_a) \to A^{\mathrm{eff}}_{\partial\Omega}$, these claims imply the area density above. This does not prove the coefficient by definition. It reduces the problem to a local aligned-interface calculation: terminal Family-A alignment must supply a universal block entropy density, its patch-area normalization, and surrounding Noether sea correlations short-range enough that the boundary count is additive up to edge residuals.

Refraction vs. Curvature

- From the $\mathbb{U}_{\mathrm{now}}$ **universe-state perspective**:
  - Primitive causal-wake support is measured by Euclidean distances in (X, Y, Z) on the absolute slice,
  - While effective ray paths and clock comparisons depend on an *effective speed* $c_{\mathrm{eff}}(\mathbf{X}, T)$ set by the local Noether braid configuration:
    $c_{\mathrm{eff}}(\mathbf{X}, T) < c_f \quad \text{in dense regions (near mass)}$ — the declared response-sign assumption of the weak-field branch, required for recovery rather than derived.
- From the **Physical Observer** (built from assemblies):
  - Light and free-falling matter appear to move along curved paths (geodesics) of an effective metric $g^{\mathrm{eff}}_{\mu\nu}$.
  - Shapiro delay, light bending, and perihelion precession become **refractive-medium effects** rather than curvature of the void itself.

A flat-space refraction analogy is therefore useful only when it is kept at the correct level. A scalar $c_{\mathrm{eff}}(\mathbf{X}, T)$ or scalar delay map can encode a first signal-path delay, but it is not by itself an effective metric. GR/PPN recovery requires the same Noether sea record to determine the observer-level lapse $N(t_{\mathrm{eff}}, x^i_{\mathrm{eff}})$, drift $u^i_{\mathrm{sea,eff}}(t_{\mathrm{eff}}, x^i_{\mathrm{eff}})$, frame field $e^a{}_i(t_{\mathrm{eff}}, x^i_{\mathrm{eff}})$, and spatial compliance $\gamma^{\mathrm{eff}}_{ij}(t_{\mathrm{eff}}, x^i_{\mathrm{eff}})$, so clock, ruler, and signal projections cannot be tuned as separate channels.

The constitutive task is to:

1. Specify the projection from native Noether sea fields into $g^{\mathrm{eff}}_{\mu\nu}(t_{\mathrm{eff}}, x^i_{\mathrm{eff}})$:

- $n(\mathbf{X},T)$ (equivalently $\rho_{\rm NS}(\mathbf{X},T)$),
- Stress/strain of the Noether sea,
- Potential $\Phi_{\rm eff}(\mathbf{X},T)$ from matter assemblies.

2. Show that in the weak-field regime this reproduces the standard GR metric (e.g. Schwarzschild) to PPN accuracy: $g_{00}^{\rm eff} \approx -\left(1+\frac{2\Phi_N}{c_0^2}\right), \quad g_{ij}^{\rm eff} \approx h_{ij}\left(1-\frac{2\Phi_N}{c_0^2}\right).$

Minimal Weak-Field Constitutive Map (for PPN Matching)

To make the mapping functional explicit at first post-Newtonian order, start in the local Noether sea rest gauge

$$u^i_{\rm sea,eff} = 0$$

with observer-channel speed $c_0 = c_{\rm eff}(\infty)$. The weak-field target is

$$N(x^k_{\rm eff}) = 1 + \frac{\Phi_N(x^k_{\rm eff})}{c_0^2} + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

$$\gamma^{\rm eff}_{ij}(x^k_{\rm eff}) = \left(1 - 2\gamma_{\rm eff}\frac{\Phi_N(x^k_{\rm eff})}{c_0^2}\right)h_{ij} + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

Equivalently, using $x^0_{\rm eff} = c_0 t_{\rm eff}$ in the observer-sector metric,

$$g^{\rm eff}_{00}(x^k_{\rm eff}) = -\left(1 + \frac{2\Phi_N(x^k_{\rm eff})}{c_0^2}\right) + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

$$g^{\rm eff}_{ij}(x^k_{\rm eff}) = \left(1 - 2\gamma_{\rm eff}\frac{\Phi_N(x^k_{\rm eff})}{c_0^2}\right)h_{ij} + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

The native Noether sea delay factor remains

$$\chi_{\rm sea}(\mathbf{X},T) \equiv \frac{c_f}{c_{\rm eff}(\mathbf{X},T)}$$

After projection into the effective chart, PPN time-of-flight comparisons normalize by the homogeneous observer speed:

$$\frac{c_0}{c_{\rm eff}(x^k_{\rm eff})} = \frac{\chi_{\rm sea}(x^k_{\rm eff})}{\chi_{\rm sea}(\infty)} = 1 - (1+\gamma_{\rm eff})\frac{\Phi_N(x^k_{\rm eff})}{c_0^2} + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

so travel time on a Euclidean anchor path Γ is

$$t_{\rm eff}[\Gamma] = \frac{1}{c_0}\int_\Gamma \frac{c_0}{c_{\rm eff}(x^i_{\rm eff})}\,ds_{\rm eff}$$

This is the concrete first-order realization of

$$(h_{ij}, n, \chi_{\rm sea}, \Phi_{\rm eff}, \text{stress}) \mapsto (N, u^i_{\rm sea,eff}, e^a{}_i, \gamma^{\rm eff}_{ij}) \mapsto g^{\rm eff}_{\mu\nu}$$

with $\gamma_{\rm eff}$ the observer-level refraction/spatial-compliance coefficient extracted from the same constitutive record whose Shapiro-delay and lensing projections are tested in ppn-parameters.

Closure Program Interface (metric constitutive map)

This chapter is the constitutive anchor for the gravity-side closure:

$$(h_{ij}, n, \chi_{\rm sea}, \Phi_{\rm eff}, \text{stress}) \mapsto (N, u^i_{\rm sea,eff}, e^a{}_i, \gamma^{\rm eff}_{ij}) \mapsto g^{\rm eff}_{\mu\nu}$$

Distribute proof obligations as:

- constitutive metric form and observer map: **this chapter**,
- explicit 1PN observables/estimators: spacetime/ppn-parameters.md,
- clock-law extraction and coefficient fitting: spacetime/proper-time-and-time-dilation.md,
- final acceptance thresholds: validation/constraint-ledger.md.

Minimal closure condition:

1. Eikonal path-time extremals in the refractive picture match null geodesics of $g^{\rm eff}_{\mu\nu}$ in weak field.

2. The same N, $u^i_{\mathrm{sea,eff}}$, $e^a{}_i$, and $\gamma^{\mathrm{eff}}_{ij}$ coefficients predict Shapiro delay, lensing, redshift, weak-field acceleration, and preferred-frame residuals without re-fitting per observable.
3. The long-distance GR-EFT correction to weak gravity is recovered from the same constitutive record, without treating the effective metric as microscopic ontology.

A proposed recovery that supplies only $c_{\mathrm{eff}}(x^i_{\mathrm{eff}})$ or $\chi_{\mathrm{sea}}(x^i_{\mathrm{eff}})$ therefore closes only a refractive signal model. It becomes a metric recovery candidate only after that scalar row is embedded in one shared clock/ruler/signal map for N, $u^i_{\mathrm{sea,eff}}$, $e^a{}_i$, and $\gamma^{\mathrm{eff}}_{ij}$.

Weak-Field Geodesic Handoff (ADM Constitutive Subclass)

The scalar/disformal bridge is the ADM/Cartan subclass obtained by choosing the local Noether sea rest gauge:

$$u^i_{\mathrm{sea,eff}} = 0, \qquad \gamma^{\mathrm{eff}}_{ij} = \Omega^2(n,\lambda)h_{ij}, \qquad N = \Omega(n,\lambda)\xi$$

Here ξ is the Noether braid envelope shape ratio $\xi = R_\parallel / R_\perp$, not a synonym for the clock-rate factor. The stationary ideal clock-rate factor in this metric subclass is $N = \Omega\xi$ only after the geometry-to-clock map is fixed.

Define the clock-channel potential by the observer-side lapse:

$$\Phi_{\mathrm{eff}}(x^i_{\mathrm{eff}}) \equiv c_0^2 \ln N(x^i_{\mathrm{eff}}) = c_0^2 \ln\big(\Omega(x^i_{\mathrm{eff}})\xi(x^i_{\mathrm{eff}})\big), \qquad N(x^i_{\mathrm{eff}}) = e^{\Phi_{\mathrm{eff}}(x^i_{\mathrm{eff}})/c_0^2}$$

The c_0^2 prefactor calibrates the observer-sector potential; in the weak homogeneous branch, the residual between the primitive wake speed c_f and the measured limiting speed c_0 is what operationally defines ϵ_{LV} — the two agree up to $O(\epsilon_{\mathrm{LV}} c_0)$ by that definition, as a residual bounded by the Lorentz-violation budget rather than an asserted derivation.

With $x^0_{\mathrm{eff}} = c_0 t_{\mathrm{eff}}$, the Noether sea rest-frame metric components are

$$g^{\mathrm{eff}}_{00} = -N^2, \qquad g^{\mathrm{eff}}_{ij} = \Omega^2 h_{ij}$$

For a slowly moving test assembly in a stationary medium, the dominant connection piece is

$$\Gamma^i_{00} = -\frac{1}{2} g^{ij}_{\mathrm{eff}} \partial_j g^{\mathrm{eff}}_{00} = \xi^2\, \partial^i \ln(\Omega\xi) = \xi^2 \frac{\partial^i \Phi_{\mathrm{eff}}}{c_0^2}$$

Using $dx^0_{\mathrm{eff}}/dt_{\mathrm{eff}} \approx c_0$, the spatial geodesic equation gives

$$\frac{d^2 x^i_{\mathrm{eff}}}{dt^2_{\mathrm{eff}}} \approx -\Gamma^i_{00} \left(\frac{dx^0_{\mathrm{eff}}}{dt_{\mathrm{eff}}}\right)^2 = -\xi^2 \nabla^i \Phi_{\mathrm{eff}}$$

Hence, in weak field ($\xi \to 1$, a subclass boundary condition of the declared branch),

$$\frac{d^2 x^i_{\mathrm{eff}}}{dt^2_{\mathrm{eff}}} = -\gamma^{ij}_{\mathrm{eff}} \partial_{x^j_{\mathrm{eff}}} \Phi_{\mathrm{eff}} + O\big(\left|1-\xi^2\right|\, |\nabla \Phi_{\mathrm{eff}}|\big)$$

which is the Newtonian limit.

PPN extraction for this constitutive subclass is defined canonically in
ppn-parameters,
including the full g_{00}/g_{ij} expansions, preferred-frame leakage map,
and weak-field closure vector.

In that canonical map:

$$\beta_{\mathrm{PPN}} = 1$$

for the exponential clock-law channel — a declared subclass whose clock law is
not yet derived from primitives; see the exponential clock-law subclass
discussion in PPN Parameters — while γ_{PPN}
is fixed by first-order clock-channel partitioning between Ω and ξ.

General Relativity

This chapter is the observer-facing checklist for the spacetime branch. It says, in one place, which general-relativistic observables must be matched by the constitutive medium picture and where the framework is allowed to differ only after that closure is secured.

Read it as a phenomenology gate rather than as a derivation chapter. The metric and PPN notes carry the constitutive work; this page states the observable obligations and their regime boundaries.

The central question is not whether $\mathbb{AAA}$ can describe gravity in different words. The question is whether one Noether sea response record can reproduce the network of tested GR observables without switching hidden assumptions between rows. Redshift, Shapiro delay, bending, orbital precession, equivalence-principle behavior, and gravitational waves must come from the same effective-geometry map in the regime where GR already works.

Purpose

This chapter is the observer-level checklist for where the spacetime branch of $\mathbb{AAA}$ must reproduce general relativity and where it is allowed to differ. It is not the constitutive derivation itself. That work lives in the metric and PPN chapters. The role of this page is to collect the observable-facing map in one place.

Core Interpretation

At the substrate level:

- space remains Euclidean,
- time remains absolute,
- and the Noether sea is the dynamical medium.

At the observer level, the same Noether sea must generate the effective metric behavior usually attributed to curved spacetime. Therefore the phenomenology requirement is:

$$\text{medium response} \implies \text{effective metric observables}$$

The closure demand is not merely qualitative resemblance. The same constitutive map must jointly recover redshift, Shapiro delay, light bending, perihelion precession, and gravitational-wave propagation in the regimes where GR is already tested.

Every row below should be treated as a test of the same medium record. If a clock result, a lensing result, and a gravitational-wave result require different hidden records, the branch has produced separate fits rather than a GR recovery.

Notation convention: G_N denotes the standard Newtonian and low-energy GR comparison constant in the observable benchmark formulas below. $G_{\text{eff}}(\theta)$ denotes the recovered constitutive coefficient of a candidate Noether sea record, and a validated weak-field branch must make $G_{\text{eff}}(\theta) \to G_N$ in the same record that recovers the clock, lensing, PPN, and gravitational-wave rows. Nearby standard-comparison formulas may retain G as ordinary GR shorthand; this chapter writes G_N when the constant belongs to the benchmark rather than to the constitutive map.

Network evidence and nuisance separation

The empirical gravity lesson is that one precise test is not enough to establish an effective metric branch. A measurement can accidentally agree with the right number while sharing an unmodeled nuisance with the theory input, as in historical redshift and solar-system cases (Pound–Rebka thermal-gradient control; Eddington-1919 eclipse-systematics). The phenomenology gate therefore treats GR recovery as a network constraint:

$$\mathcal{E}_{\text{GR}}(\theta) = \mathbf{r}_{\text{net}}(\theta)^{\mathsf{T}} C_{\text{net}}^{-1} \mathbf{r}_{\text{net}}(\theta)$$

where $\mathbf{r}_{\text{net}}$ contains the redshift, Shapiro, lensing, 1PN, preferred-frame, equivalence-principle, gravitational-wave, and CMB-derived gravity rows that are claimed by the same record θ. The covariance C_{net} must include detector calibration, astrophysical nuisance parameters, foregrounds, and external-source uncertainty. A channel passes only when the same θ survives this joint network; agreement in a single row is a prompt for cross-checks, not closure.

Causal-order and scale recovery

Before the individual observables are checked, the effective metric map has to pass a structural check: Physical Observers must infer the same causal ordering, local clock scale, and negligible preferred-frame leakage that the GR comparison metric would provide in the validated regime. The following diagnostic is imported unchanged from observer-framework.md:

$$\mathcal{R}_{\text{causal}}(\theta) = d_{\text{ord}}(\prec_{\text{eff}}(\theta), \prec_{\text{GR}}) + \lambda_\tau \left\| \frac{d\tau_{\text{eff}}}{dt_{\text{eff}}}(\theta) - \frac{d\tau_{\text{GR}}}{dt_{\text{eff}}} \right\|_W + \lambda_{\text{PF}} \sum_{i=1}^{3} \alpha_i(\theta)^2$$

The causal-order term tests the effective light-cone structure, the clock term supplies local scale, and the preferred-frame term keeps preferred-frame signatures below observational bounds. Passing this check does not replace the redshift, Shapiro, lensing, 1PN, quantum-gravity EFT, or gravitational-wave tests below; it prevents them from being fit by mutually incompatible causal and clock conventions.

The labels τ_{eff} and τ_{GR} mark the candidate observer-record clock readout and the GR comparison clock readout. They are scale readouts in the effective observer layer, not additional substrate time variables.

In plain terms, the observer cannot be allowed to recover one causal story from photons, a different clock story from matter, and a third timing story from gravitational waves. The tested regime must look like one effective spacetime to the Physical Observer.

Global continuation and cosmic-censorship comparison

Global hyperbolicity, Cauchy surfaces, Cauchy horizons, and cosmic censorship are standard GR comparison tools for asking when initial data determine a maximal observer-level spacetime. They are not substrate assumptions in $\mathbb{AAA}$, because the native dynamics live in absolute timespace with path-history records. Their retained value is as an extension discipline: when the effective metric comparison would treat a region as losing unique continuation, the native account must identify which finite boundary wake data, Noether sea state, and closure-label ensemble determine the continuation.

The comparison burden can be stated as a finite-access residual rather than as an imported global axiom. For a compact comparison region Ω and window $W = [T_i, T_f]$, the strong-field or cosmology packet must specify a continuation map from the same record class used by the weak-field observables,

$$\mathcal{T}^{\theta}_{\Omega,W} : \left(X_\Omega(T_i), \mathcal{H}^{<T_i}_\Omega, \mathcal{B}_{\partial\Omega}|_W, N_{\text{sea}}|_{\Omega\times W} \right) \longrightarrow \mathcal{S}_\Omega(T_f)$$

where $\mathcal{S}_\Omega(T_f)$ is the finite accepted endpoint or branch-label set. A GR comparison that assumes global hyperbolicity can be used only after the same θ also recovers the local causal-order, clock, PPN, and gravitational-wave observables above. If $\mathcal{S}_\Omega(T_f)$ is empty, infinite without a finite ledger, or selected by an external global assumption rather than by the recorded boundary data, the effective-metric continuation has not closed.

Weak-Field Observables That Must Match GR

Gravitational redshift and clock rates

The clock channel must reproduce

$$\frac{d\tau}{dt_{\text{eff}}} \approx \sqrt{1 + \frac{2\Phi_N}{c_0^2} - \frac{\|\mathbf{w}\|^2}{c_0^2}}$$

in the weak-field, low-velocity observer regime, where $\mathbf{w}$ is the sea-relative drift of the clock in the weak homogeneous limit and $c_0 \equiv c_{\text{eff}}(\infty)$ is the dressed asymptotic clock/signal speed. The primitive wake speed c_f still belongs inside delayed-root and self-hit equations; it is not the default denominator for observer clock dilation unless a closure result identifies the relevant dressed branch with c_f. For static clocks this reduces to

$$\frac{\Delta\nu}{\nu} \approx \frac{\Delta\Phi_N}{c_0^2}$$

Operationally, GPS offsets, Pound-Rebka, and related clock-comparison tests are the direct acceptance layer. Height-resolved optical-clock comparisons (mm-baseline Sr optical-lattice clock comparison, Bothwell-class) sharpen this layer: near Earth's surface, $\Delta\nu/\nu \approx gL/c_0^2$, so a $1\,\text{mm}$ clock-sample separation corresponds to about 1.1×10^{-19} and a $33\,\text{cm}$ separation to about 3.6×10^{-17}. The same clock law must handle both separated clocks and extended collective clock samples without replacing the constitutive coefficients used for Shapiro delay and lensing.

Shapiro delay

In the refractive-medium picture, one-way path time is

$$t_{\text{eff}}[\Gamma] = \frac{1}{c_0} \int_\Gamma \bar{\chi}_{\text{sea}}(x^i_{\text{eff}})\, ds_{\text{eff}}$$

with

$$\bar{\chi}_{\text{sea}}(x^i_{\text{eff}}) \equiv \frac{c_0}{c_{\text{eff}}(x^i_{\text{eff}})} = \frac{c_0}{c_f}\chi_{\text{sea}}(x^i_{\text{eff}}) = 1 - (1+\gamma_{\text{eff}})\frac{\Phi_N(x^i_{\text{eff}})}{c_0^2} + O(c_0^{-4})$$

For a point mass, the resulting delay is

$$\Delta t_{\text{eff}} = \frac{(1+\gamma_{\text{eff}})G_N M}{c_0^3} \ln\left(\frac{r_1 + r_2 + R}{r_1 + r_2 - R}\right) + O(c_0^{-5})$$

which must match the GR coefficient at current solar-system precision.

Light bending

The same refractive map must recover the 1PN deflection law

$$\Delta\theta \approx 2(1+\gamma_{\text{eff}})\frac{G_N M}{b\, c_0^2}$$

with impact parameter b. In the GR-matching limit $\gamma_{\text{eff}} = 1$, this reduces to the standard

$$\Delta\theta \approx \frac{4G_N M}{b\,c_0^2}$$

So Shapiro delay and lensing are not separate fit channels. They are two readouts of the same constitutive coefficient.

Perihelion and 1PN orbital structure

The effective metric subclass must also reproduce the standard 1PN orbital correction structure, summarized through the PPN parameters γ_{eff} and β_{eff}. At the phenomenology level the requirement is simple:

- Mercury-type precession,
- geodetic precession,
- and other weak-field orbital tests

must all be reproduced by the same $(\gamma_{\text{eff}}, \beta_{\text{eff}}, \alpha_i)$ package already used for light and clock observables.

For the classical weak-field suite, the comparison record can be made explicit. On an observation window W, let θ_W denote the retained Noether sea state, source assembly record, observer clock/ruler state, signal-channel data, boundary wake data, and the ADM/Cartan projection

$$\theta_W \longmapsto \left(N, u^i_{\text{sea,eff}}, e^a{}_i, \gamma^{\text{eff}}_{ij}, \Phi_{\text{eff}}, \chi_{\text{sea}}\right)$$

The observable residual bundle is then

$$\mathbf{r}_{\text{GR}}(\theta_W) = \begin{pmatrix} R_{\text{red}} \\ R_{\text{Shap}} \\ R_{\text{lens}} \\ R_{\text{acc}} \\ R_{1\text{PN}} \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}, \qquad R_{\text{acc}} = \frac{\left\| \frac{d^2 x^i_{\text{eff}}}{dt^2_{\text{eff}}} + \gamma^{ij}_{\text{eff}} \partial_{x^j_{\text{eff}}} \Phi_{\text{eff}} \right\|_W}{\left\| \gamma^{ij}_{\text{eff}} \partial_{x^j_{\text{eff}}} \Phi_{\text{eff}} \right\|_W + \varepsilon}$$

The redshift, Shapiro, lensing, acceleration, 1PN, and preferred-frame rows are acceptable only when they are projections of this same θ_W. If any row requires replacing N, $u^i_{\text{sea,eff}}$, $e^a{}_i$, γ^{eff}_{ij}, Φ_{eff}, χ_{sea}, or the boundary/noise record, the phenomenology pass has become a set of separate fits rather than a GR recovery.

Solar oblateness supplies the nuisance-control version of the same rule. Mercury-type precession may be written as

$$\Delta\varpi_{\text{obs}} = \Delta\varpi_{\text{PPN}}(\theta_W) + \Delta\varpi_{J_{2,\odot}} + \Delta\varpi_{\text{asteroid}} + \Delta\varpi_{\text{noise}}$$

where $\Delta\varpi_{J_{2,\odot}}$ is the contribution from the Sun's quadrupole moment and the remaining terms collect other modeled ephemeris corrections. A constitutive map cannot improve its PPN fit by silently moving a mismatch into $\Delta\varpi_{J_{2,\odot}}$ or by using a solar-interior assumption inconsistent with helioseismology and light-deflection records. The precession row closes only after the nuisance record is fixed independently enough that $\Delta\varpi_{\text{PPN}}$ is the recovered effect rather than a residual after subtraction.

The perihelion row should carry the explicit GR target rather than only the name of the test. For a weak-field bound orbit with semi-major axis a and eccentricity e,

$$\Delta\varpi_{\text{GR}} = \frac{6\pi G_N M}{a(1-e^2)c_0^2}$$

per orbit. In the PPN projection this is the special case of

$$\Delta\varpi_{\text{PPN}} = \frac{2\pi G_N M}{a(1-e^2)c_0^2}\left(2 + 2\gamma_{\text{PPN}} - \beta_{\text{PPN}}\right)$$

so Mercury-type precession is a joint test of the same spatial-compliance coefficient that controls lensing and the same nonlinear clock coefficient that controls β_{PPN}.

Low-Energy Quantum-Gravity EFT Benchmark

The classical weak-field observables above do not exhaust the recovery gate. Standard low-energy effective-field-theory calculations treat GR as a valid long-distance theory and separate unknown high-energy local terms from calculable infrared behavior. $\mathbb{AAA}$ does not take the quantized metric as microscopic ontology, but it must recover the same long-distance observer-level data product where the expansion is controlled.

For two slowly moving masses, use the schematic benchmark

$$V_{\text{GR-EFT}}(r) = -\frac{G_N m_1 m_2}{r}\left[1 + \alpha_{1\text{PN}}\frac{G_N(m_1+m_2)}{c_0^2 r} + \alpha_\hbar \frac{G_N \hbar}{c_0^3 r^2} + \cdots\right]$$

where $\alpha_{1\text{PN}}$ and $\alpha_\hbar$ are fixed by the standard low-energy calculation rather than fitted as new $\mathbb{AAA}$ parameters. A useful closure residual is

$$\mathcal{R}_{\text{qG}}(r;\theta) = \left|\frac{V_{\mathbb{AAA}}(r;\theta) - V_{\text{GR-EFT}}(r)}{G_N m_1 m_2 / r}\right|$$

This residual is not a demand that the Noether sea be rewritten as a graviton field. It is a demand that the same weak-field constitutive record that yields redshift, lensing, and wave propagation also recover the long-distance quantum correction in the regime where the effective theory is predictive.

Massive-superposition entanglement experiments add a second low-energy quantum-gravity benchmark. If two isolated massive probes acquire an entanglement witness through gravity alone, the retained data product is the branch-dependent interaction phase, not a decision between graviton-field ontology and quantized-geometry ontology. The corresponding validation packet in Massive-Superposition Gravity Validation Packet requires the same effective-metric record θ to generate the mediated-entanglement phase while keeping non-gravitational coupling residuals bounded and preventing the gravity-side response from becoming an unmodeled which-path record.

Equivalence-Principle Channels

The weak equivalence principle and the strong equivalence principle are distinct benchmark rows. For two compact test assemblies A and B falling toward an external source S, define the composition residual

$$\eta^S_{AB} = \frac{2(a^S_A - a^S_B)}{a^S_A + a^S_B}$$

The weak equivalence row requires η^S_{AB} to vanish within the material-composition bounds while the same clock, signal, and PPN record is held fixed. The point is not to assume equivalence as a substrate axiom, but to recover it as an observer-level constraint on the same record θ_W. If local clock/ruler states for different apparatuses are allowed to absorb the gravitational response through material-dependent scale factors $\lambda_A(x^i_{\text{eff}};\theta_W)$, the residual must also satisfy

$$\mathcal{R}^S_{\text{scale-EP}}(\theta_W) = \max_{A,B} \frac{\|\nabla \ln(\lambda_A/\lambda_B)\|_W}{\|\nabla \Phi_{\text{eff}}\|_W / c_0^2 + \varepsilon} \ll 1$$

with the source assembly, boundary wake data, cosmological record, and PPN coefficients held fixed. This forbids a flat-description or local-unit rewriting from replacing universal gravitational acceleration by apparatus-specific material response.

The same statement can be read in mechanism language. Inertial response and gravitational response need not have identical substrate triggers: one can come from imposed acceleration of the assembly ledger, while the other can come from a Noether sea gradient. They recover the equivalence principle only if both triggers perturb the same shielded internal ledger through the same weak homogeneous response map. Any Mach-like dependence on the surrounding matter distribution must therefore appear as a common-mode feature of θ_W, not as a body-specific adjustment of inertia.

Equivalence recovery therefore couples the torsion-balance row, clock-comparison row, and cosmological/boundary record: a Mach-like dependence of inertial standards on the surrounding matter distribution is admissible only if it is common to the accepted observer record and leaves no composition-dependent acceleration residue.

A separate strong-equivalence row tests whether gravitational self-energy or medium binding changes the acceleration of extended bodies:

$$\eta_{\text{SEP}} = \frac{\Delta a_{\text{self}}}{a} \Big/ \left(\frac{E_{\text{grav},1}}{m_1 c_0^2} - \frac{E_{\text{grav},2}}{m_2 c_0^2}\right)$$

where the denominator compares gravitational binding-energy fractions for two bodies in the same external field. This row is a recovery target for lunar-ranging, binary-pulsar, and compact-body tests; it is not interchangeable with the material-composition torsion-balance row. The same residual bundle must also keep active, passive, inertial, and energy-defined mass equal in the nonrelativistic limit, or else the Newtonian and PPN rows are being fit with inconsistent mass concepts.

Preferred-Frame Leakage

Because the ontology contains an absolute frame, the observer-level phenomenology must still suppress preferred-frame signatures.

That means the effective PPN drift parameters

$$\alpha_1, \alpha_2, \alpha_3$$

must be observationally negligible in validated regimes. This is not optional. If the Noether sea leaves a measurable preferred-frame residue in the solar-system and pulsar regimes, the spacetime branch fails regardless of its conceptual elegance.

Gravitational-Wave Channel

The Noether sea picture must recover the observed near-luminal propagation of gravitational disturbances:

$$\left|\frac{v_{\mathrm{GW}} - c_0}{c_0}\right| \le \varepsilon_{\mathrm{GW}}$$

Here $\varepsilon_{\mathrm{GW}}$ is the multi-messenger speed tolerance owned by the GW Speed ledger row. In this framework, gravitational waves are propagating collective disturbances of the Noether sea. Their speed, dispersion, and polarization content must remain consistent with current timing bounds and detector-mode constraints. Any large medium-dispersion signature or unsuppressed scalar/vector/longitudinal response in already-tested bands is excluded. A cosmological-scale finite-range response must therefore decouple from the weak-field gravitational-wave channel through the same constitutive coefficient record, not through an observational-channel-specific patch.

Strong-Field Regime

Weak-field GR matching is the conservative requirement. Strong-field behavior is where the theory may differ.

Use the canonical event-horizon alignment condition defined in
singularity-resolution.md.

The strong-field interpretation is therefore:

- outside the alignment regime, GR-like effective geometry should emerge to the accuracy already tested,
- near the alignment regime, departures may appear through medium saturation, coplanarity, altered signal propagation, and assembly reconfiguration,
- but those departures must be stated as predictions, not used as excuses to miss weak-field closure.

The exterior benchmark still includes the standard compact-object scales before any native horizon-interface departure is promoted:

$$r_s = \frac{2G_N M}{c_0^2}, \qquad r_{\mathrm{ph}} = \frac{3G_N M}{c_0^2}, \qquad r_{\mathrm{ISCO}} = \frac{6G_N M}{c_0^2}$$

for the Schwarzschild comparison branch. The first is the effective horizon radius, the second the null photon-orbit radius, and the third the innermost stable circular orbit for massive test bodies in the nonrotating exterior comparison. A native black-hole record may reinterpret what the horizon is made of, but it must still recover these exterior scales, or provide a declared residual template, before using strong-field ontology to explain compact-object observations.

Closure Targets

This chapter is closed only if the spacetime branch can demonstrate all of the following from one constitutive map:

1. clock slowing / redshift,
2. Shapiro delay,
3. light bending,
4. 1PN orbital corrections,
5. the standard long-distance quantum-gravity EFT correction as an observer-level weak-field benchmark,
6. negligible preferred-frame leakage in tested regimes,
7. gravitational-wave speed, dispersion, and two-mode polarization compatibility,
8. non-arbitrary finite-boundary continuation wherever a strong-field or cosmological comparison invokes global extension assumptions.

The same coefficient set must survive all eight.

Falsification Gate

The GR-observables interface fails if any of the following occur:

- redshift, lensing, and Shapiro delay require different constitutive parameter choices,
- the long-distance quantum correction to the Newtonian potential requires an independent weak-field coefficient set,
- preferred-frame leakage exceeds the bounds recorded in constraint-ledger.md,
- gravitational-wave propagation departs from observational timing, dispersion, or polarization bounds in validated regimes,
- a strong-field or cosmology packet needs an unrecorded global assumption to select its continuation,
- or the weak-field map cannot recover the GR coefficients to the required precision while remaining consistent with the rest of the substrate story.

In compact form, the required acceptance set is

$$\mathcal{C}_{\mathrm{redshift}} \cap \mathcal{C}_{\mathrm{Shapiro}} \cap \mathcal{C}_{\mathrm{lensing}} \cap \mathcal{C}_{\mathrm{1PN}} \cap \mathcal{C}_{\mathrm{qG\text{-}EFT}} \cap \mathcal{C}_{\mathrm{PF}} \cap \mathcal{C}_{\mathrm{GW}} \cap \mathcal{C}_{\mathrm{cont}} \neq \varnothing$$

If that intersection is empty, the effective-metric program is not yet viable.

PPN Parameters

This chapter is the canonical home for weak-field/PPN expansion details used by
the spacetime constitutive map.

Canonical Symbols

- n: normalized Noether braid density, with $\rho_{\text{NS}} = \rho_{\text{NS},0} n$.
- χ_{sea}: Noether sea delay factor, $\chi_{\text{sea}} = c_f / c_{\text{eff}}$.
- $c_0 \equiv c_{\text{eff}}(\infty)$: asymptotic homogeneous observer-channel speed used in weak-field PPN comparisons.
- Φ_N: Newtonian benchmark potential.
- Φ_{eff}: constitutive effective potential from the clock channel.
- $U \equiv -\Phi_N > 0$: positive PPN expansion variable (default).
- $U_\Phi \equiv -\Phi_{\text{eff}} > 0$: constitutive-channel variant used when expanding directly in Φ_{eff}.

Mapping to PPN Constraints

1. **Shapiro Delay**: Map the GR time-delay (longer path in curved space) to the $\mathbb{AAA}$ time-delay (slower c_{eff} in the Noether sea).
2. **Light Bending**: Calculate Noether sea signal propagation through the density gradient around the Sun.
3. **Geodetic Precession**: Match the transport of an assembly's spin-orientation frame through the same weak-field effective metric used for clock, signal, and orbital tests.

Here, geodetic precession means the de Sitter precession of a carried gyroscope: after the gyroscope moves through a weak gravitational field, its spin axis is rotated relative to a distant reference frame. In $\mathbb{AAA}$ this should not be introduced as a separate torque law between angular momentum and a potential gradient. It is a closure target for the effective metric: the Noether sea-induced clock, ruler, and signal-response map must make transported assembly orientations precess by the same amount that GR predicts in the validated weak-field regime. Frame dragging from a rotating source is a separate test channel.

Testing the Euclidean Anchor (Shapiro Delay)

1. **The Test**: Calculate travel time of a signal from Earth to a probe behind the Sun using the Euclidean straight-line anchor supplied by the $\mathbb{U}_{\text{now}}$ state record.
2. $\mathbb{AAA}$ **Model**: Signal follows a straight Euclidean line. Delay is caused by increased Noether sea response near the Sun, expressed by the Noether sea delay factor χ_{sea}.
3. **Comparison**: Contrast $\Delta t_{\text{eff}}^{(\mathbb{AAA})}$ with the GR weak-field form.
4. $\mathbb{U}_{\text{now}}$ **Role**: $\mathbb{U}_{\text{now}}$ provides the "straight line" benchmark against which the "curved path" of GR is compared.

Explicit Weak-Field Noether Sea Delay Map (PPN γ)

Adopt a weak-field PPN-normalized Noether sea delay-factor ansatz for signal propagation in the Noether braid medium:

$$\bar{\chi}_{\text{sea}}(\mathbf{X}, T) \equiv \frac{c_0}{c_{\text{eff}}(\mathbf{X}, T)} = \frac{c_0}{c_f} \chi_{\text{sea}}(\mathbf{X}, T) = 1 - (1 + \gamma_{\text{eff}}) \frac{\Phi_N(\mathbf{X}, T)}{c_0^2} + \mathcal{O}\left(\frac{\Phi_N^2}{c_0^4}\right)$$

with $\Phi_N < 0$ near a mass source. For a point mass M,

$$\Phi_N(r) = -\frac{GM}{r} \quad \Rightarrow \quad \bar{\chi}_{\text{sea}}(r) = 1 + (1 + \gamma_{\text{eff}}) \frac{GM}{c_0^2 r} + \mathcal{O}\left(\frac{G^2 M^2}{c_0^4 r^2}\right)$$

For a one-way signal along a Euclidean straight path Γ (the $\mathbb{U}_{\text{now}}$ anchor),

$$t_{\rm eff}^{(\mathbb{AAA})} = \frac{1}{c_0}\int_\Gamma \bar\chi_{\rm sea}(\mathbf{X},T)\,ds = \frac{R}{c_0} + \Delta t_{\rm eff}^{(\mathbb{AAA})}$$

where $R = \int_\Gamma ds$ is Euclidean path length and

$$\Delta t_{\rm eff}^{(\mathbb{AAA})} = \frac{1}{c_0}\int_\Gamma(\bar\chi_{\rm sea}-1)\,ds = \frac{(1+\gamma_{\rm eff})GM}{c_0^3}\int_\Gamma \frac{ds}{r(s)} + \mathcal{O}\left(\frac{G^2M^2}{c_0^5}\right)$$

Evaluating the line integral for endpoint radii r_1, r_2 and Euclidean endpoint separation R gives

$$\Delta t_{\rm eff}^{(\mathbb{AAA})} = \frac{(1+\gamma_{\rm eff})GM}{c_0^3}\ln\left(\frac{r_1+r_2+R}{r_1+r_2-R}\right) + \mathcal{O}\left(\frac{G^2M^2}{c_0^5}\right)$$

which is the standard 1PN Shapiro form with $\gamma \to \gamma_{\rm eff}$ and $c \to c_0$. The primitive wake speed c_f remains in the unnormalized delay factor $\chi_{\rm sea} = c_f/c_{\rm eff}$; observer-facing PPN timing uses the asymptotic dressed speed c_0.

So the operational estimator is

$$\gamma_{\rm eff} = \frac{c_0^3\,\Delta t_{\rm obs}}{GM\ln\left(\frac{r_1+r_2+R}{r_1+r_2-R}\right)} - 1$$

with $\Delta t_{\rm obs} = t_{\rm obs} - R/c_0$.

In the weak-field solar-system regime, $\gamma_{\rm eff}$ is the direct refractive-space-curvature map parameter.

The same Shapiro map also fixes the first-order signal-delay response coefficient

$$a_\chi^{\rm sig} = 1 + \gamma_{\rm eff}$$

This is not automatically the clock coefficient a_χ used in the static Γ_N endpoint row. The shared clock/signal delay branch is the additional condition

$$\Delta_\chi^{\text{clk-sig}} \equiv a_\chi - a_\chi^{\rm sig} = 0$$

When this residual vanishes, Shapiro delay and gravitational clock redshift are using the same first-order Noether sea delay response. When it does not vanish, PPN delay, redshift, lensing, pressure-response, and cosmological redshift comparisons must carry the residual explicitly rather than refitting $\chi_{\rm sea}$ per observable.

PPN Parameters and the Euclidean Anchor

Parameter γ (Space Curvature / Refraction)

- **GR Context:** Measures the amount of space curvature produced by unit rest mass.
- $\mathbb{AAA}$ **Interpretation:** Measures the refractive response of the Noether sea. A massive body increases local assembly density, slowing the effective signal speed $c_{\rm eff}(\mathbf{X},T)$ relative to the asymptotic observer speed c_0 — the declared response-sign assumption of the weak-field branch, required for recovery rather than derived — while c_f remains the primitive wake speed.
- **Observable:** Shapiro-delay coefficient in the explicit refractive integral above.

The light-bending half-test makes the same point numerically. A lapse-only weak-field map gives the Newtonian-scale deflection

$$\Delta\theta_{\rm half} = \frac{2GM}{b\,c_0^2}$$

while the full GR-matching target is

$$\Delta\theta_{\rm GR} = \frac{4GM}{b\,c_0^2}$$

In the forward projection below, the missing half is precisely the $\gamma_{\rm eff}$ spatial-compliance contribution. Therefore a constitutive map cannot claim PPN closure by matching Shapiro delay with a scalar delay factor while leaving the ruler/spatial-compliance row undefined.

Parameter β (Non-linearity of Gravity)

- **GR Context:** Measures the non-linearity in the superposition of gravitational fields.
- $\mathbb{AAA}$ **Interpretation:** Captures second-order (in potential) clock/medium response from self-hit and Noether sea constitutive nonlinearity.
- **Explicit map from constitutive expansion:** Let $U \equiv -\Phi_N > 0$. For a declared weak-field branch — conditional, like every weak-field expansion in this chapter, on the homogeneous quiescent Noether sea being an equilibrium of the constitutive dynamics, an open closure item of the Noether sea program — expand the static clock law with branch-local constitutive coefficient C_2:

$$\left.\frac{d\tau}{dt_{\text{eff}}}\right|_{v=0} = 1 - \frac{U}{c_0^2} + C_2\frac{U^2}{c_0^4} + \mathcal{O}\left(\frac{U^3}{c_0^6}\right)$$

Since $-g_{00} = (d\tau/dt_{\text{eff}})^2$ for a static observer,

$$g_{00} = -1 + 2\frac{U}{c_0^2} - \left[1 + 2C_2\right]\frac{U^2}{c_0^4} + \mathcal{O}\left(\frac{U^3}{c_0^6}\right)$$

Match to the PPN form

$$g_{00}^{\text{PPN}} = -1 + 2\frac{U}{c_0^2} - 2\beta_{\text{eff}}\frac{U^2}{c_0^4} + \cdots$$

to obtain

$$\boxed{\beta_{\text{eff}} = \frac{1 + 2C_2}{2}}$$

No cosmological (a, k) dependence is implied here; those arguments are reserved for effective cosmology transfer variables such as $\mu(a, k)$ and $G_{\text{eff}}(a, k)$.

- **Observable:** Perihelion precession and other 1PN nonlinear-potential tests.

Exponential clock-law subclass (direct map)

If the constitutive clock channel is exactly

$$\Omega\xi = e^{\Phi_{\text{eff}}/c_0^2}, \qquad g_{00} = -(\Omega\xi)^2$$

then with $U_\Phi \equiv -\Phi_{\text{eff}}$:

$$g_{00} = -e^{2\Phi_{\text{eff}}/c_0^2} = -1 + 2\frac{U_\Phi}{c_0^2} - 2\frac{U_\Phi^2}{c_0^4} + O(c_0^{-6})$$

so this subclass yields

$$\boxed{\beta_{\text{PPN}} = 1}$$

without additional fit freedom.

Here $\Omega\xi$ is the local clock-rate factor $d\tau/dt_{\text{eff}}$ in this subclass. The Noether sea cadence-stretch factor used in redshift bookkeeping is its inverse, $\Gamma_N = (\Omega\xi)^{-1}$, when the same local clock channel is being compared.

The general C_2 map above remains the umbrella constitutive form; the exponential channel is the closure-special case where it collapses to GR's $\beta = 1$ exactly.
When $\Phi_{\text{eff}} = \Phi_N + O(\Phi_N^2/c_f^2)$ at the native constitutive level, one has $U_\Phi = U + O(U^2/c_f^2)$ at weak field before observer-channel normalization to the c_0-based PPN expansion.

Preferred Frame Parameters ($\alpha_1, \alpha_2, \alpha_3$)

- **Crucial test:** In the effective relativistic limit these must vanish (no measurable preferred-frame leakage).
- **Constitutive leakage ansatz:** Let $\mathbf{w} = \mathbf{V}_{\text{cm}} - \mathbf{u}_{\text{sea}}$ be the barycentric laboratory or source-frame drift through the local Noether sea, matching the clock convention in which the material assembly moves relative to the sea. Write the lowest-order drift terms as

$$g_{0i}^{\text{leak}} = -\frac{1}{2}\Xi_1\frac{w_i U}{c_0^3} - \Xi_2\frac{w^j U_{ij}}{c_0^3}$$

$$g_{00}^{\text{leak}} = -\Xi_3\frac{w^2 U}{c_0^4} - \Xi_2\frac{w^i w^j U_{ij}}{c_0^4} + \Xi_4\frac{w^i V_i}{c_0^3}$$

Matching to standard PPN preferred-frame structure gives

$$\boxed{\alpha_1 = \Xi_1}, \qquad \boxed{\alpha_2 = \Xi_2}$$

$$\boxed{\alpha_3 = \Xi_1 - \Xi_2 - \Xi_3}$$

with consistency relation

$$\Xi_4 = 2\alpha_3 - \alpha_1 = \Xi_1 - 2\Xi_2 - 2\Xi_3$$

If a comparison source instead defines $\mathbf{w}_{\rm sea} = -\mathbf{w}$, all odd-in-$\mathbf{w}$ preferred-frame terms must be sign-translated before reading off the $\Xi_i \to \alpha_i$ map.

Terrestrial Working Drift Profiles

Terrestrial preferred-frame rows need a declared $\mathbf{u}_{\rm sea}$ profile before their $\beta_\oplus$ dependence can be evaluated numerically. Use the CMB dipole only as an observer-level comparison direction, not as proof that the CMB frame is the substrate's absolute rest frame. In that comparison chart, decompose a laboratory velocity as

$$\mathbf{V}_{\rm lab}(t_{\rm eff}) = \mathbf{V}_{\rm CMB} + \mathbf{V}_{\rm orb}(t_{\rm eff}) + \mathbf{V}_{\rm rot}(t_{\rm eff}) + \mathbf{v}_A(t_{\rm eff}),$$

where $\mathbf{V}_{\rm CMB}$ is the Solar-system motion inferred from the CMB dipole, $\mathbf{V}_{\rm orb}$ and $\mathbf{V}_{\rm rot}$ are the terrestrial orbital and rotational contributions, and $\mathbf{v}_A$ is the apparatus motion relative to the laboratory. A two-coefficient working family brackets the unresolved Noether sea response:

$$\mathbf{u}^{(f)}_{\rm sea}(t_{\rm eff}) = f_{\rm tr}\left[\mathbf{V}_{\rm CMB} + \mathbf{V}_{\rm orb}(t_{\rm eff})\right] + f_{\rm rot}\mathbf{V}_{\rm rot}(t_{\rm eff}), \qquad 0 \le f_{\rm tr}, f_{\rm rot} \le 1,$$

so that

$$\mathbf{w}^{(f)}_A = (1 - f_{\rm tr})\left(\mathbf{V}_{\rm CMB} + \mathbf{V}_{\rm orb}\right) + (1 - f_{\rm rot})\mathbf{V}_{\rm rot} + \mathbf{v}_A.$$

The non-entrained comparison is $(f_{\rm tr}, f_{\rm rot}) = (0, 0)$. Ignoring the smaller annual, daily, and apparatus contributions, the measured CMB dipole gives $|\mathbf{w}_\oplus| \approx 369\,\mathrm{km\,s^{-1}}$ and therefore $\beta_\oplus \approx 1.23 \times 10^{-3}$ when c_0 is the comparison speed. Translational entrainment uses $f_{\rm tr} \to 1$ while leaving the rotational row independently testable; local co-rotation also takes $f_{\rm rot} \to 1$. These are evaluation profiles, not derived constitutive solutions.

The existing preferred-motion bundle separates the profiles through their predicted annual and sidereal phase and amplitude. Ground-to-orbit clock and resonator comparisons add the radial discriminator: a profile that becomes less entrained with altitude changes $\mathbf{w}^{(f)}_A$ across the trajectory, whereas a CMB-comoving profile preserves the leading dipole-scale drift. The same $(f_{\rm tr}, f_{\rm rot})$ values must be used in clock, interferometer, matter-sector, and PPN rows; fitting a different terrestrial drift profile to each channel would not close the preferred-frame map.

Rotating-Source Frame Dragging

Preferred-frame leakage and physical source-current response are different g_{0i} channels. Setting $\alpha_1 = \alpha_2 = \alpha_3 = 0$ must remove dependence on a laboratory's drift through the Noether sea without removing the positive weak-field response to a rotating source. For source angular momentum $\mathbf{J}$ and $\mathbf{r} = r\hat{\mathbf{r}}$, the standard comparison row in the declared $x^0_{\rm eff} = c_0 t_{\rm eff}$ convention is

$$g^{\rm drag}_{0i} = -\frac{2G_N}{c_0^3}\frac{(\mathbf{J} \times \mathbf{r})_i}{r^3} + O(c_0^{-5}).$$

The corresponding carried-gyroscope target is the Lense-Thirring precession

$$\mathbf{\Omega}_{\rm LT} = \frac{G_N}{c_0^2 r^3}\left[3\hat{\mathbf{r}}(\mathbf{J}\cdot\hat{\mathbf{r}}) - \mathbf{J}\right].$$

In the constitutive map, this row must be projected from the same rotating-source angular-momentum ledger and Noether sea vorticity response that supply $u^i_{\rm sea,eff}$. The separation requirement is

$$g^{\rm eff}_{0i} = g^{\rm drag}_{0i}(\mathbf{J}) + g^{\rm leak}_{0i}(\mathbf{w}) + O(c_0^{-5}), \qquad g^{\rm leak}_{0i} \to 0 \text{ while } g^{\rm drag}_{0i} \not\to 0$$

for a rotating source. Lense-Thirring and geodetic precession must therefore be recovered from one effective metric but remain distinct observable projections.

Remaining PPN Parameters

The five-parameter rows used in the numerical examples below are a reduced subset, not the full PPN space. The full observer-level decision layer also contains the preferred-location parameter $\xi_{\rm W}$ and the conservation-law parameters $\zeta_1, \zeta_2, \zeta_3, \zeta_4$. The subscript on $\xi_{\rm W}$ is mandatory because the undecorated $\xi = R_\parallel/R_\perp$ is the Noether braid envelope shape ratio. Likewise, the PPN ζ_i must not be confused with the apparatus-calibration nuisance ζ_A used in the preferred-motion bundle.

For a GR-matching branch, the additional targets are

$$\xi_{\rm W} = \zeta_1 = \zeta_2 = \zeta_3 = \zeta_4 = 0.$$

Here $\xi_{\rm W}$ tests preferred-location leakage, while nonzero ζ_i would signal failure of the effective momentum/conservation bookkeeping. A wake-ledger theory cannot infer these zeros from notation: the same architrino-plus-wake-plus-medium record that closes total energy and momentum must project them below their observer-level bounds.

Zero-Leakage Conditions (Preferred-Frame Closure)

The effective theory is preferred-frame safe at the retained order if and only if all laboratory-drift couplings vanish:

$$\Xi_1 = \Xi_2 = \Xi_3 = \Xi_4 = 0 \quad \Longleftrightarrow \quad \alpha_1 = \alpha_2 = \alpha_3 = 0$$

Equivalent constitutive conditions:

$$\left.\frac{\partial g_{\mu\nu}}{\partial w_i}\right|_{\mathbf{w}=0} = 0, \qquad \left.\frac{\partial^2 g_{00}}{\partial w_i \partial w_j}\right|_{\mathbf{w}=0} \propto \delta_{ij} \text{ with zero traceless part}$$

and no momentum-density coupling term $w^i V_i$ at the retained PN order.

The coefficients $(\Xi_1, \Xi_2, \Xi_3, \Xi_4)$ parameterize preferred-frame leakage terms in the weak-field constitutive expansion.
This condition does not set the rotating-source row $g_{0i}^{\text{drag}}(\mathbf{J})$ to zero.

Preferred-Motion Null-Test Bundle

Historical clock, interferometer, Zeeman-splitting, and gravimeter tests show how many different apparatus types can search for the same preferred-frame leakage without sharing the same dominant nuisance. In $\mathbb{AAA}$ this becomes a bundle test on the same drift coefficients, not a set of independent fit parameters. For an apparatus channel A with orientation $\hat{\mathbf{n}}_A(t_{\text{eff}})$ and laboratory drift $\mathbf{w}(t_{\text{eff}})$ through the local Noether sea, write the leading fractional readout as

$$y_A(t_{\text{eff}}) = y_{A,0} + \mathbf{s}_A^{\mathsf{T}} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix} \frac{w^2(t_{\text{eff}})}{c_0^2} + \zeta_A \frac{\left(\mathbf{w}(t_{\text{eff}}) \cdot \hat{\mathbf{n}}_A(t_{\text{eff}})\right)^2 - w^2(t_{\text{eff}})/3}{c_0^2} + n_A(t_{\text{eff}})$$

Here $\mathbf{s}_A$ is the PPN sensitivity row for the channel, ζ_A is an allowed apparatus-calibration nuisance fixed by the instrument model, n_A is detector/environment noise, and y_A^θ is the model readout projected from the retained record tuple θ. The shared preferred-frame residual is

$$\mathcal{R}_{\text{PF-bundle}} = \sum_A \left\| y_A^{\text{obs}} - y_A^\theta \right\|_{C_A^{-1}}^2 + \lambda_{\text{PF}} \left(\alpha_1^2 + \alpha_2^2 + \alpha_3^2\right)$$

The bundle fails if one clock or material channel requires a nonzero α_i that another channel excludes, or if the orientation/annual term is hidden in ζ_A rather than projected through $(\Xi_1, \Xi_2, \Xi_3, \Xi_4)$.

Weak-Field Constraint Table (Decision Layer)

Use this table to close the constitutive loop against modern benchmarks.

Channel	Model estimator	GR/PPN target	Closure requirement
Time nonlinearity	β_{PPN} from g_{00} expansion	$\beta_{\text{PPN}} = 1$	Residual inside ledger tolerance
Space curvature/refraction	γ_{eff} from the shared spatial-compliance row, with Shapiro and lensing as projections	$\gamma_{\text{PPN}} = 1$	Residual inside ledger tolerance
Preferred-frame leakage	$(\alpha_1, \alpha_2, \alpha_3)$ from $(\Xi_1, \Xi_2, \Xi_3, \Xi_4)$	all ≈ 0	No significant nonzero leakage
Rotating-source frame dragging	$g_{0i}^{\text{drag}}(\mathbf{J})$ and $\mathbf{\Omega}_{\text{LT}}$ from the source-current row	Lense-Thirring comparison	Recover the nonzero source response without preferred-frame leakage
Preferred-location leakage	ξ_{W} from the same effective metric record	$\xi_{\text{W}} = 0$	No significant nonzero leakage
Conservation-law leakage	$(\zeta_1, \zeta_2, \zeta_3, \zeta_4)$ from the full architrino-plus-wake-plus-medium ledger	all $= 0$	No observer-level nonconservation residual
Newtonian limit	$\mathbf{a} = -\nabla\Phi_{\text{eff}}$ (weak field)	exact leading-order recovery	No constitutive contradiction
Cross-observable consistency	same constitutive coefficients across delay, redshift, precession, lensing, acceleration, and preferred-frame tests	single-parameter-set closure	No per-observable re-fit

Numeric pass/fail thresholds are taken from validation/constraint-ledger.md.

Source-Mined Benchmark Bound Vector

The current Will-style numerical comparison is not a single “GR matches” flag. It is a reduced five-row bound vector on the channels already carried by the numerical fit:

$$\mathbf{b}_{\text{Will}} = \begin{pmatrix} 2.3 \times 10^{-5} \\ 8 \times 10^{-5} \\ 4 \times 10^{-5} \\ 2 \times 10^{-9} \\ 4 \times 10^{-20} \end{pmatrix}$$

ordered as

$$(|\gamma_{\rm PPN}-1|, |\beta_{\rm PPN}-1|, |\alpha_1|, |\alpha_2|, |\alpha_3|)$$

The first row is the Cassini time-delay bound on $\gamma_{\rm PPN}-1$; the second uses the perihelion-shift row for $\beta_{\rm PPN}-1$; the preferred-frame rows use the best listed weak-field/strong-field analogue bounds, namely the α_1 row from lunar-laser-ranging plus binary-pulsar bounds, the α_2 row from the solar-spin-axis alignment bound, and the α_3 row from pulsar-population $\dot{p}$ statistics, per the Will PPN living-review compilation. Strong-field pulsar bounds should not be silently reclassified as solar-system PPN measurements, but they are valid closure pressure: any $\mathbb{AAA}$ drift leakage that survives in ordinary clocks, orbits, or pulsar timing must project below the corresponding row unless a separate strong-field screening mechanism is derived.

The decision residual is therefore the componentwise normalized vector

$$\mathbf{q}_{\rm PPN} = \mathrm{diag}(\mathbf{b}_{\rm Will})^{-1} \begin{pmatrix} \gamma_{\rm PPN}-1 \\ \beta_{\rm PPN}-1 \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

Weak-field closure requires

$$\|\mathbf{q}_{\rm PPN}\|_\infty \le 1$$

before any strong-field deviation is advertised as a prediction. This is stricter than matching Shapiro delay alone because it forces the same constitutive metric row to suppress preferred-frame terms in $g^{\rm eff}_{0i}$ and $g^{\rm eff}_{00}$.

The SME-style Lorentz-test family supplies a second, non-PPN layer. Photon-sector cavity tests constrain two-way orientation-dependent frequency shifts at the $\Delta\nu/\nu \sim 10^{-18}$ level, while the SME data tables organize photon, matter, neutrino, and gravity coefficients in the standard Sun-centered frame. For this chapter the safe import is not a new ontology. It is the validation rule that any effective metric or clock/ruler channel must report which SME-like residual it would excite:

$$\epsilon^{\rm eff}_{\rm SME} = \max\left(\|\tilde{\kappa}^{\rm eff}_{e-}\|, \|\tilde{\kappa}^{\rm eff}_{o+}\|, |\tilde{\kappa}^{\rm eff}_{\rm tr}|, \|\bar{s}^{\mu\nu}_{\rm eff}\|\right)$$

with $\tilde{\kappa}^{\rm eff}_{\bullet}$ used as photon-sector comparison coefficients and $\bar{s}^{\mu\nu}_{\rm eff}$ used as a gravity-sector comparison coefficient. These are observer-level projection diagnostics; they are not substrate coefficients added to the Euclidean void.

Closure Program Interface (Observable Decision Layer)

This chapter is the observable-side gate for the emergent-metric closure.

Define the PPN decision vector:

$$\mathbf{p}_{\rm PPN} = \left(\gamma_{\rm eff}-1,\ \beta_{\rm eff}-1,\ \xi_{\rm W},\ \alpha_1,\ \alpha_2,\ \alpha_3,\ \zeta_1,\ \zeta_2,\ \zeta_3,\ \zeta_4\right)$$

The weak-field closure target is

$$\mathbf{p}_{\rm PPN} \approx \mathbf{0}$$

within the benchmark tolerances listed in the validation ledger.

The synthetic calibration and likelihood sections below remain explicitly reduced fits over $(\gamma_{\rm eff}, C_2, \Xi_1, \Xi_2, \Xi_3)$. They do not numerically evaluate $\xi_{\rm W}$, ζ_i, or the Lense-Thirring source-current row, so passing those reduced examples is not full PPN closure.

Cross-chapter integration:

- constitutive map source: spacetime/emergent-metric.md
- clock-law coefficient extraction: spacetime/proper-time-and-time-dilation.md
- threshold enforcement: validation/constraint-ledger.md

ADM/Cartan Extraction Equations

The PPN vector must be extracted from the same ADM/Cartan fields used by the effective metric map, not from observable-specific fits. With $x^0_{\rm eff} = c_0 t_{\rm eff}$, the line element

$$ds^2_{\rm eff} = -N^2 c_0^2 dt^2_{\rm eff} + \gamma^{\rm eff}_{ij}\left(dx^i_{\rm eff} - u^i_{\rm sea,eff}dt_{\rm eff}\right)\left(dx^j_{\rm eff} - u^j_{\rm sea,eff}dt_{\rm eff}\right)$$

gives the observer-sector metric components

$$g_{00}^{\mathrm{eff}} = -N^2 + \frac{\gamma_{ij}^{\mathrm{eff}} u_{\mathrm{sea,eff}}^i u_{\mathrm{sea,eff}}^j}{c_0^2}, \qquad g_{0i}^{\mathrm{eff}} = -\frac{\gamma_{ij}^{\mathrm{eff}} u_{\mathrm{sea,eff}}^j}{c_0}, \qquad g_{ij}^{\mathrm{eff}} = \gamma_{ij}^{\mathrm{eff}}$$

In the local Noether sea rest weak-field row, write

$$N = 1 - \frac{U_\Phi}{c_0^2} + C_2 \frac{U_\Phi^2}{c_0^4} + O(c_0^{-6}, \epsilon_{\mathrm{LV}})$$

and extract

$$\gamma_{\mathrm{PPN}} = \frac{c_0^2}{2U_\Phi}\left(\frac{h^{ij}\gamma_{ij}^{\mathrm{eff}}}{3} - 1\right) + O(U_\Phi/c_0^2, \epsilon_{\mathrm{LV}}), \qquad \beta_{\mathrm{PPN}} - 1 = C_2 - \frac{1}{2}$$

The preferred-frame coefficients are the retained drift coefficients in g_{0i}^{eff} and g_{00}^{eff} under the $(\Xi_1, \Xi_2, \Xi_3, \Xi_4)$ expansion above, with

$$\alpha_1 = \Xi_1, \qquad \alpha_2 = \Xi_2, \qquad \alpha_3 = \Xi_1 - \Xi_2 - \Xi_3$$

For a declared observation window W and retained record tuple θ, the shared weak-field residual can be recorded as

$$\mathbf{r}_{\mathrm{weak}}(\theta; W) = \begin{pmatrix} R_{\mathrm{red}} \\ R_{\mathrm{Shap}} \\ R_{\mathrm{lens}} \\ R_{\mathrm{acc}} \\ \gamma_{\mathrm{PPN}} - 1 \\ \beta_{\mathrm{PPN}} - 1 \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

with

$$R_{\mathrm{acc}} = \frac{\left\| \frac{d^2 x_{\mathrm{eff}}^i}{dt_{\mathrm{eff}}^2} + \gamma_{\mathrm{eff}}^{ij} \partial_{x_{\mathrm{eff}}^j} \Phi_{\mathrm{eff}} \right\|_W}{\left\| \gamma_{\mathrm{eff}}^{ij} \partial_{x_{\mathrm{eff}}^j} \Phi_{\mathrm{eff}} \right\|_W + \varepsilon}$$

The other residuals are the redshift, Shapiro, and lensing differences computed from the same retained record tuple θ and the forward projection below. This strengthens the existing decision layer; it is not a separate gate.

Numeric Closure Pipeline and Global Objective

To enforce cross-observable closure without parameter bloat, use a single constitutive vector and a fixed projection to the PPN decision manifold.

Define the PPN constitutive vector

$$\boldsymbol{\vartheta}_{\mathrm{PPN}} \equiv \begin{pmatrix} \gamma_{\mathrm{eff}} \\ C_2 \\ \Xi_1 \\ \Xi_2 \\ \Xi_3 \end{pmatrix}, \qquad \mathbf{p}_{\mathrm{PPN}} \equiv \begin{pmatrix} \gamma_{\mathrm{PPN}} - 1 \\ \beta_{\mathrm{PPN}} - 1 \\ \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{pmatrix}$$

Using

$$\beta_{\mathrm{PPN}} - 1 = \left(\frac{1 + 2C_2}{2}\right) - 1 = C_2 - \frac{1}{2}, \qquad \alpha_1 = \Xi_1,\ \alpha_2 = \Xi_2,\ \alpha_3 = \Xi_1 - \Xi_2 - \Xi_3$$

the map is the exact linear projection

$$\mathbf{p}_{\mathrm{PPN}} = \mathbf{J}\boldsymbol{\vartheta}_{\mathrm{PPN}} - \mathbf{p}_0$$

with

$$\mathbf{p}_0 = \begin{pmatrix} 1 \\ \frac{1}{2} \\ 0 \\ 0 \\ 0 \end{pmatrix}, \qquad \mathbf{J} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & -1 & -1 \end{pmatrix}$$

If Σ_ϑ is the covariance of the constitutive fit from micro-simulations, propagate uncertainty by

$$\Sigma_{\mathrm{PPN}} = \mathbf{J}\Sigma_{\vartheta}\mathbf{J}^{\mathsf{T}}$$

Define the single Tier-1 weighted closure objective

$$\mathcal{L}(\boldsymbol{\vartheta}_{\mathrm{PPN}}) = \mathbf{p}_{\mathrm{PPN}}^{\mathsf{T}}\mathbf{W}\,\mathbf{p}_{\mathrm{PPN}}$$

where $\mathbf{W}$ is the precision matrix from ledger tolerances.
With the source-mined benchmark vector above,

$$\mathbf{W} = \mathrm{diag}\big((2.3\times10^{-5})^{-2}, (8\times10^{-5})^{-2}, (4\times10^{-5})^{-2}, (2\times10^{-9})^{-2}, (4\times10^{-20})^{-2}\big)$$

Forward-only evaluation rule:

1. Calibrate $\boldsymbol{\vartheta}_{\mathrm{PPN}}$ and Σ_{ϑ} from micro-scale clock/refraction simulations.
2. Project once to $(\mathbf{p}_{\mathrm{PPN}}, \Sigma_{\mathrm{PPN}})$ and evaluate $\mathcal{L}(\boldsymbol{\vartheta}_{\mathrm{PPN}})$.
3. Predict macroscopic observables (Shapiro, precession, redshift, lensing) with this fixed parameter set.
4. If any observable fails its ledger gate, reject the constitutive map; do not refit per observable.

Forward Observable Projection (Weak-Field Classical Set)

To force cross-observable closure in a single forward pass, define

$$\mathbf{O}(\boldsymbol{\vartheta}_{\mathrm{PPN}}) \equiv \begin{pmatrix} \Delta t_{\mathrm{Shap}} \\ \Delta\phi_{\mathrm{Def}} \\ \Delta\omega_{\mathrm{Prec}} \\ z_{\mathrm{Red}} \end{pmatrix}$$

Using the weak-field constitutive map of $\mathbb{AAA}$:

1. Shapiro delay:

$$O_1(\boldsymbol{\vartheta}_{\mathrm{PPN}}) = K_{\mathrm{Shap}}(1+\gamma_{\mathrm{eff}}), \qquad K_{\mathrm{Shap}} = \frac{GM}{c_0^3}\ln\!\left(\frac{r_1+r_2+R}{r_1+r_2-R}\right)$$

For two-way radar-style Shapiro measurements, apply the same kernel on each leg and sum the two one-way contributions.
2. Light deflection:

$$O_2(\boldsymbol{\vartheta}_{\mathrm{PPN}}) = K_{\mathrm{Def}}(1+\gamma_{\mathrm{eff}}), \qquad K_{\mathrm{Def}} = \frac{2GM}{b\,c_0^2}$$

3. Perihelion precession per orbit:

$$O_3(\boldsymbol{\vartheta}_{\mathrm{PPN}}) = K_{\mathrm{Prec}}\,(2+2\gamma_{\mathrm{PPN}}-\beta_{\mathrm{PPN}}) = K_{\mathrm{Prec}}\,(1.5+2\gamma_{\mathrm{eff}}-C_2)$$

$$K_{\mathrm{Prec}} = \frac{2\pi GM}{a(1-e^2)c_0^2}$$

4. Gravitational redshift (to retained order):

$$O_4(\boldsymbol{\vartheta}_{\mathrm{PPN}}) = K_{\mathrm{Red1}} - K_{\mathrm{Red2}}C_2, \qquad K_{\mathrm{Red1}} = \frac{\Delta U}{c_0^2}, \quad K_{\mathrm{Red2}} = \frac{\Delta(U^2)}{c_0^4}$$

First-order observable sensitivities are

$$\mathbf{J}_O \equiv \frac{\partial\mathbf{O}}{\partial\boldsymbol{\vartheta}_{\mathrm{PPN}}} = \begin{pmatrix} K_{\mathrm{Shap}} & 0 & 0 & 0 & 0 \\ K_{\mathrm{Def}} & 0 & 0 & 0 & 0 \\ 2K_{\mathrm{Prec}} & -K_{\mathrm{Prec}} & 0 & 0 & 0 \\ 0 & -K_{\mathrm{Red2}} & 0 & 0 & 0 \end{pmatrix}$$

and the propagated covariance is

$$\Sigma_O = \mathbf{J}_O\Sigma_{\vartheta}\mathbf{J}_O^{\mathsf{T}}$$

For this spherically symmetric classical set, preferred-frame channels (Ξ_1, Ξ_2, Ξ_3) decouple at leading order; they are constrained by dedicated drift/leakage observables.

Worked Solar-System Reference Projection (Synthetic Calibration Example)

Use

$$\frac{GM_\odot}{c_0^2} = 1.4766 \times 10^3\ \mathrm{m}, \qquad \frac{GM_\odot}{c_0^3} = 4.925 \times 10^{-6}\ \mathrm{s}$$

with reference kernels

$$K_{\rm Shap} = 70.4\ \mu\mathrm{s}, \quad K_{\rm Def} = 0.875'', \quad K_{\rm Prec} = 14.3''/\mathrm{cy}, \quad K_{\rm Red1} = 2.12 \times 10^{-6}, \quad K_{\rm Red2} = 4.50 \times 10^{-12}$$

Take a synthetic constitutive fit

$$\boldsymbol{\vartheta}_{\rm PPN} = \begin{pmatrix} 1 + 1.2 \times 10^{-5} \\ 0.5 + 0.8 \times 10^{-5} \\ 10^{-18} \\ -0.5 \times 10^{-18} \\ 0.2 \times 10^{-18} \end{pmatrix}$$

$$\Sigma_\vartheta = \mathrm{diag}\big(0.25 \times 10^{-10}, 0.16 \times 10^{-10}, 10^{-36}, 10^{-36}, 10^{-36}\big)$$

This block is an internal consistency projection example, not a claim of experimental pass/fail by itself.

Projection to decision space gives

$$\gamma_{\rm PPN} - 1 = 1.2 \times 10^{-5}, \quad \beta_{\rm PPN} - 1 = 0.8 \times 10^{-5}, \quad (\alpha_1, \alpha_2, \alpha_3) = \big(10^{-18}, -0.5 \times 10^{-18}, 1.3 \times 10^{-18}\big)$$

Forward observables are

$$\Delta t_{\rm Shap} = 140.80084\ \mu\mathrm{s}, \quad \Delta\phi_{\rm Def} = 1.75001\,\mathrm{arcsec}, \quad \Delta\omega_{\rm Prec} = 42.9002\,\mathrm{arcsec/cy}$$

$$z_{\rm Red} \approx 2.119997 \times 10^{-6}$$

Propagated 1σ scales (diagonal approximation) are

$$\sigma_{\rm Shap} \approx 3.5 \times 10^{-4}\ \mu\mathrm{s}, \quad \sigma_{\rm Def} \approx 4.3 \times 10^{-6}\,\mathrm{arcsec}, \quad \sigma_{\rm Prec} \approx 1.5 \times 10^{-4}\,\mathrm{arcsec/cy}, \quad \sigma_{\rm Red} \approx 1.8 \times 10^{-17}$$

Failure rule for this closure layer:
if any observed value lies outside

$$\mathbf{O}(\boldsymbol{\vartheta}_{\rm PPN}) \pm 3\sqrt{\mathrm{diag}(\Sigma_O)}$$

the constitutive map fails this gate and must be replaced rather than re-fit per observable.

Benchmark-Input Joint Likelihood (Reduced Fit)

This reduced likelihood uses benchmark rows as inputs to test internal projection consistency; it is not an archived end-to-end reprocessing of the raw experiments. Using the forward map above, define the joint likelihood

$$\ln \mathcal{L}(\boldsymbol{\vartheta}_{\rm PPN}) = -\frac{1}{2}\big(\mathbf{O}(\boldsymbol{\vartheta}_{\rm PPN}) - \mathbf{O}_{\rm obs}\big)^{\mathsf{T}} \Sigma_{\rm obs}^{-1} \big(\mathbf{O}(\boldsymbol{\vartheta}_{\rm PPN}) - \mathbf{O}_{\rm obs}\big)$$

with

$$\boldsymbol{\vartheta}_{\rm PPN} = (\gamma_{\rm eff}, C_2, \Xi_1, \Xi_2, \Xi_3)^{\mathsf{T}}$$

Benchmark observable inputs for the classical weak-field suite are:

1. Cassini Shapiro: $\gamma_{\rm obs} - 1 = (2.1 \pm 2.3) \times 10^{-5}$.
2. VLBI solar deflection: $\gamma_{\rm obs} - 1 = (-0.8 \pm 1.2) \times 10^{-4}$.
3. Mercury precession combination: $(2\gamma_{\rm obs} - \beta_{\rm obs}) = 1 \pm 3.0 \times 10^{-5}$.
4. Galileo/GPA redshift channel: first-order limit $\sim 2.5 \times 10^{-5}$ with weak second-order sensitivity to C_2.

For this spherical classical set, the Jacobian structure satisfies

$$\frac{\partial \mathbf{O}}{\partial \Xi_1} = \frac{\partial \mathbf{O}}{\partial \Xi_2} = \frac{\partial \mathbf{O}}{\partial \Xi_3} = \mathbf{0}$$

so the Fisher matrix is rank-2 in this fit and (Ξ_1, Ξ_2, Ξ_3) remain unconstrained by this subset alone.

The following is an inline reduced-fit example; no archived artifact, reproducible from the declared formulas and inputs above.

Reducing to $\boldsymbol{\vartheta}_{\rm red} = (\gamma_{\rm eff}, C_2)^{\mathsf{T}}$, the inferred covariance is

$$\Sigma_{\text{red}} = \begin{pmatrix} 5.1\times10^{-10} & 1.02\times10^{-9} \\ 1.02\times10^{-9} & 2.94\times10^{-9} \end{pmatrix}$$

with maximum-likelihood point

$$\gamma_{\text{eff}} = 1 + (2.03 \pm 2.26)\times10^{-5}, \qquad C_2 = 0.5 + (4.06 \pm 5.42)\times10^{-5}$$

and correlation

$$\rho(\gamma_{\text{eff}}, C_2) = +0.83$$

Interpretation for closure:

1. A single constitutive vector can fit the selected classical observables without per-observable retuning; read this as consistency of the projection algebra, not independent evidence for the constitutive map.
2. Preferred-frame channels require additional drift-sensitive observables (LLR, pulsar timing, dedicated anisotropy tests) to close (Ξ_1, Ξ_2, Ξ_3) .
3. The positive γ_{eff}-C_2 covariance defines the accepted trade-off direction when matching precession jointly with refractive observables.

Preferred-Frame Parameter Degeneracy Resolution (Augmented Likelihood)

Define the preferred-frame constitutive vector

$$\boldsymbol{\Xi} \equiv (\Xi_1, \Xi_2, \Xi_3)^{\mathsf{T}}$$

For the spherical classical set above, $\boldsymbol{\Xi}$ is unconstrained. For an expanded drift-sensitive baseline (ephemerides + LLR + anisotropy channels), treat the preferred-frame Fisher block as

$$\mathcal{I}_{\Xi,\text{base}} = -\mathbb{E}\left[\nabla_{\boldsymbol{\Xi}} \nabla_{\boldsymbol{\Xi}}^{\mathsf{T}} \ln \mathcal{L}_{\text{base}}\right]$$

with rank-2 degeneracy and null direction $\hat{n}$:

$$\mathcal{I}_{\Xi,\text{base}} \hat{n} = \mathbf{0}$$

Minimal augmentation:

1. Binary-pulsar eccentricity drift channel $\dot{e}$ (orbital polarization sensitivity).
2. Solitary millisecond-pulsar spin channel $\dot{P}$ (self-acceleration sensitivity).

Use joint likelihood

$$\ln \mathcal{L}_{\text{joint}}(\boldsymbol{\Xi} \mid \mathcal{D}) = \ln \mathcal{L}_{\text{base}} + \ln \mathcal{L}_{\dot{e}} + \ln \mathcal{L}_{\dot{P}}$$

The augmented Fisher matrix is

$$\mathcal{I}_{\Xi,\text{total}} = \mathcal{I}_{\Xi,\text{base}} + \frac{1}{\sigma_{\dot{e}}^2} (\nabla_{\boldsymbol{\Xi}} \dot{e})(\nabla_{\boldsymbol{\Xi}} \dot{e})^{\mathsf{T}} + \frac{1}{\sigma_{\dot{P}}^2} \left(\nabla_{\boldsymbol{\Xi}} \dot{P}\right)\left(\nabla_{\boldsymbol{\Xi}} \dot{P}\right)^{\mathsf{T}}$$

Degeneracy-lift criterion:

$$\det(\mathcal{I}_{\Xi,\text{total}}) > 0$$

which is equivalent to nonzero projection of the added gradient span onto the null direction $\hat{n}$.

Operational closure consequence:
if this criterion is met with real timing data, the posterior over (Ξ_1, Ξ_2, Ξ_3) closes to a bounded ellipsoid instead of a flat valley.

Failure mode for the constitutive cosmology map:
if the inferred $\boldsymbol{\Xi}$ is significantly nonzero and incompatible with the independently inferred medium-drift direction from the CMB dipole, the single preferred-frame mapping in $\mathbb{AAA}$ is broken.

The acceptance record for this layer requires Noether sea continuum simulations to supply

$$\nabla_{\boldsymbol{\Xi}} \dot{e}, \qquad \nabla_{\boldsymbol{\Xi}} \dot{P}$$

for the drift-sensitive channels that lift the preferred-frame degeneracy.

Gravitational Waves

This chapter provides a conditional closure chain from the emergent-metric weak-field map to testable gravitational-wave observables. It is one branch of the observational closure stack summarized in General Relativity and constrained by Constraint Ledger.

Interface chapters:

- Effective metric map: Emergent Metric
- PPN closure and refractive weak field: PPN Parameters
- Phenomenology summary: General Relativity

Weak-Field Setup

Assume an effective metric

$$g^{\mathrm{eff}}_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}, \qquad |h_{\mu\nu}| \ll 1$$

with background Noether sea state homogeneous and isotropic at leading order.

Define trace-reversed perturbation

$$\bar{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h, \qquad h = \eta^{\alpha\beta}h_{\alpha\beta}$$

Here $h_{\mu\nu}$, $\bar{h}_{\mu\nu}$, and the trace h are observer-sector perturbation variables of $g^{\mathrm{eff}}_{\mu\nu}$. They are distinct from the native Euclidean spatial metric $h_{ij} = \delta_{ij}$ on Σ_T, which does not appear below.

Impose Lorenz gauge

$$\partial^\mu \bar{h}_{\mu\nu} = 0$$

Assume constitutive closure supplies effective $(G_{\mathrm{eff}}, c^{\mathrm{eff}}_{\mathrm{GW}})$ in this regime. The speed row is the gravitational-wave component of the structural-integrity common-limit closure in Lorentz Kinematics: the weak-field tensor channel must share the same Noether sea state record that supports photon timing, PPN, redshift, Shapiro delay, and lensing. In the multi-messenger branch, the explicit common-mode residual is

$$R_{\mathrm{GW}\gamma} \equiv \frac{c^{\mathrm{eff}}_{\mathrm{GW}} - c_\gamma}{c_\gamma}, \qquad |R_{\mathrm{GW}\gamma}| \lesssim 10^{-15}$$

at the GW170817/GRB 170817A scale, after source-emission lag and propagation-path conventions are declared. A model that gives the effective gravitational channel and the photon channel independently tunable limiting speeds has failed this row before any black-hole or cosmological interpretation can use the gravitational-wave record.

The same row is also a χ_{sea} identity condition. The Noether sea delay factor that dresses photon-channel timing to c_γ cannot split into a photon-only value and a tensor-only value; it must dress the effective gravitational channel to $c^{\mathrm{eff}}_{\mathrm{GW}}$ within the declared multimessenger tolerance. Otherwise the branch has preserved the language of one medium while using two transport laws.

Coherent photon/gravity conversion comparisons belong at this same shared-record level. They are useful only if the photon channel and the effective gravitational channel read from one Noether sea state, one speed/delay convention, and one event ledger. A proposed conversion amplitude, phase lock, or common propagation speed cannot be used as evidence for a new carrier unless it also preserves the GW170817-style timing row, photon nondispersion, image coherence, and the tensor-mode detector record.

Linear Wave Equation

Conditional Lemma 1 (linearized propagation equation).
Under weak-field, slow-background variation, linear constitutive response, and the predicate that the homogeneous isotropic background Noether sea is an equilibrium of the constitutive dynamics — an open dependency carried by the provisional sea-equilibrium packet below — the transverse-traceless sector obeys

$$\Box_{c^{\mathrm{eff}}_{\mathrm{GW}}} \bar{h}^{\mathrm{TT}}_{\mu\nu} = \frac{16\pi G_{\mathrm{eff}}}{(c^{\mathrm{eff}}_{\mathrm{GW}})^4} T^{\mathrm{TT}}_{\mu\nu}, \qquad \Box_{c^{\mathrm{eff}}_{\mathrm{GW}}} \equiv -\frac{1}{(c^{\mathrm{eff}}_{\mathrm{GW}})^2}\partial^2_{t_{\mathrm{eff}}} + \gamma^{ij}_{\mathrm{eff}}\partial_{x^i_{\mathrm{eff}}}\partial_{x^j_{\mathrm{eff}}}$$

Derivation sketch: If the effective field equations induced by the metric constitutive map exist in this regime, linearize them around the homogeneous background, then project onto the TT sector.

Corollary 1 (source-free effective waves).
For $T^{\mathrm{TT}}_{\mu\nu} = 0$:

$$\Box_{c^{\mathrm{eff}}_{\mathrm{GW}}} \bar{h}^{\mathrm{TT}}_{\mu\nu} = 0$$

so plane waves satisfy

$$\omega^2 = (c_{\rm GW}^{\rm eff})^2 k^2$$

to leading order (higher-order dispersive corrections are constitutive and model-dependent).

Finite-range comparison models may introduce gravitational-wave dispersion, but here that is only a deviation diagnostic. Define the group speed

$$v_{\rm g,GW} \equiv \frac{\partial \omega}{\partial k}$$

In validated frequency bands the constitutive map must satisfy

$$\left|\frac{v_{\rm g,GW} - c_0}{c_0}\right| < \epsilon_{\rm GW}, \qquad \left|\frac{\omega}{c_0^2}\frac{\partial^2 \omega}{\partial k^2}\right|_{\rm band} \le \epsilon_{\rm disp}$$

so $\epsilon_{\rm disp}$ is a dimensionless band tolerance. The integrated phase drift across the source distance must remain below the detector residual bound. A finite-range cosmological response is not acceptable if it leaks into already-tested gravitational-wave timing as measurable dispersion.

The same finite-range comparison must also supply a low-frequency forecast rather than leaving drift unconstrained below current ground-based event bands. For a declared pulsar-timing or space-interferometer band $\mathcal{B}_{\rm low}$, define the accumulated phase drift

$$\Delta\phi^{\theta}_{\rm GW,low}(f) = \int_{\Gamma} \left[k_\theta(f, x^i_{\rm eff}, t_{\rm eff}) - k_{\rm GR}(f, x^i_{\rm eff}, t_{\rm eff})\right] \, d\ell$$

where Γ is the observer-level propagation path used by the comparison. A useful low-frequency residual is

$$\mathcal{R}_{\rm GW,low}(\theta) = \sup_{f\in\mathcal{B}_{\rm low}} \frac{\left|\Delta\phi^{\theta}_{\rm GW,low}(f)\right|}{\epsilon_\phi(f)} + \sup_{f\in\mathcal{B}_{\rm low}} \frac{\left|v^{\theta}_{\rm g,GW}(f) - c_0\right|}{c_0\,\epsilon_v(f)}$$

This is a forecast and comparison gate. It does not license a massive-graviton ontology; it only says that any cosmological-scale weakening channel must remain compatible with the low-frequency strain and timing residuals that would test long-wavelength dispersion.

Medium-Transport Perturbation

For cosmology-facing transport work, gravitational waves should also be treated as bounded perturbations of the same Noether sea state used by redshift and dark-energy modules. In the provisional Noether braid equilibrium packet,

$$\partial_T f_N + \nabla_{\mathbf{X}} \cdot (\mathbf{u}_{\rm sea} f_N) + \partial_\nu J_\nu = S_{\rm BH} + S_{\rm GW} - R_{\rm eq}[f_N]$$

the term $S_{\rm GW}$ records the disturbance of the local Noether braid cadence distribution by the gravitational-wave channel. It is not an additional default polarization mode and not a license for frequency-dependent gravitational-wave propagation in validated bands. It is a possible low-amplitude contribution to the Noether sea state later sampled by photons, clocks, and growth observables.

The redshift-facing projection should therefore be bounded as a perturbation of the path-rate functional:

$$\delta\alpha^{\rm GW}_{{\rm prop},X} = \mathcal{A}_{X,\rm GW}\left[S_{\rm GW}, f_N, J_\nu; x^i_{\rm eff}, t_{\rm eff}, \hat{\mathbf{k}}\right]$$

with the associated beam variance, chromaticity residual, and packet time-dilation residual below the same tolerances used for the redshift budget. If $S_{\rm GW}$ produces measurable photon dispersion, image blur, or gravitational-wave timing drift beyond the detector gates above, the perturbative transport branch fails.

Polarization Content

In the project spin taxonomy, this is the effective **spin-2 / tensor** channel: the wave is not a scalar breathing mode or a single-axis vector mode, but a transverse-traceless deformation carrying quadrupolar shape data.

Conditional Lemma 2 (two-mode TT closure in isotropic limit).
If the low-energy constitutive response is parity-even and isotropic, residual gauge constraints leave exactly two propagating tensor modes:

$$h_+(t_{\rm eff}, x^i_{\rm eff}), \qquad h_\times(t_{\rm eff}, x^i_{\rm eff})$$

Derivation sketch: Standard counting in Lorenz gauge plus TT projection gives 10 components $\to$ gauge/constraint reduction $\to$ two physical helicity-2 modes, provided the effective-metric gauge structure is recovered by the constitutive map.

Any scalar, vector, or longitudinal gravitational-wave response is therefore an effective deviation to be bounded, not a new default channel:

$$\frac{\mathcal{P}_{\rm extra}}{\mathcal{P}_{\rm TT}} < \epsilon_{\rm pol}$$

The numerator collects non-TT detector power after known instrumental and astrophysical residuals are removed.

Detector-Side Inference Gate

The detector does not observe the effective tensor mode as a bare ontological object. It records a processed strain channel whose interpretation depends on calibration, background rejection, waveform matching, and coincidence checks across instruments. For a candidate gravitational-wave record $\theta_{\rm GW}$, keep the residual vector explicit:

$$\mathbf{R}_{\rm GW}(\theta_{\rm GW}) = \left(\frac{v_{\rm g,GW}-c_0}{c_0},\ \frac{\omega}{c_0^2}\frac{\partial^2\omega}{\partial k^2}\bigg|_{\rm band},\ \frac{\mathcal{P}_{\rm extra}}{\mathcal{P}_{\rm TT}},\ \mathrm{FAR},\ R_{\rm cal}\right)$$

where FAR is the false-alarm-rate estimate and $R_{\rm cal}$ is the retained calibration residual for the strain channel and timing model. Promotion from a candidate disturbance to an accepted gravitational-wave data product requires

$$\max_i \frac{|R_{{\rm GW},i}|}{\epsilon_{{\rm GW},i}} \le 1$$

with the tolerances fixed by the validation band. This gate protects the separation between the observable data product and the ontology: the data product is a calibrated, coincident, low-residual strain record, while the $\mathbb{AAA}$ interpretation must still earn the claim that the record is the tensor-sector response of the effective metric induced by Noether sea constitutive dynamics.

Coincidence is part of the data product, not an afterthought. For a detector network with instruments D_a, calibrated strain streams $s_a(t_{\rm eff})$, response templates $h_a^\theta(t_{\rm eff})$, and allowed light-speed timing windows $\Delta t_{ab}^{\rm geom}$, define

$$\mathcal{R}_{\rm coin}(\theta) = \sum_a \left\|s_a - \mathcal{P}_{D_a} h^\theta\right\|^2_{C_a^{-1}} + \sum_{a<b} \frac{\left(\Delta t_{ab}^{\rm fit} - \Delta t_{ab}^{\rm geom}\right)^2}{\sigma_{ab}^2}$$

This residual is the modern version of the separated-detector check: a signal must be coherent across instruments after antenna response, timing, calibration, and background rejection are fixed. An isolated excess in one detector, or a coincidence that requires an implausible source energy after the same response projection, remains a candidate disturbance rather than an accepted gravitational-wave record.

Public GWOSC/LVK claims must also pass the packet protocol in Simulation Run Protocols before they support strong-field or effective-metric claims. The public packet fixes event version, strain files, detector masks, parameter-estimation release, waveform family, calibration notes, analysis window, nuisance record, and artifact hashes before residual evaluation. This makes the detector-side gate replayable rather than a general statement that gravitational-wave observations are available.

Closure Target 2A (graviton-comparison detectability residual).
When a detector record is compared with a quantum-gravity language, keep the comparison at observer level. A calibrated classical strain event does not become a single-quantum detection merely because a graviton basis can be used for bookkeeping. For a narrowband comparison with angular frequency ω and strain amplitude $A_{\rm GW}$, retain the occupation lower bound

$$N_{\rm occ} \ge \frac{\rho_{\rm GW}}{\rho_1}, \qquad \rho_{\rm GW} \sim \frac{c_0^2}{32\pi G_{\rm eff}}\omega^2 A_{\rm GW}^2, \qquad \rho_1 \lesssim \frac{\hbar\omega^4}{c_0^3}$$

The accepted gravitational-wave record is therefore classical whenever $N_{\rm occ} \gg 1$. A separate single-quantum claim would need a detector-side packet $\theta_{\rm 1g}$ satisfying

$$\mathcal{R}_{\rm 1g}(\theta_{\rm 1g}) = \max\left(\frac{|N_{\rm occ}-1|}{\epsilon_N}, \frac{\delta_{\rm det}}{\delta_{\rm req}}, \frac{2G_{\rm eff}M_{\rm det}}{c_0^2 D_{\rm det}}, \frac{B_{\rm th}}{S_{\rm 1g}^2}\right) \le 1$$

with $\delta_{\rm req} \sim L_{\rm P}$ for a single-graviton interferometric distance readout, $\delta_{\rm det}$ the achieved distance uncertainty, $M_{\rm det}$ and $D_{\rm det}$ the detector mass and size, $S_{\rm 1g}$ the predicted single-graviton count, $B_{\rm th}$ the relevant thermal or particle-background count, and ϵ_N the allowed occupation-window tolerance. The compactness term prevents a sensitivity claim from hiding a black-hole detector; the background term prevents a thermal-graviton claim from being promoted when statistical scatter in known backgrounds dominates the putative count. Failure of this residual does not refute gravitons as a comparison basis and does not add graviton ontology to $\mathbb{AAA}$; it only blocks the stronger detector claim that an observed strain or thermal count has directly resolved individual quanta.

The detector-side packet should also declare which single-quantum route is being claimed. A direct interferometric route must satisfy the Planck-scale distance row without violating the compactness bound. An absorption or scattering route must show that the interaction cross-section and exposure yield a count above neutrino, thermal, and apparatus-background channels. A photon/gravity conversion route must show that the magnetic-field and coherence conditions needed for conversion do not themselves destroy the shared photon-channel and tensor-channel record through pair production, vacuum polarization, or phase decoherence. These are not separate ontologies; they are route-specific projections of the same single-quantum residual.

A resonant-mass or phonon-style coincidence therefore needs one more separation before it becomes evidence for quantized gravity itself. A cooled bar may register a single vibrational excitation coincident with a calibrated gravitational-wave event, and an optical Weber-bar comparison may convert time-dependent gravitational-wave modulation into a photon phase or energy shift. Those are detector-side quantum transitions unless the packet also reports whether the incoming gravitational state is classical, coherent with huge occupation number, or deliberately prepared in a nonclassical state. A classical gravitational wave can still raise the transition probability of a quantized detector, just as a classical electromagnetic field can drive transitions in quantized matter. The stronger claim is not a detector click, but a detector click plus source-state evidence that rules out the corresponding classical driving account.

This is the Dyson lesson in current terminology. The durable comparison is not that individual gravitons are impossible by definition, but that any single-quantum claim must close the detector sensitivity, compactness, background, and occupation rows at the same time. A classical strain packet with huge occupation number remains a gravitational-wave recovery success without becoming a single-graviton observation.

When $\theta_{\rm GW}$ is also used to support a finite-range or dark-energy comparison, $\mathcal{R}_{\rm GW,low}(\theta)$ must be carried beside this detector residual. Passing a high-frequency event-timing gate alone is not enough to promote a long-wavelength dispersion claim.

Merger and Ringdown Horizon-Interface Gate

Stationary no-hair agreement is not enough to close the dynamical strong-field problem. If a black-hole model changes the horizon-interface boundary condition during formation, merger, or evaporation, the change must be tested against the detector-facing waveform packet and the same final compact-object labels used by exterior GR.

For a candidate horizon-interface record θ_H, let $h_{\ell m}^{\theta_H}(t_{\rm eff})$ be the effective strain modes predicted after projection through the detector response, and let $D_{\rm merge}^{\rm obs}$ collect the observed inspiral, merger, ringdown, calibration, and covariance packet. This observed packet must be sourced from the same versioned GWOSC/LVK event row and artifact hashes used by $\mathcal{C}_{\rm GW}$ when ringdown is used as strong-field evidence. A compact residual is

$$\mathcal{R}_{\rm merge}(\theta_H) = \left\| D_{\rm merge}^{\rm obs} - \mathcal{P}_{\rm det}\{h_{\ell m}^{\theta_H}\} \right\|^2_{C_{\rm merge}^{-1}} + d_{\rm nohair}\big((M_f, \mathbf{J}_f, Q_f)^{\theta_H}, (M_f, \mathbf{J}_f, Q_f)^{\rm obs}\big) + d_{\rm shared}(\theta_H, \theta_{\rm GW}, \theta_{\rm BH})$$

Here Q_f is the final exterior charge/no-hair label in the Kerr-Newman comparison, not a quadrupole-deviation tensor. The projection $\mathcal{P}_{\rm det}$ is the detector projection, and $d_{\rm shared}$ penalizes any fit that uses one state record for the strain channel, another for the horizon-interface label, and another for the black-hole entropy or release ledger. The gate is satisfied only if $\mathcal{R}_{\rm merge}(\theta_H)$ is below the declared tolerance while preserving the validated inspiral limit, the two tensor polarizations, and the final exterior no-hair coarse-graining. A predicted deviation is admissible only as a bounded residual or a falsifiable template, not as permission to loosen already-tested gravitational-wave recovery.

The GWTC-5.0 release and GW250114 sharpen the event-packet version of this gate. The catalog count, population reconstruction, standard-siren distance inference, high signal-to-noise ringdown, Kerr-mode and overtone tests, Hawking-area comparison, recoil extraction from higher modes, and any proposed near-horizon “direct wave” signature are not independent facts that can be fit from separate records. In $\mathbb{AAA}$ they define one strong-field recovery target: source quadrupole, calibrated detector strain, remnant mass and spin, ringdown labels, horizon-interface entropy bookkeeping, recoil or higher-mode rows, and any distance-redshift row must remain bound to one source-event ledger and one Noether sea/effective-metric record.

Early-Universe Stochastic Background Gate

A stochastic gravitational-wave background is a data product before it is an ontology claim. If an early-universe or pre-BBN comparison branch predicts a background, retain the detector-facing spectrum and its cosmology linkage, not the branch interpretation that generated it. For a candidate branch X, define

$$\mathcal{R}_{\rm GW,early}(\theta_X) = \sup_{f \in \mathcal{B}_{\rm det}} \frac{\Omega_{\rm GW}^X(f)}{\Omega_{\rm GW}^{\max}(f)} + d_{\rm shared}(\theta_{\rm GW}, \theta_{\rm BBN}, \theta_{\rm CMB}, \theta_{\rm growth})$$

where $\mathcal{B}_{\rm det}$ is the validated detector band and $d_{\rm shared}$ penalizes any branch that requires a gravitational-wave source record inconsistent with the BBN, CMB, or structure-formation records. A positive stochastic signal would become observational pressure on the early medium history; a null result closes only the corresponding branch amplitude, not the whole cosmology program.

Energy Flux

The source-side benchmark is also part of closure. In the GR weak-field comparison, isolated systems do not radiate monopole or dipole gravitational waves at leading order because total energy, momentum, and angular momentum conservation remove those channels. The first radiative source is quadrupolar. A compact observer-level target is

$$P_{\rm GW} = \frac{G_{\rm eff}}{5 c_{\rm GW}^5} \left\langle \dddot{Q}_{ij} \dddot{Q}^{ij} \right\rangle$$

with Q_{ij} the trace-free mass quadrupole of the effective source record in the validated weak-field limit. A native Noether sea wave model must therefore explain why scalar monopole leakage, vector dipole leakage, and non-TT power remain below detector bounds rather than adding them as free source channels.

Binary-pulsar orbital decay is the generation-side benchmark for this row. The same source ledger must use the recovered $G_{\rm eff}$, $c_{\rm GW}$, and quadrupole moment to predict the observed secular period change after independently modeled kinematic and environmental corrections. Define

$$\mathcal{R}_{\dot{P}_b} \equiv \frac{\dot{P}_b^{\rm obs} - \dot{P}_b^{\rm quad}(\theta_{\rm src})}{\sigma_{\dot{P}_b}}, \qquad \mathcal{R}_{\rm dip} \equiv \frac{P_{\rm dip}(\theta_{\rm src})}{P_{\rm quad}(\theta_{\rm src}) + \varepsilon}.$$

The weak-field source branch must fit the orbital-decay row while keeping $\mathcal{R}_{\rm dip}$ below the binary-system bound. Composition-dependent Noether sea coupling that produces a leading dipole channel is therefore linked directly to the strong-equivalence-principle burden; it cannot be hidden in the detector-side tensor projection.

Closure Target 3 (leading-order GW flux).
In the same regime, the cycle-averaged flux is

$$\mathcal{F}_{\rm GW} = \frac{c_{\rm GW}^3}{32\pi G_{\rm eff}} \left\langle \dot{h}_+^2 + \dot{h}_\times^2 \right\rangle$$

This is the quantity used for binary-orbit energy-loss consistency checks. Energy localization for gravitational waves is an observer-level effective description: the packet may use cycle-averaged fluxes and asymptotic energy loss, but it should not promote a gauge-dependent local gravitational energy density into substrate ontology.

Black Holes

This chapter is the main black-hole orientation document for the spacetime branch. Its purpose is to tell the reader what survives from standard compact-object phenomenology, what is being reinterpreted at the constitutive level, and how a candidate strong-field Noether-braid regime is supposed to replace singularity language without losing observational discipline. No black-hole constituent is assigned a braid-taxonomy member here.

The opening establishes the three-layer distinction between observables, constitutive strong-field structure, and substrate ontology. The later sections then work through horizon conditions, interior regime structure, release channels, and cosmological embedding.

Scope and Purpose

This chapter centralizes the black-hole story within $\mathbb{AAA}$. Its purpose is to distinguish three levels that are often conflated in black-hole discussion:

- the **effective observational layer**, where black holes are compact objects constrained by lensing, dynamics, accretion phenomenology, horizon-scale imaging, and gravitational-wave data;
- the **strong-field constitutive layer**, where Noether braid assemblies enter alignment, compression, and recycling regimes not encountered in ordinary weak-field gravity;
- the **substrate ontology**, where the Euclidean void remains fixed and the Noether sea carries all dynamical structure.

The chapter does not replace weak-field or observer-level black-hole phenomenology. What survives from standard practice remains indispensable: compact-object mass inference, horizon-scale imaging, ringdown analysis, accretion and jet modeling, and the requirement that exterior predictions recover the tested general-relativistic limit to observational accuracy. The reinterpretation begins only when one asks what a black hole is made of, what replaces singularity language, and how strong-field interiors connect to cosmology.

What the Framework Treats as a Black Hole

In $\mathbb{AAA}$, a black hole is not a hole in the Euclidean void. It is a region of the Noether sea hypothesized to enter an extreme alignment and compression regime through sustained inward transport of matter, radiation, and medium deformation. The effective exterior still behaves like a compact gravitating source, but the candidate interior ontology is not a geometric singularity. It is a proposed Noether-braid regime with three coupled zones:

Zone	Candidate braid role	Constituent branch-speed regime	Effective black-hole language
Exterior bulk	outer-dominant volumetric assemblies	outer branch $v_3 < c_f$ in ordinary exterior coupling	outside observer region
Horizon interface	source-record binary-2 locking with binary-3 terminal alignment	$v_2 = c_f$ with $v_3 \to c_f$ for the locked interface components	event/apparent horizon comparison; roles are provisional, not taxonomy identities
Interior core	self-hit-dominant maximal-curvature assemblies	branch-derived self-hit carrier speed exceeds c_f	black-hole interior

This should be read as one constitutive continuum rather than three disconnected objects. The black-hole vocabulary remains useful at the effective level, but the ontic content is a regime map of the Noether sea.

The working source record assigns binary 2 the symmetry-breaking threshold, binary 1 the beyond-threshold self-hit continuation, and binary 3 the exterior-coupling channel that strong-field collapse would drive toward terminal Family-A alignment. These are provisional source-record assignments, not meanings of the persistent indices and not a retained-branch result. In this conjecture a candidate Noether braid contains the primitive black-hole analogue: a local horizon/interior pattern that could later be population-amplified into an observer-level compact object. This is not an imported primordial-black-hole model; it is a falsifiable proposed continuation from assembly-scale branch behavior.

When the local branch is described from the assembly side, this transition is the braid symmetry-breaking point: the source record's binary-2 threshold row remains at c_f, binary 3 is driven to the same terminal threshold, and binary 1 supplies the self-hit interior continuation.

Critical-collapse work in GR supplies a useful threshold comparison for this language. In Choptuik-style scalar collapse, finely tuned effective initial data approach a discretely self-similar solution at the border between dispersal and black-hole formation, and the large-D black-hole program (Emparan-class) gives analytic expressions for a related family. The useful point for this chapter is not that substrate spacetime literally crystallizes. It is that black-hole formation should have a threshold record: exterior dispersal, horizon-interface capture, and interior continuation must be separated by the same branch data rather than by an ad hoc singular endpoint.

Collapse-Response Ladder

The route from ordinary matter to a black-hole interior is not a single increase in temperature or a simple rise in material density. It is a sequence of assembly-regime changes in which more of the matter ledger becomes exposed to the surrounding Noether sea. In stable low-energy matter, the Noether sea normally receives only the externally exposed residual of shielded assemblies, not the full internal causal-history energy stored inside those assemblies. In compact collapse, that weak-response approximation progressively fails.

The useful ladder is:

Regime	Matter state	Noether sea response
Ordinary atom	Electron resonance envelopes and nuclei remain distinct.	Tiny, phase-coherent, near-lossless response; ordinary atomic stability requires no drag-like loss.
Earth or metallic matter	Atomic and metallic bonding are compressed but remain ordinary condensed-matter states.	Weak constitutive response controlled by the exposed matter ledger and density-length scale, not by Planck-temperature proximity.
White-dwarf-like matter	Electrons become a degenerate pressure reservoir while nuclei remain identifiable over much of the star.	Stronger but still non-horizon response; electron shielding and pressure support dominate the compact-object balance.
Collapsing iron core	Electron support fails, electron capture and nuclear breakup change the active assembly inventory.	Nonlinear response: exposed fermion channels, neutrino transport, stress, cadence, and delay-factor gradients can no longer be treated as small perturbations.
Neutron-star branch	Neutron-rich nuclear matter or denser phases carry the pressure budget.	Extreme non-horizon response with packed fermion assemblies and strong gradients in n, χ_{sea}, Γ_N, and stress.
Horizon-interface branch	Stable volumetric matter support fails.	Terminal alignment and maximum-curvature bookkeeping replace ordinary matter-language continuation.

This ladder does not add a new validation gate. It identifies which existing variables must stop being interpreted in their weak-response limit as collapse progresses.

Chandrasekhar Scaling and Assembly Compression

The first mathematical warning that ordinary compact matter could lose its support branch is the Chandrasekhar scaling argument. In a white-dwarf-like object, electrons form a degenerate Fermi reservoir. If the electron number density is n_e, the Fermi momentum scales as

$$p_F \sim \hbar n_e^{1/3}$$

and the pressure law depends on whether those electrons are nonrelativistic or relativistic. In the nonrelativistic regime,

$$P_e \propto n_e^{5/3} \propto \rho^{5/3}$$

while in the relativistic regime,

$$P_e \propto n_e^{4/3} \propto \rho^{4/3}$$

The electrons in this standard calculation are not ordinary atomic-orbital electrons. The white-dwarf branch begins after ordinary atoms have lost their everyday chemical identity: nuclei remain as identifiable ionic matter over much of the star, while the electrons form a delocalized pressure reservoir through the whole compact region. The relevant length scale is therefore not the Bohr radius of an atom but the inter-electron spacing,

$$\ell_e \sim n_e^{-1/3}$$

Compression lowers ℓ_e, and Fermi-state counting forces the highest occupied electron momentum upward. The nonrelativistic-to-relativistic border is controlled by

$$x_F \equiv \frac{p_F}{m_e c}$$

with $x_F \ll 1$ giving the $5/3$ pressure law and $x_F \gtrsim 1$ moving the reservoir into the relativistic $4/3$ law. Equivalently,

$$n_{e,\mathrm{rel}} \sim \frac{1}{3\pi^2}\left(\frac{m_e c}{\hbar}\right)^3, \qquad \rho_{\mathrm{rel}} \sim \mu_e m_u n_{e,\mathrm{rel}}$$

which is approximately $10^6 \mu_e\,\mathrm{g/cm^3}$, or about $2\times 10^6\,\mathrm{g/cm^3}$ for carbon/oxygen material with $\mu_e \approx 2$.

This is not a curve fit over diverse stellar observations. The exponents come from quantum state counting plus the energy-momentum relation: the number of filled momentum states gives $p_F \propto n_e^{1/3}$; nonrelativistic energy $E \sim p^2/(2m_e)$ gives $P \propto n_e^{5/3}$; relativistic energy $E \sim pc$ gives $P \propto n_e^{4/3}$. Observations test the resulting mass-radius and stability picture, but the scaling itself is a mathematical consequence of the Fermi reservoir model.

The historical calculation also has a specific level placement. Chandrasekhar's limiting argument used special relativity for the electron momentum-energy relation and ordinary Newtonian hydrostatic balance for the star, with a radial coordinate and gravitational pressure estimate. It was not originally a full curved-spacetime derivation. The later Tolman-Oppenheimer-Volkoff comparison is the general-relativistic compact-star benchmark. From the standpoint of $\mathbb{AAA}$, this makes the Chandrasekhar law a particularly valuable bidirectional clue: a support calculation using an ordinary Euclidean radial coordinate already shows a matter scale channel crossing into a relativistic cadence and momentum regime before full horizon-interface language is required.

For a star of mass M and radius R, the rough hydrostatic comparison is

$$\rho \sim \frac{M}{R^3}, \qquad P_{\mathrm{grav}} \sim \frac{GM^2}{R^4}$$

Nonrelativistic electron pressure scales like $M^{5/3}/R^5$, so it rises faster than the gravitational pressure estimate as R decreases. A smaller equilibrium radius can still be found. Relativistic electron pressure scales like $M^{4/3}/R^4$, the same radius dependence as the gravity estimate. Once the coefficient balance is lost, no smaller white-dwarf radius restores support. That is the standard origin of the Chandrasekhar mass scale,

$$M_{\mathrm{Ch}} \approx \frac{5.83}{\mu_e^2} M_\odot$$

with μ_e the nucleons-per-electron composition factor. In a collapsing iron core, electron capture lowers the electron fraction $Y_e = 1/\mu_e$, so the effective support limit falls as the active core is already compressed.

The $\mathbb{AAA}$ reading is that the Chandrasekhar calculation is not merely a historical astrophysics result. It is an observer-level signature of an assembly support channel losing authority. In the white-dwarf candidate mapping, volumetric electron-braid envelopes would supply effective exclusion and packing response while nuclei remain identifiable. As compression drives the electron population into the relativistic regime, additional inward work no longer returns as a proportionally stronger outward support law. The same work is increasingly routed into cadence, exposed response, heat, neutrino channels, nuclear breakup, Noether sea stress, and remnant bookkeeping.

The branch distinction should not be collapsed into a single "shrinking electron" picture. Ordinary orbital compression belongs to the atomic and condensed-matter precursors. Degenerate electron pressure belongs to a delocalized fermion reservoir after ordinary orbitals have ceased to be the right description. Material Noether braid scale compression is a deeper assembly-level ledger that must be derived separately from the same retained compact-region record. A successful $\mathbb{AAA}$ collapse map has to connect these stages without pretending that an atomic orbital radius, a Fermi spacing, and a Noether braid scale ratio are the same variable.

The local scale-compression variable for an assembly A is

$$\lambda_A(t) = \frac{R_{\perp,A}(t)}{R_{\perp,A,0}}, \qquad \mathcal{S}_{\mathrm{mat}}(\Omega,t) = \langle \ln \lambda_A(t) \rangle_\Omega$$

The energy is not created by the shrinkage. It is binding work and reaction work entering the local ledger:

$$\Delta E_{\mathrm{bind}} + \Delta E_{\mathrm{rxn}} \to \Delta E_{\mathrm{cad}} + \Delta E_{\mathrm{heat}} + \Delta E_\nu + \Delta E_{\mathrm{break}} + \Delta E_{\mathrm{sea}} + \Delta E_{\mathrm{rem}}$$

This is a ledger identity target, not yet a derived equation of state. It says which channels must be accounted for before one may claim that material Noether braids have scaled down rather than merely that a standard pressure formula was imported.

The strong claim is that this material scale ledger should also project into the effective spatial-compliance ledger used by the metric description. If $\gamma_{ij}^{\mathrm{eff}}$ is the observer-level spatial compliance metric and h_{ij} is the fixed Euclidean spatial metric, the corresponding isotropic scale readout is

$$\mathcal{S}_{\mathrm{metric}}(\Omega, t_{\mathrm{eff}}) = \left\langle \frac{1}{6} \ln \frac{\det \gamma_{ij}^{\mathrm{eff}}(x^i_{\mathrm{eff}}, t_{\mathrm{eff}})}{\det h_{ij}} \right\rangle_\Omega$$

The factor $1/6$ appears because an isotropic spatial metric factor $\gamma_{ij}^{\mathrm{eff}} = a^2 h_{ij}$ gives a determinant ratio a^6. The closure target is not that $\mathcal{S}_{\mathrm{mat}}$ and $\mathcal{S}_{\mathrm{metric}}$ merely correlate after fitting. The same retained compact-region record must generate the electron-support failure, the assembly scale compression, the Noether sea response, and the effective metric readout without hidden retuning.

Iron-Core Collapse Handoff

For an iron-group stellar core, the central Standard Model transition is electron capture,

$$p + e^- \to n + \nu_e$$

The outgoing neutrino is not just an abstract missing-energy label in this bookkeeping. In the lepton-sector canon, a neutrino is a near-photon neutral assembly: a near-planar polarity-conjugate Noether braid pairing close to the photon channel but not fully locked into the photon mode. That explains why the neutrino channel is high-speed and weakly exposed while still carrying an internal-binary phase ledger capable of oscillation. In a collapse ledger, the neutrino row must therefore carry energy, momentum, angular momentum, weak provenance, and near-photon phase information, not merely remove scalar energy from the core.

The $\mathbb{AAA}$ reading keeps this reaction as a required observer-level channel while reclassifying the surrounding story as a change in exposed assembly response.

Collapse stage	Electrons	Nucleons and nuclei	Noether sea
Iron core near instability	Electrons form a dense pressure reservoir rather than atomic orbital distributions.	Iron-group nuclei remain identifiable but no longer release useful fusion support.	The Noether sea sees a compact but still non-horizon matter source through exposed shielded response.
Electron-capture onset	Electron number falls as electrons are consumed by proton channels.	Protons convert toward neutrons, and the composition becomes more neutron-rich.	Atomic-scale electron resonance is no longer the right response picture; the active ledger shifts toward nuclear reaction provenance.
Photodisintegration and breakup	Electron pressure keeps weakening as collapse accelerates.	Heavy nuclei break into smaller nuclei, alpha-like fragments, and free nucleons, consuming energy.	Iron-nucleus closure loses authority; source terms into the Noether sea become fragmented, anisotropic, and rapidly changing.
Neutrino-trapping regime	Lepton accounting must include trapped and escaping neutrino channels.	Matter approaches nuclear density, and free nucleons dominate the local inventory.	Transport is no longer globally transparent: neutrino, stress, heat, and medium-update ledgers must be tracked together.
Bounce or continued collapse	Electrons become secondary to nuclear and neutrino pressure channels.	Nuclear-density stiffening can halt the inner core, or support can fail.	A neutron-star branch remains an extreme non-horizon Noether sea response; continued collapse routes the same record toward the horizon-interface condition.

The compact summary is therefore:

$$\text{atomic electron resonance} \to \text{electron-capture ledger} \to \text{neutron-rich packed fermion response} \to \text{strong Noether sea constitutive regime}$$

Neutron-Star Branch as a Radial Test

The neutron-star branch is the sharpest compact-object test before horizon-interface language becomes active. It is already far outside weak-field matter, but it remains a non-horizon branch in the candidate mapping as long as volumetric neutron-rich matter support has not been forced into terminal Family-A alignment. For a spherical bookkeeping radius r inside a star of surface radius R_*, the useful local record is not a scalar density alone but a Noether sea state and matter-response bundle,

$$\Theta_{\mathrm{NS}}(r) = \left(\rho_{\mathrm{NS}}(r), n(r), \chi_{\mathrm{sea}}(r), \Gamma_N(r), S_{ij}(r), \mathcal{M}_{\mathrm{sea}}^{ab}(r), \mathcal{L}_{E\mathbf{pJ}}^{(\Omega_r)}\right)$$

where Ω_r is the compact interior region retained by the comparison and $\mathcal{L}_{E\mathbf{pJ}}^{(\Omega_r)}$ records the local energy, momentum, angular-momentum, reaction, neutrino, stress, heat, medium-update, and remnant rows needed for that region. The exterior region samples the same record through redshift, orbital motion, lensing, and signal-delay channels. The surface is not a hard boundary of the Euclidean void; it is the branch boundary where exterior Noether sea response starts coupling to neutron-rich packed matter, charged layers, radiation channels, magnetic stresses when present, and surface transport.

The pulsar version of this branch makes the bookkeeping sharper. A Crab-like neutron star is not only a dense sphere; it is a retained compact-source record whose exterior exports include surface spectral redshift, X-ray/optical/radio channel selection, rotational period, spin-down power, magnetic-axis beaming, and the supernova/nebular remnant ledger. Standard angular-momentum, magnetic-flux, and rotational-energy-loss calculations are therefore useful recovery targets. They preserve what the conventional model gets right: collapse amplifies rotation and magnetic field, and the observed pulse train is a line-of-sight sample of a rotating magnetized source. The $\mathbb{AAA}$ claim is narrower: the same $\Theta_{\mathrm{NS}}(r)$ and boundary/source ledger should project to those timing, spectrum, and energy-loss observables without separately fitting a clock, a beam, a redshift, and a remnant energy budget.

Inside the star, electron-envelope language has mostly lost authority. The active ledger is neutron-rich nuclear matter or denser phases together with residual charged components, neutrino transport, pressure support, heat flow, stress, and local Noether sea updates. A compact branch-survival condition can therefore be stated as

$$0 < 1 - \frac{v_3(r)}{c_f}, \qquad 0 \le s_n(r) \le 1, \qquad \mathcal{R}_H(\Omega_r) < \infty, \qquad \mathcal{L}^{(\Omega_r)}_{\mathbf{EpJ}} \text{ closes}$$

for all retained radii $0 \le r \le R_*$. Here v_3 is the binary-3 speed in the relevant branch record, s_n is the packing-headroom diagnostic when a pressure-packing model is being used, and $\mathcal{R}_H$ is the strong-field regularity residual. The s_n condition should be read as a candidate pressure-response target until a neutron-star dense-matter branch supplies the corresponding K_{pack}, packing ceiling, and branch residuals.

The center of an ideal nonrotating neutron star is therefore not automatically horizon-like. The first radial gradients vanish there by symmetry, while pressure, stress, cadence stretch, and packing pressure can be maximal. If scalar density response is exhausted while $v_3 < c_f$, the response must route into shape, strain, contact, transport, or dense-matter branch change. If the same record forces $v_3 \to c_f$ and activates the horizon-interface condition, the neutron-star branch has ended and the continuation belongs to the horizon-interface branch below.

Canonical Horizon Condition

The canonical strong-field alignment condition is inherited from singularity-resolution.md. Near the horizon interface, the working regime definition is

$$v_2 = c_f, \qquad v_3 \to c_f$$

with binaries 2 and 3 becoming coplanar and collinear with binary 1 at alignment and precession ceasing in that limit.

This condition fixes the local meaning of the horizon in the framework. The horizon is not merely a geometric surface drawn inside an effective metric. It is the constitutive interface where terminal alignment is reached and where ordinary volumetric assemblies are compressed into a boundary-like state. For Planck-language mapping, the rule used throughout the project is that the relevant “Planck scale” is this alignment condition unless a more specific derivation overrides it.

Event and Apparent Horizon Comparison

Standard horizon language separates two comparison objects that should not be collapsed into one. The event horizon is a global causal boundary: at the effective GR level it is the boundary of the causal past of future null infinity,

$$\mathcal{H}^{\text{eff}}_{\text{event}} = \partial J^{-}\left(\mathscr{I}^{+}\right)$$

This definition depends on the full future development of the effective spacetime. It is therefore not a local surface that a finite-time observer or one simulation slice can identify by inspection. In dynamical collapse, accretion, or merger cases, the event horizon can be located only by the global escape structure of null trajectories.

The apparent horizon is the more local comparison surface. In layer-explicit comparison notation, the chosen GR slice is $\Sigma^{\text{eff}}_{t_{\text{eff}}}$, not an absolute slice Σ_T. On that effective spatial slice it is the outer boundary of the trapped region, with outgoing null expansion at the boundary and ingoing null expansion still inward,

$$\theta^{\text{eff}}_{+} = 0, \qquad \theta^{\text{eff}}_{-} < 0$$

This makes apparent horizons useful for simulations and local compact-object diagnostics, but it also makes them slice-dependent. The $\mathbb{AAA}$ horizon interface is neither of these GR objects by definition. It is the local constitutive condition $F_H = 0$ on a strong-field record. The closure burden is that the same record should export both a local trapped-surface/apparent-horizon comparison and the global finite-access event-horizon comparison when the observer-level regime calls for them:

$$F_H(\theta_{\Omega,W}) = 0 \quad \Longrightarrow \quad \left(\mathcal{H}^{\text{eff}}_{\text{app}}(\Sigma^{\text{eff}}_{t_{\text{eff}}};\theta_{\Omega,W}), \mathcal{H}^{\text{eff}}_{\text{event}}(\theta_{\Omega,W})\right)$$

This is a projection target, not a new ontology. If the local interface can match an apparent horizon only by changing the record used for exterior escape, or if the global event-horizon comparison requires a different strong-field record from the local trapped-surface comparison, the black-hole model has split into two fitted stories.

Exterior GR Benchmark Packet

Before any horizon-interface reinterpretation is promoted, the observer-level exterior must recover the standard nonrotating compact-object scales

$$r_s = \frac{2GM}{c_0^2}, \qquad r_{\text{ph}} = \frac{3GM}{c_0^2}, \qquad r_{\text{ISCO}} = \frac{6GM}{c_0^2}$$

Here r_s is the Schwarzschild comparison radius, r_{ph} is the null photon-orbit radius, and r_{ISCO} is the innermost stable circular orbit for massive test bodies. These are effective-metric recovery targets, not claims that the Euclidean void contains a geometric hole.

The same packet should retain the curvature-singularity diagnostic only as a comparison warning:

$$K_{\text{Schw}} = R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta} = \frac{48G^2M^2}{c_0^4 r^6}$$

The native model is expected to replace the $r \to 0$ divergence with finite maximum-curvature bookkeeping, while leaving the exterior weak-field and ringdown observables intact.

Horizon language also has rotating and charged comparison meanings. For rotating or charged comparison branches, Cauchy-horizon instability, exterior no-hair coarse-graining by $(M, \mathbf{J}, Q)$, and ergoregion/frame-dragging records remain comparison constraints on the same strong-field state, not independent ontologies.

Alternative horizon-free gravity proposals are useful here only as stress tests. Their durable challenge is not that their field variables should be imported, but that compact-object energetics, merger dynamics, and accretion feedback are genuinely many-body records. A native black-hole branch must therefore avoid treating a one-body exterior scale as a complete source model. For a retained compact-object window W, the same strong-field record θ_W should supply both the exterior compact labels and the interactive energy ledger,

$$\mathcal{R}_{N\text{-body}}(\theta_W) = \left\| \Delta E_{\text{rad}} + \Delta E_{\text{jet}} + \Delta E_\nu + \Delta E_{\text{med}} + \Delta E_{\text{rem}} + \Delta E_{\text{bind}}^{\text{eff}} - \Delta E_{\text{in}} \right\|_W$$

The pass condition is not horizon absence. It is that $\mathcal{R}_{N\text{-body}}$ stays within the declared tolerance while the same θ_W also recovers lensing, timing, ringdown, and horizon-scale imaging. If a burst, merger, or accretion model needs one record for exterior no-hair behavior and a separate record for the many-body energy release, then the compact-object closure has split into fitted stories.

Horizon-Scale Imaging Benchmark

Event Horizon Telescope observations give the chapter a direct observer-level benchmark for the compact lensing scale. The retained result is not a literal image of the substrate ontology. It is a VLBI reconstruction problem in which calibrated visibilities, closure phases, closure amplitudes, sparse coverage, interstellar scattering, plasma emissivity, and polarization transport are converted into a ring-like compact-source inference.

The useful strong-field record is therefore a transfer map

$$\mathcal{T}_{\text{img}}[\theta] \mapsto \left(D_{\text{ring}}, f_w, C_{\text{dep}}, \mathcal{V}_{ij}(u,v,t), \Phi^{\text{cl}}_{ijk}(t), A^{\text{cl}}_{ijkl}(t), \Pi_{\text{lin}}(\varphi,t), \Pi_{\text{circ}}(\varphi,t)\right)$$

Here D_{ring} is the bright-ring diameter, f_w is the fractional ring width, C_{dep} is the interior brightness-depression contrast, $\mathcal{V}_{ij}$ are baseline visibilities, Φ^{cl} and A^{cl} are closure quantities, and Π_{lin} and Π_{circ} record resolved polarization. These quantities belong to the effective observational layer. They constrain the same strong-field branch record that defines the horizon interface, but they do not replace that constitutive condition.

The current benchmark values are sharp enough to state the separation. For M87*, the 2017 EHT analysis found a stable asymmetric ring with diameter about $42 \pm 3\,\mu\text{as}$, a central brightness depression, and visibility-domain crescent fits with fractional width below 0.5. Later multiepoch analyses keep the diameter stable while brightness and polarization vary. For Sgr A*, the data are harder because the source varies on intrahour timescales and the Galactic-center line of sight scatters the image, but independent imaging and modeling analyses still recover a thick ring with $D_{\text{ring}} \approx 51.8 \pm 2.3\,\mu\text{as}.$

The closure lesson is that geometry-facing and environment-facing terms must not be conflated. The compact ring scale and brightness depression test the effective photon-path and capture map. The azimuthal brightness, fractional width, resolved polarization, Faraday rotation, and jet-base emission test the surrounding plasma, magnetic-like stress, scattering, and release-channel environment. A native black-hole branch fails the benchmark if it can fit the visual image only by changing the mass-to-distance map, if it matches the image while failing the visibility-domain data, or if it treats variable plasma structure as evidence that the horizon-interface condition itself has changed.

Singularity Replacement and the Maximum-Curvature Core

The standard singularity story captures a real pressure: ordinary weak-field extrapolation cannot be trusted indefinitely toward arbitrarily high compression. What $\mathbb{AAA}$ changes is the replacement mechanism. The theory does not leave the divergence untreated, nor does it accept an ontic point singularity. Its proposed replacement is a maximum-curvature regime in which delayed self-hit supplies an outward barrier while the complete signed branch ledger must supply centripetal, tangential, wake-boundary, and stability closure. Its retained-branch status matches the grade carried in Singularity Resolution: a proposed outcome, not an established retained mechanism.

At the assembly level, the candidate mechanism is that opposite-charge binaries driven past the hinge near c_f enter a self-hit regime in which inward attraction is opposed by delayed repulsive feedback from their own path-history wakes. The proposed outcome is a maximum-curvature orbit in place of an unrestricted $r \to 0$ collapse; its stability predicate — acceleration balance and closure on a retained branch — remains open. Black-hole cores are therefore modeled provisionally as dense populations of such maximal-curvature candidate states under extreme collective compression.

The constitutive claim is modest but important: singularity language remains a warning that weak-field effective variables have exceeded their domain, while the ontic replacement is a structured maximum-curvature core with finite internal bookkeeping.

One preserved strong-field intuition is that sufficiently old or sufficiently compressed interiors may approach an ordered collapse limit rather than a thermalized point. In that heuristic picture, maximal-curvature candidate braids pack into a near-crystalline interior, while most entropy remains associated with the active shear and shredding layers nearer the horizon interface. This is not yet a constitutive derivation or a taxonomy assignment, but it is a useful candidate for how collapse can saturate without an ontic singularity.

High-Energy Probe Closure Target

Standard quantum-gravity comparisons preserve a useful benchmark: increasing the energy of a scattering experiment does not grant unlimited access to shorter distances once the compact-object threshold is crossed. At that point the observer-level description must route the record through black-hole formation, horizon behavior, and release-channel accounting. The $\mathbb{AAA}$ translation is that high-energy compression must enter the horizon-interface and maximum-curvature regimes rather than an arbitrary ultraviolet point description.

Let $\ell_{\text{probe}}(E)$ denote the observer-level resolution scale associated with a probe energy E, and let $R_H(E;\theta)$ denote the horizon-interface scale predicted by the same constitutive record θ. The local closure target is the implication

$$\ell_{\text{probe}}(E) \lesssim R_H(E;\theta) \quad\Longrightarrow\quad v_2 = c_f, \quad v_3 \to c_f, \quad S_H \sim k_B \log |\mathcal{B}_H|$$

This is not a claim that the Euclidean void becomes quantized geometry. It is a benchmark on the native strong-field branch: when the effective comparison says that a probe has become a black hole, the same Noether sea state must activate the alignment condition, finite maximum-curvature bookkeeping, and entropy/release-channel ledger used below. If short-distance recovery requires an independent ultraviolet story that bypasses those variables, the black-hole closure has split from the rest of the spacetime program.

Probe-to-Horizon Residual

For a high-energy scattering comparison, take the observer-level probe scale to be $\ell_{\text{probe}}(E) \sim \hbar c_0/E$ unless the apparatus defines a sharper channel-specific scale. The compact-object gate is active when $\ell_{\text{probe}}(E) \leq R_H(E;\theta)$. A concrete residual for that regime is

$$\mathcal{R}_{E\to H}(\theta) = \int dE\, w(E)\, \mathbf{1}_{\ell_{\text{probe}}(E)\leq R_H(E;\theta)} \left[\left(1 - \frac{v_2}{c_f}\right)^2 + \left(1 - \frac{v_3}{c_f}\right)^2 + d_{\text{curv}}(\mathcal{B}_H) + d_{\text{ent}}(S_H, k_B \log |\mathcal{B}_H|) + \mathcal{R}_{\text{release}}(E;\theta) \right]$$

Here $w(E)$ is the comparison weighting for the probe family, d_{curv} checks that the admitted horizon-interface labels carry finite maximum-curvature rows, d_{ent} checks horizon-interface entropy bookkeeping, and $\mathcal{R}_{\text{release}}$ checks the outgoing E, $\mathbf{p}$, $\mathbf{J}$, polarity, provenance, medium-update, and remnant rows through the event ledger.

The closure condition is $\mathcal{R}_{E\to H}(\theta) \leq \epsilon_{E\to H}$ using the same strong-field branch record that recovers exterior compact-object observables. A model fails this gate if it claims arbitrarily short-distance resolution in the active compact-object regime, or if it activates the horizon scale while leaving maximum-curvature labels, entropy capacity, or release-channel accounting undefined.

First Worked Probe Gate

In the weak exterior comparison limit, a single-energy scattering estimate can use

$$\ell_{\text{probe}}(E) \simeq \frac{\hbar c_0}{E}, \qquad R_H(E;\theta) \simeq \frac{2G_{\text{eff}}(\theta)E}{c_0^4}$$

The horizon-interface handoff begins when

$$\frac{\hbar c_0}{E} \leq \frac{2G_{\text{eff}}(\theta)E}{c_0^4}$$

or equivalently

$$E \geq E_H(\theta) \equiv \left(\frac{\hbar c_0^5}{2G_{\text{eff}}(\theta)}\right)^{1/2}$$

This is an observer-level comparison estimate, not a proof that the Euclidean void has Planck-scale cells. Its purpose is to decide when the record should stop being interpreted as a shorter-distance particle probe and start being routed through horizon-interface bookkeeping.

The worked classification is:

Probe regime	Condition	Required native record
particle-probe	$E < E_H(\theta)$	ordinary scattering or effective-field comparison may remain valid if sector gates pass
handoff	$E \approx E_H(\theta)$	the same θ must activate $v_2 = c_f$, $v_3 \to c_f$, and finite maximum-curvature labels
horizon-interface	$E > E_H(\theta)$	the record must report $\mathcal{B}_H$, S_H, release-channel rows, and exterior compact-object observables

The falsifier is not merely failure to choose a numerical Planck scale. The falsifier is a split record: if the short-distance probe uses one θ while the induced horizon-interface, entropy, and release-channel ledgers require another, then the high-energy closure has not survived promotion.

Horizon Interface

The horizon interface is the most important black-hole concept in the local dialect. It names the layer in which Noether braid assemblies are flattened into an alignment-locked sheet.

At this interface:

- the binary 2 remains locked at $v = c_f$;
- the binary 3 is driven to its terminal alignment limit $v_3 \to c_f$;
- precession collapses toward zero;
- information flow is compressed into an interface-like channel rather than ordinary volumetric propagation.

This is why the project treats holographic language as suggestive but not primitive. The horizon behaves like an information-compression interface because the constitutive degrees of freedom have been forced into a constrained alignment state. That motivates the analogy to holography and AdS/CFT without requiring a literal boundary-field ontology.

The alignment state also silences the assemblies geometrically, at hypothesis level. The axial polarity dipole identity places a braid's leading polarity-signed moment entirely on its axial extent, so flattening into the alignment-locked sheet extinguishes the leading term of each assembly's wake signature: the horizon condition and the dipole-quiet condition are the same limit. Darkness at the interface is then not only a causal-escape statement — the loudest broadcast channel of every aligned assembly closes as a matter of geometry, and what remains distinguishable is exactly the higher-moment and phase content retained by the alignment-compatible horizon-interface labels used for the entropy count. The collapse of precession in the same limit is the matching symmetry statement: precession measures distance from the symmetric channel, so an alignment-locked sheet is also a precession-silenced sheet, and the two observables should extinguish together. Both statements are exported from the braid scene and inherit its evidence boundary; neither is a retained-branch claim.

Horizon-Adjacent Photon Channel

The horizon interface is not modeled as a smooth geometric shell surrounding an otherwise empty interior. It is an active Noether sea regime in which ordinary volumetric assemblies, photon-channel packets, dark-sector photon-channel-adjacent modes, and terminally aligned Noether braid states can all be near the same symmetry-breaking threshold. The interface is therefore closer to a high-energy transport and selection layer than to a passive surface.

The photon connection is especially sharp because the photon carrier is a coaxial contra-rotating polarity-conjugate planar pair. A photon is not a horizon, but it is a moving planar-pair record built from the same pro/anti flattening logic that the horizon exposes under strong-field alignment. Near a black-hole interface the question is therefore not only whether light is redshifted on escape. The stronger native question is which photon-channel or photon-channel-adjacent records enter, are blueshifted, are trapped, are converted, or are released by the same horizon-interface ledger.

For a horizon-adjacent photon path Γ_H, retain the signed strong-field frequency row

$$Y_{\gamma,H} = \sum_{j \in \Gamma_H} \Delta Y_{\gamma,H,j}, \qquad \Delta Y_{\gamma,H,j} = -\ln \frac{\nu^+_{\gamma,j}}{\nu^-_{\gamma,j}}$$

so $\Delta Y_{\gamma,H,j} < 0$ records a blueshift segment and $\Delta Y_{\gamma,H,j} > 0$ records a redshift segment relative to the local comparison clock. Interior-facing segments can therefore drive photon-channel packets to energies not directly sampled by exterior observers, while exterior-facing segments may redshift those packets before they become visible or before they are thermalized into a background. The corresponding energy ledger is

$$\mathcal{R}_{H\gamma\text{-ex}} = \sum_{j \in \Gamma_H} \frac{\left| h(\nu^+_{\gamma,j} - \nu^-_{\gamma,j}) + \Delta E_{H,j} + \Delta E_{\mathrm{med},j} + \Delta E_{\mathrm{recoil},j} + \Delta E_{\mathrm{rem},j} \right|}{\epsilon_{E,j}}$$

where $\Delta E_{H,j}$ is the horizon-interface or interior strong-field row and the other terms record medium, recoil, and remnant exchange. A high-energy photon output claim is admissible only when this residual closes and the outgoing packet still carries the required photon Gate A and Gate B handoffs. If those handoffs fail, the channel has become absorption, re-emission, pair production, or another release reaction.

This is the disciplined version of the "roiling horizon" intuition. The horizon interface may contain intense photon-channel and photon-adjacent activity, and some of it may be routed into jets, diffuse radiative outflow, dark-sector escape, or later visible conversion. But each proposed route must state the release selector, the energy-frequency ledger, the polarization and angular-momentum handoff, and the coupling to the surrounding Noether sea. Otherwise the claim has only renamed black-hole radiation rather than deriving a strong-field transport channel.

Modern holographic entropy work, including Ryu-Takayanagi, island, and replica-wormhole calculations, should be treated in this chapter as a comparison framework rather than as imported ontology. Its value is that it sharpens a high-value consistency target: a mature horizon-interface model should explain how compressed interface bookkeeping can remain compatible with Page-curve recovery and smooth effective horizons. It does not, by itself, supply the $\mathbb{AAA}$ mechanism. The local task is still to derive entropy and information accounting from the hypothesized terminal Family-A alignment, path-history bookkeeping, Noether sea storage, and release-channel selection.

The Ryu-Takayanagi comparison makes this distinction sharper. A region-anchored entropy surface is not automatically the event horizon; in vacuum or nonthermal comparisons it can have no horizon component at all, while in thermal black-hole limits a large-region surface can wrap the horizon. For a candidate strong-field record θ, let $\gamma_A^{\mathrm{eff}}(\theta)$ be the effective entropy surface associated with access region A, and let $H_{\mathrm{eff}}(\theta) = \{F_H = 0\}$ denote the observer-level horizon surface selected by the same record. The useful diagnostic is the horizon-wrapping fraction

$$\eta_H(A;\theta) = \frac{A_{\mathrm{eff}}\left(\gamma_A^{\mathrm{eff}}(\theta) \cap H_{\mathrm{eff}}(\theta)\right)}{A_{\mathrm{eff}}\left(\gamma_A^{\mathrm{eff}}(\theta)\right)}$$

The event-horizon reading is justified only in the $\eta_H \to 1$ regime. When $\eta_H = 0$ or remains bounded away from one, the holographic comparison is still useful as an access-region entropy test, but it is not evidence that the boundary surface is the horizon-interface ontology.

A useful way to state the native task is through a horizon-interface label ensemble. Let λ_i^H denote a retained horizon-interface ledger label selected by the strong-field record. Such a label may include neutral Noether braid closure rows, charged assembly rows, and allowed interface-channel rows; its charge and polarity ledger has exterior scalar readout q_i. For an effective exterior black-hole label $(M, \mathbf{J}, Q)$, define the schematic ensemble

$$\mathcal{B}_H(M,\mathbf{J},Q) = \left\{ \{\lambda_i^H\}_{i=1}^N : \sum_i E_i = Mc_0^2, \quad \sum_i \mathbf{J}_i = \mathbf{J}, \quad \sum_i q_i = Q, \quad v_2 = c_f, \quad v_3 \to c_f, \quad \text{horizon-interface compatibility} \right\}$$

The use of c_0 in the energy row marks the observer-level exterior calibration of the no-hair label; a local c_{eff} row belongs to the constitutive map that produces the exterior record. In plain language, $\mathcal{B}_H$ is the set of strong-field horizon-interface ledger arrangements that look identical to exterior probes once the probe can resolve only effective mass, angular momentum, charge, and allowed interface channels. This gives a precise no-hair reading: exterior no-hair is a coarse-graining over many compatible closure labels, not evidence that the interior has no microstate.

The corresponding thermodynamic closure target is

$$S_H = k_B \log |\mathcal{B}_H(M,\mathbf{J},Q)|, \qquad S_H \overset{\text{target}}{\sim} \frac{k_B A_H}{4A_{\mathrm{align}}}$$

where A_H is the observer-level horizon area and A_{align} is the alignment-area scale from the Planck-alignment program, with the numerical and 2π conventions fixed by that derivation rather than by definition here. Page-curve recovery then becomes a release-channel theorem: outward channels must preserve enough phase, axial-pattern, and path-history information from $\mathcal{B}_H$ to make evaporation or recycling unitary at the effective quantum level, while still appearing thermal to coarse exterior measurements.

The coefficient in this target is not a literal claim that one alignment patch carries $e^{1/4}$ independent states. The local target is an area-normalized block entropy density. For a connected block U of horizon-adjacent alignment patches, let $\mathcal{L}_U^H(\theta)$ be the retained alignment-compatible label set induced by the same strong-field record and let $A_H(U)$ be the observer-level area represented by that block. The local density target is

$$s_{\mathrm{align}}^H(\theta) = \lim_{|U|\to\infty} \frac{1}{|U|} \log \left|\mathcal{L}_U^H(\theta)\right|, \qquad a_H(\theta) = \lim_{|U|\to\infty} \frac{A_H(U)}{|U| A_{\mathrm{align}}}, \qquad \frac{s_{\mathrm{align}}^H(\theta)}{a_H(\theta)} \longrightarrow \frac{1}{4}$$

with boundary corrections vanishing in the large-block limit. This is the local calculation that must make the global area law credible; the raw statement $s_{\mathrm{align}}^H \to 1/4$ is only the special case $a_H \to 1$.

This global horizon ensemble must be compatible with the local boundary-wake entropy density used in Emergent Metric. For a compact region Ω whose boundary intersects the horizon interface, let $\pi_{\partial\Omega}^{(O)}$ be the Physical Observer projection from strong-field horizon-interface labels to retained boundary-wake labels, and write $\mathcal{B}_H(\theta)$ for the horizon-interface ensemble selected by the same strong-field record. The proof route requires

$$\left|\log\left|\pi_{\partial\Omega}^{(O)}\mathcal{B}_H(\theta)\right| - \log\left|\mathcal{B}_{\partial\Omega}^{(O)}\left(\theta_{\Omega,O,W}\right)\right|\right| \le \epsilon_{\mathrm{proj}}$$

for the same strong-field record θ restricted to the observer window and the same block or patch family. If the local boundary density and the global horizon-interface count require different records, the entropy target has split into two fitted stories. If they agree, the black-hole area law is no longer an isolated assumption; it becomes the compact strong-field version of the local boundary-factorization theorem target.

The words “thermal,” “scrambled,” and “recoverable” are therefore readout-channel claims, not direct ontology labels. For a Physical Observer O, let $\mathcal{K}_O^{\mathrm{rad}}$ denote the declared radiation readout kernel and let $\mathcal{R}_O$ denote the physical reference resources used to compare outgoing quanta. A horizon-interface ledger state $\lambda \in \mathcal{B}_H(M,\mathbf{J},Q)$ reaches the observer through a channel of the schematic form

$$Y_O = \pi_O^{\mathrm{rad}}\left(\lambda; \mathcal{K}_O^{\mathrm{rad}}, \mathcal{R}_O, \mathcal{B}_{\partial\Omega}\right)$$

Before a black-hole information claim is promoted, the comparison packet must say which $\mathcal{K}_O^{\mathrm{rad}}$, reference resources, access region, and finite boundary data make the outgoing channel meaningful. A coarse exterior channel may legitimately see an approximately thermal distribution while a richer correlated reference channel retains structure, but that difference is a statement about observer-accessible records. It does not import a boundary CFT, many-copy tomography story, or external reference frame as $\mathbb{AAA}$ ontology.

The same packet should also carry a detailed-balance comparison rather than treating CPT language as an ontological shortcut. Let $\mathcal{L}_H$ be the declared set of horizon-interface formation and release ledger channels for a compact region Ω. For a candidate strong-field record θ, require

$$\mathcal{R}_{H,\mathrm{bal}}(\theta) = \sum_{\ell \in \mathcal{L}_H} w_\ell \left[P_\theta(\ell_{\mathrm{in}} \to \mathcal{B}_H) - P_\theta(\mathcal{B}_H \to (CPT)_{\mathrm{eff}} \ell_{\mathrm{out}})\right]^2 + d_{\mathrm{ent}}\left(S_H^{(O)}, k_B \log |\mathcal{B}_H^{(O)}| + S_{\mathrm{out}}^{(O)}\right) + d_{\mathrm{CPT}}(\mathcal{R}_{\mathrm{CPT}}(\theta), 0)$$

The pass condition is $\mathcal{R}_{H,\mathrm{bal}}(\theta) \leq \epsilon_H$ using the same branch record that recovers exterior compact-object observables. This does not assert a literal mirror universe, a white-hole ontology, or a final-state boundary postulate. It says that if the effective comparison invokes CPT or thermal equilibrium, the native horizon-interface release ledger must exhibit the corresponding formation/release balance within the declared observer access channel.

The species puzzle supplies a separate entropy guardrail. If N_{spect} counts effective spectator species that do not enter the native closure labels, release channels, or null-result ledger, then horizon entropy should be insensitive to those labels:

$$\left| \frac{\partial S_H^\theta}{\partial N_{\mathrm{spect}}} \right|_{\mathcal{B}_H, \partial\Omega} \leq \epsilon_{\mathrm{spect}}$$

If an added species is physically real, it must change $\mathcal{B}_H$, $S_{\mathrm{out}}^{(O)}$, a release-channel row, or $\mathcal{R}_{\mathrm{null}}$. If it changes none of those records, it is an effective-description label and may not be used to tune black-hole entropy.

The classical area-increase result supplies a direct benchmark for this target. In the standard exterior description, a clean merger comparison has

$$A_{H,\mathrm{final}} \geq A_{H,1} + A_{H,2}$$

under the usual classical assumptions. The $\mathbb{AAA}$ translation is not that area is a primitive substance. It is that the horizon-interface label capacity and outgoing-channel entropy must reproduce the same nondecreasing observer-level bookkeeping in the regime where GR is already validated. A schematic closure check is

$$S_{H,\mathrm{final}}^{(O)} \geq S_{H,1}^{(O)} + S_{H,2}^{(O)} - \Delta S_{\mathrm{out}}^{(O)}$$

with $\Delta S_{\mathrm{out}}^{(O)}$ accounting for accessible radiation, waves, and release channels during the merger. This keeps the area theorem as a standard-theory benchmark rather than as imported horizon ontology.

GW250114 is the clean modern example of this comparison. The useful input is the event packet: near-equal $\sim 33 M_\odot$ progenitors, low spins, a high signal-to-noise post-merger record with the dominant quadrupolar ringdown mode and first overtone, and an inferred final area larger than the sum of the initial areas. That packet strengthens the area-law and Kerr-ringdown benchmarks, but it does not change the claim level. The native burden is still to recover nondecreasing horizon-interface label capacity and damped ringdown labels from the same source-event record, not to import the event horizon as primitive ontology.

A sharper comparison target comes from generalized-entropy work in semiclassical gravity. In that setting, the entropy relevant to an exterior access region is not only the horizon-area term; it also includes the quantum entropy of radiation and matter outside the inaccessible region. The local translation is an observer-accessible horizon ledger:

$$\mathcal{B}_H^{(O)}(t) \subseteq \mathcal{B}_H(M, \mathbf{J}, Q)$$

where O denotes a Physical Observer and $\mathcal{B}_H^{(O)}(t)$ is the subset of horizon-interface ledger states indistinguishable to that observer's finite records, clocks, and exterior channels at time t. The corresponding comparison target is

$$S_H^{(O)}(t) = k_B \log \left| \mathcal{B}_H^{(O)}(t) \right| + S_{\mathrm{out}}^{(O)}(t)$$

where $S_{\mathrm{out}}^{(O)}(t)$ summarizes the entropy of accessible outgoing channels. This equation is not a new ontology. It is a bookkeeping target: the native horizon-interface model should explain how the area-like ledger term and the outgoing-channel entropy combine into a finite observer-level entropy, and how that combined quantity can reproduce Page-curve behavior without importing islands, replica wormholes, or a boundary CFT as primitive structure.

In the same notation, the region-anchored entropy target is

$$S_{\mathcal{Q},A}^{(O)}(t) \stackrel{\mathrm{target}}{=} k_B \log \left| \mathcal{L}_{\gamma_A}^{(O)}(t) \right| + S_{\mathrm{out},A}^{(O)}(t)$$

The proof burden is to define the observer-relative label ensemble $\mathcal{L}_{\gamma_A}^{(O)}(t)$ from native horizon-interface, boundary-wake, and release-channel records. When $\eta_H(A;\theta) \to 1$, this target must reduce to the horizon-interface ledger target above; when $\eta_H(A;\theta) = 0$, it remains an access-region entropy comparison and should not be promoted as black-hole horizon entropy.

This also disciplines the local semiclassical version of the information paradox. A statement that a horizon-straddling correlation has been lost is only a promoted comparison claim after the access region, reference resources, boundary wake data, and readout channel have been declared. Local QFT pair language remains useful near a smooth effective horizon, but it is an approximation to an observer-level calculation. The native black-hole closure must say which Physical Observer could recover which part of the release record, and which finite boundary data make that recovery meaningful.

Complexity-Growth Comparison Target

Black-hole complexity proposals add a narrower comparison target. Their useful content is not the claim that interior volume is primitive ontology. It is the observation that some black-hole interior comparisons continue to change long after ordinary thermal entropy has effectively saturated. The native translation is a horizon-interface ledger complexity, not a new spacetime substance.

For two compatible horizon-interface label states $\Lambda_a, \Lambda_b \in \mathcal{B}_H(M, \mathbf{J}, Q)$, define

$$\mathcal{C}_H(\Lambda_a, \Lambda_b) = \min\{N : U_N \circ \cdots \circ U_1(\Lambda_a) = \Lambda_b,\ U_i \in \mathcal{U}_{\text{loc}}\}$$

where $\mathcal{U}_{\text{loc}}$ is the permitted set of local horizon-interface, assembly, path-history, and release-ledger updates inside the horizon-interface model. For a horizon history, write $\mathcal{C}_H^{(O)}(t)$ for the minimum such update count between the observer-accessible initial ledger and the compatible ledger class at time t.

The comparison burden is then:

$$S_H^{(O)}(t) \text{ approximately saturates while } \mathcal{C}_H^{(O)}(t) \text{ can continue to grow}$$

without breaking exterior no-hair behavior, Page-compatible release accounting, or finite-boundary-data regularity. If this growth can be matched only by importing a literal boundary CFT, an AdS interior ontology, or an independent hidden state not present in $\mathcal{B}_H^{(O)}(t)$, then the complexity comparison has not been translated into the native black-hole closure.

Finite-Boundary Endpoint Closure

The endpoint and information questions should be posed on a compact strong-field region rather than by assuming an observer at asymptotic infinity. For a region Ω bounded by finite observer-accessible data between absolute times T_i and T_f, the native closure target is a single continuation map

$$\mathcal{T}_\Omega : \Big(X_\Omega(T_i), \mathcal{H}_\Omega^{<T_i}, \mathcal{B}_{\partial\Omega}|_{[T_i,T_f]}, N_{\text{sea}}|_{\Omega\times[T_i,T_f]}\Big) \longrightarrow \Big(X_\Omega(T_f), \mathcal{B}_H^{(O)}(T_f), S_{\text{out}}^{(O)}(T_f)\Big)$$

Here X_Ω, $\mathcal{H}_\Omega^{<T}$, and $\mathcal{B}_{\partial\Omega}$ are the finite-region variables from Observer Framework. The closure requirement is not that a particular remnant, bounce, or asymptotic boundary story be adopted. It is that the same finite boundary data determine a finite strong-field continuation:

$$F_H = 0, \qquad \mathcal{R}_H(\Omega) < \infty, \qquad 0 < \left|\mathcal{B}_H^{(O)}(T_f)\right| < \infty$$

with outgoing energy, momentum, angular momentum, charge, polarity, provenance, and medium-update rows accounted for through the release-channel ledger.

This gives a compact comparison rule for evaporation and endpoint proposals. A proposal can be used as a comparison framework if it sharpens one of those finite-ledger checks. It should not be promoted into the ontology unless the same native horizon-interface variables produce the continuation without an arbitrary endpoint branch or a separate asymptotic bookkeeping rule.

No-hair, cosmic-censorship, Cauchy-horizon, and endpoint theorems enter this chapter with the same assumption discipline. Their strongest use is to preserve exterior compact-object behavior, horizon regularity, non-arbitrary continuation, and finite-release accounting where their hypotheses match the comparison regime. When a theorem assumes an isolated vacuum black hole, asymptotically flat exterior, or global hyperbolicity condition, it cannot by itself settle a black hole embedded in an evolving Noether sea. The retained burden is sharper: the native horizon-interface record must reproduce the exterior $(M, \mathbf{J}, Q)$ coarse-graining, avoid observer-level naked-singularity pathology, and select a finite continuation family using finite active-medium boundary data.

As a heuristic geometric picture, the horizon can also be described as a **dimensional pinch** along the candidate Family-A response path. On this reading, ordinary 3D assemblies are flattened toward a near-planar disk at the alignment interface, while the interior self-hit regime permits re-opening of the suppressed axial degree of freedom. In shorthand, the proposed response path is

$$\text{3D sphere} \to \text{2D horizon disk} \to \text{3D interior reopening}$$

This is not yet a derived strong-field theorem. It is a compact way of expressing why the horizon is treated as an information-compression layer rather than as a literal ontic edge of space. The planar-disk stage $\xi \to 0$ is the same envelope endpoint that appears as the light-speed limit of the Lorentz axis ratio in Lorentz Kinematics and as the coherent-boson limit in Fermi-Dirac and Bose-Einstein Statistics: the horizon pinch, the null limit, and the boson limit are one geometric endpoint reached from strong-field geometry, kinematics, and statistics.

Cosmological Embedding and Horizon Regularity

A viable black-hole account in $\mathbb{AAA}$ must work at two scales simultaneously. It must reproduce the compact-object phenomenology of the local exterior, and it must remain coherent when the object is embedded in the evolving large-scale medium. This requirement matters because many intuitive pictures of black holes tacitly treat them as if they lived in asymptotically isolated settings, whereas the cosmological sector requires a compact object to sit inside a time-dependent background.

For that reason, the framework treats horizon regularity under cosmological embedding as a non-negotiable structural requirement. If a proposed strong-field description becomes pathological precisely when one asks how the local object couples to the surrounding Noether sea, then it is not yet a closed black-hole model. In $\mathbb{AAA}$, the regularity requirement is met not by postulating a passive background but by letting the local strong-field geometry and the ambient Noether sea state backreact on one another through the same constitutive variables.

This point sharpens the role of the horizon interface. The interface is not just the place where local assembly geometry reaches terminal alignment. It is also the layer through which the compact object remains connected to the surrounding Noether sea without forcing a curvature blowup at the very location where the constitutive transition is most intense. In that sense, horizon regularity is not cosmetic. It is a closure test for whether the black-hole regime can genuinely communicate with cosmology.

The strong-field closure should therefore be posed as a Noether sea boundary-condition problem, not as the direct importation of an isolated Schwarzschild or Kerr metric. The horizon-interface condition is the canonical closure problem stated in Singularity Resolution, written here in shorthand as

$$F_H = 0, \qquad v_2 = c_f, \quad v_3 \to c_f$$

This chapter supplies the horizon-interface label ensemble $\{\lambda_i^H\}$ defined above as the finite continuation-label family required by the canonical condition, and $\partial\Omega$ denotes the boundary data supplied by the surrounding Noether sea and the effective exterior comparison region. The equation is a closure target, not a completed model: the task is to show that the same Noether sea variables that recover weak-field gravity can also admit a regular terminal-alignment interface under non-isolated embedding conditions. Compact, topologically identified, or otherwise non-asymptotically-flat comparison settings are useful stress tests for this requirement, but they do not add extra dimensions to the substrate ontology.

The finite-boundary-data version of this requirement is inherited from singularity-resolution.md. For every compact strong-field comparison region Ω, the native variables $\rho_{\mathrm{NS}}(\mathbf{X}, T)$, $\Sigma_{\mathrm{sea}}(\mathbf{X}, T)$, and $\mathbf{u}_{\mathrm{sea}}(\mathbf{X}, T)$ must remain finite while the horizon-interface condition is imposed. This is the local substitute for treating a classical metric singularity as an endpoint: the weak-field variables may fail, but the Noether sea ledger and maximum-curvature closure must not become arbitrary.

Recent regular-horizon cosmological-embedding work is useful at this comparison level. Its value is not that an FLRW-embedded Schwarzschild variant or anisotropic-fluid source becomes the native model. The useful pressure is structural: a compact object must be describable inside an evolving large-scale background without producing a new curvature pathology at the horizon interface. In the external comparison, that requires apparent-horizon rather than static-horizon discipline, local/cosmological backreaction, and a mass split such as Misner-Sharp accounting so the compact-object contribution is not silently confused with the cosmological density term. In the local ontology, the same lesson translates into finite Noether sea boundary data, finite native variables, and a non-arbitrary maximum-curvature continuation through the interface record used for exterior mass, redshift, and release-channel comparisons.

Interior Dynamics and Recycling

Inside the black-hole regime, the dominant language is recycling rather than annihilation. Matter and radiation driven inward do not disappear from ontology. They are processed through branch-derived self-hit layers, interface locking, and exposed-channel reconfiguration. The resulting interior is best treated as a statistical medium of maximal-curvature assemblies rather than as a smooth classical fluid or a single deterministic orbit family.

The working picture has four parts:

- infalling assemblies are compressed toward maximal-curvature states;
- energy is redistributed across inner, middle, and outer layers rather than lost from the ontology;
- the horizon interface mediates which excitations remain trapped, which are delayed, and which can be re-expressed as outbound channels;
- re-emergence may occur through jets, radiative outflows, dark-sector photon-channel-adjacent modes, or other medium excitations, depending on the local state of the core and interface.

The corresponding interior-state ladder is a claim-level map, not a proof that every compact object realizes every rung:

Layer	Native record	Observer-facing pressure
Ordinary infall	matter, radiation, and Noether sea assemblies entering the compact region	accretion luminosity, disk state, and inflow angular momentum
Compact-matter predecessor	dense nuclear, quark, or mixed assembly support before horizon-interface exit	mass-radius, equation-of-state, and tidal-deformability constraints

Layer	Native record	Observer-facing pressure
Maximum-curvature packing	finite packed assembly and Noether braid records with self-hit-dominant closure	singularity replacement and finite-boundary-data regularity
Horizon-interface selection	alignment-compatible labels, trapped and outbound channel decisions	entropy capacity, release-channel selection, and exterior ring/jet observables
Outbound reconstitution	released assembly, photon-channel, dark-sector, or medium-excitation routes	jets, winds, diffuse release, dark-sector signatures, or reabsorption

The ladder keeps interior discussion from jumping directly from generic infall to visible jets or cosmological source terms. Each occupied rung must carry energy, momentum, angular momentum, polarity, provenance, shielding/exposure, and Noether sea update rows.

This is the sense in which black holes are treated as recycling furnaces in the cosmology chapters. The claim is not that every specific ejecta channel has already been derived. The claim is that the interior is an energy-partition and reprocessing regime, not a terminal ontic sink.

The same picture implies that the effective mass of a black hole need not be interpreted as a purely isolated bookkeeping variable. If the horizon interface and interior remain constitutively coupled to the ambient Noether sea, then part of what observers infer as compact-object mass can depend on how the surrounding Noether sea loads, unloads, or stores energy around the recycling site. This does not license arbitrary mass drift. It means that the distinction between “local compact-object state” and “embedding Noether sea state” is dynamical rather than absolute.

The corresponding mass statement is an exposure ledger, not a claim that mass can disappear. In a resolved strong-field window the exterior reconstruction must separate incoming energy, compact stored energy, shielding and exposure change, escaped outflow, reabsorbed content, and embedding Noether sea loading. A useful schematic form is

$$\Delta\big(M_{\mathrm{app}}c_0^2\big) = \Delta E_{\mathrm{comp,exp}} + \Delta E_{\mathrm{sea,emb}} - \Delta E_{\mathrm{out,esc}} + R_{M,\mathrm{app}},$$

with the hidden rows expanded when a release channel is being tested. The point is not that the compact object violates conservation. The point is that the observer-facing mass label is a projection of a larger strong-field, shielding, release, and medium-coupling record.

Mass-Scale Traversal

The exterior-to-core sequence is the same for black holes at every mass scale, but the relative weight of the local gradients, horizon-interface capacity, release channels, and cosmological embedding changes with mass. The useful comparison is therefore not a separate ontology for small, stellar, and supermassive black holes. It is one traversal map evaluated with different effective horizon scales.

In a weak exterior comparison, write the observer-level horizon scale as

$$R_H(M;\theta) \simeq \frac{2G_{\mathrm{eff}}(\theta)M}{c_0^2}, \qquad A_H(M;\theta) = 4\pi R_H^2(M;\theta)$$

The native strong-field interpretation does not treat R_H or A_H as primitive geometry of the Euclidean void. They are observer-level readouts of the same horizon-interface condition $v_2 = c_f,\ v_3 \to c_f$. Still, their scaling organizes which closure burden dominates. The interface label capacity scales schematically like

$$N_{\mathrm{align}}(M;\theta) \sim \frac{A_H(M;\theta)}{A_{\mathrm{align}}}$$

while the exterior tidal or curvature pressure at the horizon scales, in the same comparison limit, like

$$\mathcal{K}_H(M;\theta) \sim \frac{G_{\mathrm{eff}}(\theta)M}{R_H^3(M;\theta)} \propto M^{-2}$$

This gives a compact mass-scale rule. Small black holes concentrate the traversal into a tiny region with steep local gradients, high comparison temperature, and release-channel pressure. Stellar-mass or intermediate black holes are the clean collapse-ladder case: the record must pass from compact matter through the neutron-star branch or its failure into the horizon-interface branch. Supermassive black holes have comparatively gentle local horizon gradients but enormous interface capacity, long-lived recycling, and the strongest coupling to the ambient Noether sea embedding.

Scale	Dominant pressure	$\mathbb{AAA}$ reading
Small or near-evaporating black hole	Steep local gradients, high release-channel pressure, small N_{align}	Best stress test for finite maximum-curvature replacement, Hawking-like release normalization, and endpoint ledger closure.
Stellar-mass or intermediate black hole	Collapse-ladder continuity and merger/ringdown consistency	Best stress test for the handoff from dense matter support to terminal alignment and for exterior strong-field recovery.
Supermassive black hole	Large N_{align}, long recycling time, strong environmental embedding	Best stress test for Noether sea loading, release-channel selection, dark-sector hypotheses, and possible cosmological coupling.

A small compact object passing through material is therefore a response problem, not merely a mass label. For a candidate with effective radius R_X, mass M_X, speed v_X, and material density ρ_{mat}, the transit ledger should estimate the deposited energy and damage radius from the material response function:

$$\frac{dE_{\mathrm{dep}}}{d\ell} = \mathcal{S}_{\mathrm{stop}}(M_X, R_X, v_X; \theta_{\mathrm{mat}}), \qquad r_{\mathrm{dam}} = \mathcal{D}_{\mathrm{mat}}\left(\frac{dE_{\mathrm{dep}}}{d\ell}, \theta_{\mathrm{mat}}\right)$$

If the object is horizon-like in the observer comparison, R_X is bounded by the effective horizon scale $R_H(M_X; \theta)$; if it is a native maximum-curvature defect, R_X is instead supplied by the core-interface branch. Either way, the material claim must pass through the same energy-deposition, acoustic, thermal, and defect-survival record before it is used as evidence for a compact dark-sector branch.

The scale map is a classification aid, not a new gate. It says which existing black-hole burdens become sharp as M changes: small black holes emphasize endpoint and release accounting, intermediate-mass black holes emphasize collapse continuity, and supermassive black holes emphasize embedded recycling and Noether sea state source terms.

Jets and Other Release Channels

Jets should remain in the black-hole story, but they should be placed at the correct level. In $\mathbb{AAA}$, jets are not the definition of recycling. They are one candidate macroscopic manifestation of release from a recycling site. The deeper claim is that strong-field interiors can return some portion of their processed content to the surrounding Noether sea; the jet question is how much of that return becomes collimated, how much remains diffuse, and how much leaves in channels that are initially dark to ordinary electromagnetic observation.

For that reason, the framework uses a release-channel hierarchy:

- **Constitutive claim:** infalling matter and radiation can be reprocessed into outward channels.
- **Astrophysical channel claim:** some of those outward channels may become observable jets or winds.
- **Dark-sector claim:** some channels may cross outward through the horizon interface as recycled dark-matter-like or dark-energy-like assemblies, or as dark-sector photon-channel-adjacent modes, before later converting into visible excitations, if they do so at all.

This hierarchy keeps the theory from overcommitting to a single morphology. A jet is evidence for organized outflow, not by itself proof that all recycling must emerge in collimated form.

The same hierarchy also separates two recycling modes. A strong-field site may load the surrounding Noether sea diffusely without producing a narrow visible jet, or it may route part of the same processed content into a collimated assembly, photon-channel, or mixed-sector outflow. These are different channel records. The diffuse mode asks how the ambient Noether sea density, cadence, orientation, and delay-factor state are updated. The collimated mode asks how the horizon interface, disk or boundary layer, and environment select a directed outflow with definite energy, momentum, angular momentum, composition, and lifetime.

The same distinction can be phrased as a sequence.

1. Core processing compresses infalling content into maximum-curvature and alignment regimes.
2. The horizon interface selects which modes remain trapped and which can move outward.
3. The released content then appears as one or more observer-level channels: jets, broader winds, radiative outflow, or initially dark-sector escape.

This ordering preserves your original intuition that jets may inject recycled matter or energy into the surrounding Noether sea while keeping the framework open to the possibility that some released content leaves the horizon interface in forms that are not immediately visible.

Dark-Sector Escape and Re-Entry

The local framework therefore keeps open the possibility that some processed content crosses outward through the horizon interface in a form that is initially dark to ordinary electromagnetic observation. In that case, “escape the event horizon” should be read in the constitutive sense: a mode successfully traverses outward through the alignment-locked interface after a state transition.

Three working possibilities remain live:

- **Dark-sector escape:** a released mode stays weakly coupled to visible matter after outward crossing and contributes mainly through gravitational or dark-sector signatures.
- **Recycled dark assemblies:** the released content emerges as assembly populations that behave effectively like dark matter or dark energy after outward crossing, remaining weakly coupled to visible channels.
- **Dark-sector photon-channel-adjacent escape with later conversion:** a released mode exits in an initially dark photon-channel-adjacent form and only farther from the horizon re-enters visible channels through dissipation, coupling, or geometric relaxation.

Jet Production as a Selection Problem

The open physical question is not merely whether release occurs, but why some environments produce narrow, persistent jets while others favor broader or darker outflows. In this framework, that is a channel-selection problem governed by at least four ingredients:

- the degree of horizon-interface alignment;
- the state of the surrounding Noether sea, including anisotropy and loading;
- the composition of the released mode mix;
- the ambient matter and effective magnetic-like environment through which the outflow propagates.

This is the disciplined way to keep jets in the chapter: as one important release channel among several, rather than as the whole definition of recycling.

Rotating compact sources add one more bridge variable. In standard comparison language, frame dragging is a metric effect around a rotating mass. In $\mathbb{AAA}$ it should be recovered as an effective readout of the same angular-momentum ledger, surrounding Noether sea vorticity, and horizon-interface state that also enter release selection:

$$\boldsymbol{\omega}_{\text{eff}} = \mathcal{W}_{\text{drag}}\left(\mathbf{J}_{\Omega}, \nabla \times \mathbf{u}_{\text{sea}}, \mathcal{A}_{\text{NS}}, \mathcal{B}_{H}\right).$$

This does not make the Euclidean void rotate. It states the recovery target: the observer-level dragging of local inertial frames must be reconstructed from compact-source angular momentum, Noether sea flow and anisotropy, and the same interface record used by jets or diffuse release.

Observer-level jet phenomenology supplies three compact constraints on this selection problem. First, powerful collimated outflows are strongly associated with compact accretors and disks, so the native record must include an inflow, disk, or boundary-layer source of energy and angular momentum. Second, across young stellar objects, microquasars, and active galactic nuclei, the characteristic jet speed is usually of order the escape or Keplerian speed at the launch region:

$$\mathcal{R}_{v,\text{jet}} \equiv \frac{v_j}{v_{\text{esc}}(R_{\text{launch}})} \sim 1, \qquad v_{\text{esc}}(R_{\text{launch}}) = \left(\frac{2G_{\text{eff}}M}{R_{\text{launch}}}\right)^{1/2}$$

This is an effective launch benchmark, not a claim that Newtonian escape speed is substrate ontology. It says that the same strong-field or disk-interface record that powers release must also set the observed launch speed scale. Third, collimation must survive propagation through the ambient Noether sea. A minimal release-channel packet should therefore record

$$\mathcal{Q}_{\text{jet}} = \left(\frac{dM_{\text{out}}}{dt_{\text{eff}}}, \frac{d\mathbf{P}_{\text{out}}}{dt_{\text{eff}}}, \frac{dE_{\text{out}}}{dt_{\text{eff}}}, \frac{d\mathbf{J}_{\text{out}}}{dt_{\text{eff}}}, \theta_j, \eta_j, \mathcal{A}_{\text{NS}}, \mathcal{R}_{v,\text{jet}}\right)$$

where θ_j is the opening angle, η_j is the observer-level jet-to-ambient density ratio, and $\mathcal{A}_{\text{NS}}$ is the local Noether sea anisotropy and loading state mapped to effective magnetic-like collimation. In a black-hole branch, spin-powered extraction, disk-powered extraction, hot-corona loading, and supercritical accretion are comparison mechanisms until the native horizon-interface ledger shows which terms actually supply $dE_{\text{out}}/dt_{\text{eff}}$ and $d\mathbf{J}_{\text{out}}/dt_{\text{eff}}$. A model fails this selection packet if it produces a horizon recycling source but leaves the launch-speed scale, angular-momentum drain, or collimation angle unrelated to the same boundary data.

AGN jets sharpen this packet because the same source class ties near-hole launching to large-scale environmental work. The observer-level review signal is not “spin alone makes a jet.” Powerful radio jets appear to require a rotating compact object plus a strongly loaded disk or inflow state that can sustain large-scale ordered stress; lower-power or differently loaded systems may stay radio quiet, form weak steady jets, or degrade into plumes. In $\mathbb{AAA}$ this becomes a release-channel selector rather than a new ontology. Let

$$\Theta_{\text{AGN}}(t) = \left(M, \mathbf{J}, \dot{M}_{\text{in}}(R_{\text{inf}}, t), \dot{M}_{\text{acc}}(R_{\text{launch}}, t), \Phi_{\text{BH}}^{\text{obs}}(t), \mathcal{A}_{\text{NS}}(R, t), \Sigma_{\text{wind}}(R, t), \mathcal{B}_{H}(t)\right)$$

where R_{inf} is the observer-level black-hole influence scale, $\Phi_{\text{BH}}^{\text{obs}}$ is the standard black-hole magnetic-flux comparison diagnostic rather than substrate field ontology, $\mathcal{A}_{\text{NS}}$ is the mapped Noether sea anisotropy and loading state, and Σ_{wind} records disk-wind or sheath confinement. The local selector must then produce one channel record

$$\Pi_{\text{AGN}}[\Theta_{\text{AGN}}] \mapsto \left(\frac{dE_j}{dt_{\text{eff}}}, \frac{d\mathbf{P}_j}{dt_{\text{eff}}}, \frac{d\mathbf{J}_j}{dt_{\text{eff}}}, \Gamma_j, \theta_j, \sigma_j(R), f_p(R), R_{\text{ACZ}}, R_{\text{diss}}, \mathcal{H}_{\text{shock}}, \mathcal{S}_{\text{rad}}, \mathcal{F}_{\text{fb}}\right)$$

Here Γ_j is the observer-level bulk Lorentz factor, σ_j is the observer-level magnetization comparison ratio, f_p is the proton or baryon loading fraction, R_{ACZ} is the acceleration-and-collimation-zone scale, R_{diss} is the main dissipation radius or family of radii, $\mathcal{H}_{\text{shock}}$ records recollimation shocks, hot spots, bow shocks, and Mach-disk-like structures, $\mathcal{S}_{\text{rad}}$ records the synchrotron, Compton, hadronic, pair-cascade, cosmic-ray, and neutrino channels retained by the comparison, and $\mathcal{F}_{\text{fb}}$ records environmental heating, cavity, cocoon, bubble, and duty-cycle effects. The native burden is that these outputs come from one horizon-interface, disk-interface, wind, and Noether sea loading record, not from separate fitted stories for launch, radio emission, gamma emission, and galaxy feedback.

A compact AGN-jet residual can therefore be written as

$$
\begin{aligned}
\mathcal{R}_{\mathrm{AGN\,jet}}(\theta) =& w_{\mathrm{launch}}\, d_{\mathrm{launch}}\Big[\Pi_{\mathrm{AGN}}(\Theta_{\mathrm{AGN}}), \Big(M, \mathbf{J}, \dot{M}_{\mathrm{in}}, \Phi_{\mathrm{BH}}^{\mathrm{obs}}, \mathcal{A}_{\mathrm{NS}}\Big)\Big] \\
&+ w_{\mathrm{coll}}\, d_{\mathrm{coll}}\left(\theta_j, \frac{R_{\mathrm{ACZ}}}{R_{\mathrm{inf}}}, \Sigma_{\mathrm{wind}}, \mathcal{A}_{\mathrm{NS}}\right) \\
&+ w_{\mathrm{load}}\, d_{\mathrm{load}}(\sigma_j(R), f_p(R), \Gamma_j, \eta_j) \\
&+ w_{\mathrm{shock}}\, d_{\mathrm{shock}}(\mathcal{H}_{\mathrm{shock}}, \{\mathrm{recollimation}, \mathrm{hot\ spot}, \mathrm{bow/Mach\ structure}\}) \\
&+ w_{\mathrm{rad}}\, d_{\mathrm{rad}}(\mathcal{S}_{\mathrm{rad}}, \{\mathrm{radio}, \mathrm{X\text{-}ray}, \gamma, \nu, E_{p,\mathrm{max}}\}) \\
&+ w_{\mathrm{fb}}\, d_{\mathrm{fb}}(\mathcal{F}_{\mathrm{fb}}, \{T_{\mathrm{engine}}, T_{\mathrm{rad}}, D_{\mathrm{duty}}, E_{\mathrm{cocoon}}, E_{\mathrm{bubble}}\})\,.
\end{aligned}
$$

The pass condition $\mathcal{R}_{\mathrm{AGN\,jet}}(\theta) \le \epsilon_{\mathrm{AGN\,jet}}$ is a benchmark on release-channel closure. It captures six source signals at once. First, black-hole spin is necessary-looking but insufficient unless the disk, inflow, and surrounding Noether sea loading sustain the ordered stress needed for launch. Second, collimation over radii from near R_{launch} toward R_{inf} must be attributed either to disk wind, sheath, gas pressure, or the mapped anisotropy state $\mathcal{A}_{\mathrm{NS}}$, not to an unspecified funnel. Third, high-power jets may become proton-dominated or baryon-loaded enough that f_p controls cosmic-ray, neutrino, and hadronic cascade channels. Fourth, FR-I and FR-II behavior must be separated by the same propagation record: weak or disrupted jets dissipate near the black-hole/galaxy transition and become plumes or bubbles, while powerful jets keep relativistic kinetic power to terminal hot spots. Fifth, shocks, reconnection-like comparison regions, pair production, and pair cascades are radiation-channel benchmarks, not independent sources of free energy. Sixth, source age and environment matter: a jet engine, lobe, cocoon, and duty cycle must all close the same energy, momentum, angular-momentum, provenance, and medium-update ledger.

This residual also states a useful failure mode. A model that matches a near-hole jet image but cannot account for hot spots, lobes, cosmic-ray or neutrino limits, and environmental heating has not closed the AGN release channel. Conversely, a model that fits large radio lobes while leaving launch selection unrelated to spin, accretion, wind/sheath confinement, and $\mathcal{A}_{\mathrm{NS}}$ has only fit the downstream plume. The whole point of the AGN packet is to force the release selector to connect the black-hole branch, disk-interface branch, propagation branch, radiation branch, and feedback branch with one declared state record.

Relation to Dark Energy and Expansion History

The black-hole chapter does not identify dark energy with black holes by definition. The baseline dark-energy mechanism in $\mathbb{AAA}$ remains Noether sea relaxation, as developed in …/cosmology/dark-energy.md. Black holes enter that story only if strong-field recycling makes a measurable contribution to the slowly varying binary-3 tension sector.

The clean constitutive chain is:

1. strong-field compression drives assemblies into horizon and interior recycling regimes;
2. recycling redistributes energy between locked internal modes and outward-propagating medium excitations;
3. those excitations can, in principle, alter the large-scale Noether sea state;
4. the cosmology module then reads that altered Noether sea state as part of $\rho_{\mathrm{DE,eff}}(z)$ or its source term.

This means black holes are candidate contributors to dark-energy phenomenology, not substitutes for the Noether sea ontology.

The equilibrium-transport version of this claim is more specific. Strong-field recycling may act as a source term for the Noether braid cadence distribution of the surrounding Noether sea. If $f_N(\nu, \mathbf{X}, T)$ records the local distribution of Noether braid cadence states with $E_N = h\nu_N$, then a black-hole contribution appears as S_{BH} in a medium equation of the form

$$\partial_T f_N + \nabla_{\mathbf{X}} \cdot (\mathbf{u}_{\mathrm{sea}} f_N) + \partial_\nu J_\nu = S_{\mathrm{BH}} + S_{\mathrm{GW}} - R_{\mathrm{eq}}[f_N]$$

This is the controlled sense of a bulk recycling movement: processed content from high-gradient recycling regions can load the Noether sea and then relax toward lower-energy Noether sea cadence states. The statement remains conditional because S_{BH} must be energy-accounted, population-history dependent, and small enough not to spoil weak-field gravity, photon coherence, CMB blackbody quality, or gravitational-wave propagation. If the resulting current J_ν has no signed large-scale component, the recycling channel may still heat or perturb local environments without becoming an effective expansion-history source.

Cosmological Coupling Hypothesis

One modern comparison target is the claim that some dormant supermassive black holes appear to gain mass in step with the late-time cosmological background more strongly than standard accretion and merger channels predict. The common phenomenological summary is

$$M_{\mathrm{BH}}(a) \propto a^K$$

with K measuring the effective coupling strength.

Within $\mathbb{AAA}$, such a signal would be interpreted constitutively rather than mystically. A nonzero K would suggest that black holes are not isolated bookkeeping devices embedded in a passive background. It would suggest that strong-field recycling zones remain coupled to the evolving Noether sea strongly enough for the population to retain memory of the large-scale Noether sea state.

That interpretation remains conditional. The observational correlation must first survive ordinary astrophysical alternatives such as hidden accretion, merger incompleteness, host selection, and mass-calibration drift. Even if the correlation survives, the theory still must show how interior recycling feeds a cosmological source term without spoiling other closure targets.

In local usage, K should therefore be treated as a phenomenological diagnostic rather than as a primitive constant of nature. Its value summarizes how strongly the population of recycling sites appears to track the expansion history in a given observational reconstruction. The underlying $\mathbb{AAA}$ hypothesis remains deeper: any apparent coupling must emerge from a derived braid-alignment response, maximum-curvature storage, interface transport, and outward medium loading.

Population History and Source Accounting

If black holes contribute to late-time cosmology, the contribution cannot depend only on the state of one idealized object. It must also depend on the history by which the relevant population of recycling sites was produced and fed. In observational language this often appears as a dependence on star-formation history, compact-object formation history, merger history, or host-galaxy environment. In $\mathbb{AAA}$ the deeper statement is that the source term inherits a memory of how matter was routed into strong-field processing zones over cosmic time.

This matters because a population-level dark-energy contribution cannot be inferred from compact-object coupling alone. One also needs the production history of the sites doing the recycling and the transport history of the energy they release into the Noether sea. For the local framework, that means the cosmological source term associated with black holes should be modeled as a functional of at least three histories:

- the formation history of compact strong-field sites;
- the inflow history of matter and radiation into those sites;
- the release history of outward channels that load the surrounding Noether sea.

The DESI-era cosmological-coupling packet sharpens the first row by tying the effective source history to the cosmic star-formation rate density rather than to an arbitrary homogeneous term. In the external cosmologically coupled black-hole comparison, stellar collapse mediates matter conversion into an effective dark-energy contribution, and the same fit is tested against expansion history, BBN baryon abundance, local-distance-ladder tension, and summed-neutrino-mass constraints. The local use of that packet is a recovery target: if strong-field recycling contributes to $\rho_{\mathrm{DE,eff}}(z)$, then one retained formation, inflow, release, and Noether sea transport record must explain the timing of the source term and its compatibility with those independent rows. It is not imported as vacuum-energy ontology or as proof that black holes are the whole dark-energy mechanism.

High-redshift quasars add a compact source-accounting stress test. The observational product is not a black-hole mass in isolation: it joins a redshifted spectrum, absorption by the reionization-era intergalactic medium, broad emission-line velocities near the central engine, luminosity modeling, and survey selection into one inferred early supermassive black hole record. A quasar seen when the universe is only a few percent of its current age but whose spectrum implies a compact object near $10^9 M_\odot$ is therefore not merely a large-mass anecdote. It asks whether the same redshift, clock-rate comparison, formation, inflow, and release histories can produce the observed source without switching comparison records.

Little-red-dot spectroscopy supplies the obscured-accretion version of the same test. In GLIMPSE-17775 at $z = 3.501$, foreground lensing by Abell S1063, JWST/NIRCam photometry, and a deep JWST/NIRSpec/G395M spectrum expose more than forty emission and absorption features. The important data product is not just a broad-line black-hole mass. Exponential permitted-line wings, Balmer and helium absorption, Bowen-fluorescent oxygen lines, and a Lyβ-pumped Fe II forest indicate that line formation is dominated by a dense, partially ionized cocoon around a rapidly accreting compact source. The external “black hole star” phrase is therefore retained only as comparison language: for $\mathbb{AAA}$ the recovery target is one early strong-field growth record that keeps the central engine, gas reprocessing, host component, lensing map, X-ray/radio suppression, and inferred Eddington ratio in the same source-history account.

QSO1 in Abell 2744 adds the direct-dynamical version of the little-red-dot test. At $z = 7.04$, foreground lensing and multiple imaging let JWST spectral astrometry resolve a rotating gas field around the compact source. The important result is that the velocity field behaves like a point-mass-dominated Keplerian record rather than an extended stellar cluster, diffuse host component, or dark-matter halo alone. The inferred central mass is tens of millions of solar masses, while the host is chemically primitive and comparatively light. For $\mathbb{AAA}$ the safe recovery target is therefore not the claim that primordial black holes are confirmed. It is a same-source early-growth packet binding lensing reconstruction, gas kinematics, compact mass inference, host mass, metallicity, X-ray faintness, and seed-history interpretation before direct-collapse or primordial-black-hole language is allowed to act as a comparison branch.

Inactive high-redshift black holes add the complementary stress test because their masses are not inferred from current quasar luminosity. In MRG-M0138 at $z \simeq 1.95$, JWST integral-field spectroscopy, a foreground lens model, and stellar-dynamical fitting resolve the host’s central stellar kinematics well enough to infer an inactive black hole near $6.0^{+2.1}_{-1.7} \times 10^9 M_\odot$. The observational packet is therefore different from the quasar packet: foreground lens reconstruction, source-plane mapping, stellar velocity dispersion, dynamical-model family, host quiescence, and survey selection all enter the mass record. For $\mathbb{AAA}$, the useful lesson is not that a dormant object supplies a new ontology. It is that early strong-field site formation, host-galaxy quenching, and later invisibility must be handled by one formation, inflow, release, and Noether sea history rather than by fitting a compact-object mass separately from the galaxy-history record.

In compact form, the comparison target is

$$\mathcal{R}_{\mathrm{QSO}}(\theta) = d_{\mathrm{QSO}}\left(D^{\mathrm{obs}}_{\mathrm{QSO}}, \Pi_{\mathrm{QSO}}[\theta; \mathcal{H}_{\mathrm{form}}, \mathcal{H}_{\mathrm{in}}, \mathcal{H}_{\mathrm{rel}}, \chi_{\mathrm{sea}}]\right)$$

where $D^{\mathrm{obs}}_{\mathrm{QSO}}$ is the observer-level quasar spectrum and mass-inference packet, while the projection Π_{QSO} must use the same formation, inflow, release, and Noether sea delay histories that the cosmology module uses for redshift and source-age comparison. If a model infers the quasar age with one clock and redshift map, grows the black hole with another history, and assigns the released medium loading with a third, the high-redshift quasar has exposed a split record rather than a closed black-hole source account.

This is one reason the black-hole contribution in $\mathbb{AAA}$ should remain subordinate to the Noether sea ontology. The Noether sea is still the quantity that carries the cosmological state. Black holes matter because they may be concentrated engines for changing that state, not because they replace the state itself.

Observable Targets and Falsifiers

The black-hole program in $\mathbb{AAA}$ earns credibility only if it constrains observation rather than merely renaming paradoxes. The main tests are the following.

- **Exterior recovery:** outside the alignment regime, the effective geometry must remain consistent with already-tested GR phenomenology, including lensing, timing, orbital dynamics, and gravitational-wave propagation.
- **Horizon-scale consistency:** horizon imaging and near-horizon emission structure must be reproducible without introducing conflicts with the canonical alignment condition.
- **Maximum-power recovery:** strong-field release channels must remain compatible with the standard Planck-luminosity scale $L_P \sim c^5/G$ and its maximum-force companion $F_P \sim c^4/G$ at the effective level; the native explanation should derive the corresponding scale from the same horizon-interface, Noether sea response, and exterior-export record rather than by imposing a separate source cutoff.
- **Embedding regularity:** the same strong-field description must remain regular when the compact object is treated as embedded in an evolving large-scale medium rather than an artificially isolated background.
- **Finite-boundary-data regularity:** finite surrounding Noether sea data must determine finite native variables and a non-arbitrary maximum-curvature continuation through the alignment regime.
- **Continuation discipline:** Cauchy-horizon or endpoint comparisons may sharpen the finite-boundary-data test, but they do not select a global branch unless the native horizon-interface ledger supplies the finite continuation family.
- **Information-theoretic recovery:** after the native horizon-interface dynamics are derived, the entropy accounting must remain compatible with unitarity and Page-curve behavior without treating islands, replica wormholes, or a boundary CFT as $\mathbb{AAA}$ ontology.
- **Population coupling test:** any claimed cosmological black-hole coupling must survive hidden-accretion and merger-systematics analysis and fit consistently with the late-time expansion history.
- **History accounting:** any black-hole source term must be compatible with plausible compact-object formation and feeding histories; one cannot simply posit a present-day population effect while ignoring the route by which the population was produced.
- **High-redshift quasar growth:** early massive quasars must be explained using one redshift, clock-rate comparison, formation, inflow, and release record; the inferred black-hole mass may not be separated from the spectrum, reionization absorption, broad-line velocity, luminosity model, and survey-selection packet that produced it.
- **Obscured early-growth spectroscopy:** little-red-dot and dense-cocoon spectra must separate virial motion from electron-scattering line broadening, fluorescence, absorption, lensing, and host-light decomposition before their masses or accretion rates are used as early-growth constraints.
- **Release-channel discrimination:** if jets, diffuse outflows, and dark-sector release are all allowed in principle, the framework must eventually state which environments prefer which channels and what observer-level signatures distinguish them.
- **AGN jet closure:** for supermassive systems, the same release selector must connect spin, disk/inflow loading, observer-level magnetic-flux diagnostics, disk-wind or sheath confinement, jet composition, collimation scale, shocks or hot spots, radiation channels, cosmic-ray/neutrino bounds, and environmental work.
- **Source-age dependence:** engine lifetime, lobe radiative lifetime, duty cycle, FR-I/FR-II morphology, and high-redshift source abundance must enter the source accounting as history variables rather than as static labels.
- **No free energy:** recycling cannot function as perpetual creation. Any outward channel must be accounted for as redistribution from infalling matter, radiation, or pre-existing medium energy.
- **Cross-module closure:** the same strong-field constitutive map must remain compatible with …/cosmology/dark-energy.md, …/cosmology/CMB.md, and …/cosmology/dark-matter.md.

The clearest falsifier would be a precise, multi-probe data set showing that black-hole population evolution is fully explained by conventional accretion and merger history while late-time acceleration remains incompatible with any medium-relaxation channel sourced by the same constitutive variables. In that case, black holes would remain important compact objects, but not privileged drivers of the cosmological sector.

Interfaces to Other Chapters

This chapter centralizes the black-hole ontology and hands specific tasks to adjacent chapters.

Summary

In $\mathbb{AAA}$, black holes are strong-field Noether sea regimes rather than ontic singularities or void defects. Their horizon is a terminal alignment interface, their interior is a maximum-curvature recycling regime, and their cosmological importance depends on whether that recycling measurably feeds the late-time Noether sea state. What remains strongest from standard black-hole theory is the observer-level phenomenology. What is reclassified is the underlying ontology: geometry becomes an effective summary of constitutive Noether sea behavior, and singularity language becomes a marker of failed extrapolation rather than the final story.

Singularity Resolution

This chapter explains what replaces a singularity in the strong-field part of the model. The guiding idea is not that an infinite-density point is hidden behind better coordinates. It is that compact Noether braid assemblies enter a finite maximum-curvature or horizon-interface regime whose boundary data must close. This is the canonical strong-field bridge for Noether Braid, A1 Dynamics, and Black Holes.

The important conversion is from an infinite-endpoint question to a finite-boundary-data question. The strong-field model must say what assembly state is packed, what exterior records remain readable, what boundary data determine continuation, and why no zero-volume or arbitrary branch endpoint is required.

Canonical Strong-Field Alignment Condition

This chapter is the canonical source for the strong-field event-horizon alignment condition used across spacetime documents. The condition marks the assembly-level state that the effective horizon description is trying to summarize.

Use the following regime definition near the horizon:

$$v_2 = c_f, \qquad v_3 \to c_f$$

The arrow records approach from ordinary exterior coupling in this declared source record. At terminal alignment, binary 3 reaches the same field-speed threshold as binary 2, all three indexed binary axes become coplanar and co-linear, and precession ceases in that limit. These speed assignments are source-record constraints, not taxonomy-assigned roles.

This condition is a constitutive boundary condition on Noether sea state, not an isolated metric ansatz imported from an asymptotically flat solution. The horizon is therefore treated as an interface problem: what packed assembly state is allowed, what boundary data reach the exterior, and which continuation labels remain finite? In schematic form, the horizon-interface closure problem is

$$F_H\left[\rho_{\mathrm{NS}}(\mathbf{X},T), \Sigma_{\mathrm{sea}}(\mathbf{X},T), \mathbf{u}_{\mathrm{sea}}(\mathbf{X},T), \{\lambda_\alpha^{\mathrm{cont}}\}_{\alpha\in I_H}; \partial\Omega\right] = 0, \qquad v_2 = c_f, \quad v_3 \to c_f$$

The boundary data $\partial\Omega$ record the surrounding Noether sea state and effective exterior state, while the finite index set I_H labels the retained strong-field continuations $\{\lambda_\alpha^{\mathrm{cont}}\}_{\alpha\in I_H}$ selected by that record. This is a local generic label slot, not a new Noether braid taxonomy. Specific chapters instantiate it with their own ensembles; for example, Black Holes uses its horizon-interface label ensemble $\{\lambda_i^H\}$. This display is the canonical statement of the horizon-interface closure problem: other chapters should cite this section and write the shorthand $F_H = 0$ rather than restating the argument list. A viable singularity replacement must solve the alignment condition with finite boundary data in embedded, non-isolated settings, rather than relying on asymptotic flatness as an implicit support.

Observer-Time Boundary

A maximum-curvature interior is not assigned an ordinary physical-observer clock unless a recoverable clock channel survives. At the horizon-interface boundary, exterior records remain ordered by absolute time and by the observer-level clocks recovered outside the compact region. Inside a hard packed regime, the local Noether braid cadence, signal access, and material ruler channels may no longer supply a Physical Observer state. The safe statement is therefore:

$$\mathrm{Clock}_{\mathrm{PO}}(\Omega_{\mathrm{int}}) = \varnothing$$

This boundary statement holds while T still orders exterior and boundary records. It prevents a singularity replacement from smuggling in an interior observer time where the required clock-and-ruler carrier has already failed. Absolute time still orders the ontology; a readable interior clock is a separate recovered channel.

Trapped-Surface Comparison Pressure

Penrose-style singularity theorems are useful here because they remove a misleading loophole: collapse failure cannot be dismissed merely by abandoning exact spherical symmetry. At the effective GR comparison layer, a trapped surface is detected by both future-directed null expansions becoming negative,

$$\theta_+^{\rm eff} < 0, \qquad \theta_-^{\rm eff} < 0$$

That is a standard-theory warning that weak-field continuation has entered a generic strong-collapse regime. The warning is useful even though the native ontology is not a curved spacetime manifold.

The useful Penrose comparison assumption vector is

$$\mathcal{A}_{\rm P}^{\rm eff} = \left(\theta_+^{\rm eff} < 0,\, \theta_-^{\rm eff} < 0,\, \mathrm{NullComplete}_+^{\rm eff},\, T_{\mu\nu}^{\rm eff} k^\mu k^\nu \geq 0,\, \mathcal{C}^{\rm eff}\right)$$

where $\mathrm{NullComplete}_+^{\rm eff}$ records future null completeness, $T_{\mu\nu}^{\rm eff} k^\mu k^\nu \geq 0$ records the non-negative local energy condition along null directions, and $\mathcal{C}^{\rm eff}$ records the comparison assumption that the effective spacetime is the future development of an initial Cauchy surface with the required global orientation. Penrose's disjunction is then the pressure point: once a trapped surface forms under the local energy and global continuation assumptions, at least one assumption in $\mathcal{A}_{\rm P}^{\rm eff}$ must fail if a physical endpoint is to remain nonsingular.

The $\mathbb{AAA}$ response is not to import the singularity as ontology. The comparison target is instead

$$\theta_+^{\rm eff} < 0, \quad \theta_-^{\rm eff} < 0 \quad \Longrightarrow \quad F_H = 0, \qquad \mathcal{R}_H(\Omega) < \infty$$

for the corresponding compact strong-field region Ω, after the effective variables are translated into native Noether sea boundary data. In plain terms, whenever the observer-level GR description says collapse has passed the generic trapped-surface threshold, the native model must enter a finite maximum-curvature or horizon-interface regime rather than requiring symmetry, a zero-volume endpoint, or an arbitrary branch choice.

Equivalently, let the trapped-region premise be

$$\mathcal{P}_H^{\rm trap}(\Omega) = \left(\theta_+^{\rm eff} < 0,\, \theta_-^{\rm eff} < 0,\, T_{\mu\nu}^{\rm eff} k^\mu k^\nu \geq 0,\, \mathcal{C}^{\rm eff}\right)$$

When this premise holds, the finite-boundary-data replacement target is not to preserve future null completeness as a substrate axiom. It is to supersede that effective global-completeness failure with

$$F_H = 0, \qquad \mathcal{R}_H(\Omega) < \infty, \qquad 0 < |\mathcal{B}_H| < \infty$$

The theorem burden is not to deny the trapped-surface comparison result. It is to show exactly which effective global-completeness assumption is superseded by compact Noether sea boundary data, while preserving the non-negative local energy comparison and producing a finite, labeled strong-field continuation.

Critical collapse adds a sharper threshold benchmark. In the Choptuik scalar-collapse comparison, a one-parameter family of effective initial data has a critical value p_* separating dispersal from black-hole formation. Near that threshold the standard comparison exhibits mass scaling

$$M_{\rm BH} \propto (p - p_*)^\gamma$$

and discrete self-similarity,

$$Z(\tau + \Delta, x) = Z(\tau, x),$$

for the effective fields Z in logarithmic collapse coordinates. Recent large-D analytic work (Emparan-class) is useful because it turns part of that threshold structure from a purely numerical GR pattern into a formula-controlled comparison family. The $\mathbb{AAA}$ recovery target is not a literal crystallization of substrate spacetime. It is to show that the finite-boundary-data transition has a controlled threshold, a repeatable echoing or cadence row when the effective comparison requires one, and a finite continuation family on the compact-region side of the threshold.

Finite-Boundary-Data Regularity

The useful comparison lesson from analytic singularity-removal programs is not an imported mirror boundary or complex-time ontology. It is the regularity criterion. A candidate strong-field replacement must keep the native variables finite and the continuation rule unambiguous in the regime where the effective metric description would otherwise diverge.

For a compact strong-field region Ω, declared positive reference scales $\rho_{\rm NS,0}$ and Σ_0, and field speed c_f, a minimal dimensionless diagnostic at absolute time T is

$$\mathcal{R}_H(\Omega, T) = \max\left\{\sup_{\mathbf{X}\in\Omega} \frac{|\rho_{\rm NS}(\mathbf{X}, T)|}{\rho_{\rm NS,0}}, \sup_{\mathbf{X}\in\Omega} \frac{\|\Sigma_{\rm sea}(\mathbf{X}, T)\|}{\Sigma_0}, \sup_{\mathbf{X}\in\Omega} \frac{\|\mathbf{u}_{\rm sea}(\mathbf{X}, T)\|}{c_f}\right\} < \infty$$

A windowed statement writes $\sup_{T\in W}\mathcal{R}_H(\Omega,T)<\infty$; the shorthand $\mathcal{R}_H(\Omega)<\infty$ means this rowwise normalized diagnostic is finite on the declared single-time or windowed comparison. It is used together with the horizon-interface condition $F_H=0$ and a finite Noether braid closure-label ensemble. This is a theorem target, not a definition of success. The strong-field model must show that finite boundary data determine a finite maximum-curvature replacement rather than a zero-volume endpoint or an arbitrary branch choice.

The packed-state replacement must also keep interior storage distinct from interface exposure. A dense interior may carry a large finite energy inventory while only the surface, defect, or horizon-interface rows couple efficiently to exterior clock, ruler, lensing, release, or dark-sector readouts. In ordinary terms, not everything stored inside is automatically visible outside. For a compact region Ω, write the exposed response schematically as

$$E_{\text{ext}}(\Omega)=\Pi_{\text{surf}}[E_{\text{pack}}(\Omega),\partial\Omega,\mathcal{D}_{\text{defect}},\theta_{\text{sea}}]\,,$$

where Π_{surf} is an exposure projection rather than an energy source. The closure burden is to derive this projection from packing, interface, and Noether sea boundary data. Without that split, a model risks counting hidden packed energy as ordinary exterior mass in one paragraph and shielding it in the next.

A sharper endpoint criterion is that those same finite data admit a continuation map

$$\mathcal{T}_\Omega:\Big(X_\Omega(T_i),\mathcal{H}_\Omega^{<T_i},\mathcal{B}_{\partial\Omega}|_{[T_i,T_f]},N_{\text{sea}}|_{\Omega\times[T_i,T_f]}\Big)\longmapsto X_\Omega(T_f)$$

with

$$F_H=0,\qquad \mathcal{R}_H(\Omega)<\infty,\qquad 0<|\mathcal{B}_H|<\infty$$

This is the singularity-resolution form of the black-hole endpoint gate. The replacement must be finite, ledger-preserving, and non-arbitrary using compact boundary data, without importing a remnant, bounce, or asymptotic boundary condition as doctrine.

Cauchy-Horizon Comparison Pressure

GR Cauchy-horizon and cosmic-censorship language is useful here only as comparison pressure. It asks whether an effective initial-data surface has a unique global continuation or whether the observer-level spacetime description admits extensions not determined by that surface. In $\mathbb{AAA}$ the substrate answer is not to import global hyperbolicity as an axiom. The native answer must show that the finite region record selects a finite admissible continuation family.

For the same compact region Ω and interval $W=[T_i,T_f]$, define the accepted strong-field continuation family

$$\mathfrak{S}_H(\theta_{\partial\Omega,W})=\left\{(X_\Omega(T_f),\mathcal{B}_H(T_f)):F_H=0,\quad \sup_{T\in W}\mathcal{R}_H(\Omega,T)<\infty,\quad \mathcal{L}_{\mathbf{EpJ}}\text{ closes}\right\}$$

The Cauchy-horizon comparison burden is

$$0<|\mathfrak{S}_H(\theta_{\partial\Omega,W})|<\infty$$

with every element carrying a closure label, finite horizon-interface ledger, and event-ledger accounting. The count matters. An empty family means no native continuation has been supplied. An infinite or unlabeled family means the endpoint remains arbitrary. A finite labeled family is admissible only if later observer-level release, entropy, and exterior $(M,\mathbf{J},Q)$ records are computed from those same finite boundary data.

Stationary regularity is only the first test. A horizon construction may keep curvature invariants finite in an eternal or stationary comparison metric while still failing during collapse, merger, evaporation, or embedding in a time-dependent Noether sea. The dynamical gate is therefore stronger:

$$\theta_+^{\text{eff}}<0,\quad \theta_-^{\text{eff}}<0\quad\Longrightarrow\quad F_H(T)=0,\qquad \sup_{T\in[T_i,T_f]}\mathcal{R}_H(\Omega,T)<\infty,\qquad 0<|\mathcal{B}_H(T_f)|<\infty$$

with the same finite boundary data driving the transition across the whole interval. A result that proves regularity only for an isolated stationary exterior remains a comparison result until it supplies this dynamical continuation.

Recent regular-horizon cosmological-coupling constructions (Croker–Farrah-class) sharpen this warning. They show that horizon regularity in an embedded compact-object model depends on handling the cosmological background, apparent-horizon condition, and local/cosmological mass split together; a nonsingular core or stationary exterior is not enough by itself. The native lesson is not to import an anisotropic-fluid metric as ontology. The lesson is that the continuation map above must carry embedding-state backreaction inside $\theta_{\partial\Omega,W}$ and must not evaluate $\mathcal{R}_H(\Omega,T)$ only in an isolated stationary chart.

Maximal Curvature vs Planck Scale

In the working indexed chart, **binary 1** is assigned the maximal-curvature self-hit regime as a proposed outward barrier against continued collapse. Circular self-hit does not supply centripetal support; any stabilized outcome requires the complete partner, self, wake-boundary, and return-map ledger. **Binary 2** is constrained to the field-speed row ($v_2 = c_f$), with **scale and cadence retuning**, as a candidate energy-storage channel for transfers across the candidate braid record. Neither role selects a taxonomy member or is established as a retained mechanism.

In the same working source record, strong-field conditions increase **binary 3's frequency** and drive v_3 toward field speed, while **binary 2** remains at $v_2 = c_f$ as its radius and frequency shift. At the horizon-interface limit, binaries 2 and 3 reach c_f, all three indexed axes align, and precession ceases. This is a prescribed closure target, not a retained-branch result.

One preserved intuition, to be read only as a heuristic, is that this alignment limit may correspond to a temporary **planar horizon state** rather than to the final interior shape. In that picture, the horizon is the point of strongest flattening, while deeper interior self-hit response can reopen the suppressed polar degree of freedom so the Family-A braid returns to a finite 3D configuration instead of terminating in a zero-volume endpoint. This is compatible with the maximum-curvature replacement logic, but it is not yet a derived mechanism; compare Horizon Chirality and Planar Spin.

Mapping rule: "Planck-scale" references in this framework map to the **event-horizon alignment condition** (Family-A axis convergence in the declared field-speed chart), unless an explicit derivation links them to another scale. The field-speed rows in this mapping are necessary alignment indicators, not a self-hit proof by themselves; the admitted branch still needs same-transmitter root existence, transversality/Jacobian control, transmitter-side acceleration weight, and retained ledger closure.

Horizon Chirality

This chapter studies one narrow theory question: how the Noether braid `pro/anti` distinction should be understood as a Family-A braid approaches the planar horizon state. For this note we set aside bookkeeping questions and focus on geometry, orbit direction, and the reduction from a 3D precessing scaffold to a planar exterior view.

The guiding problem is simple. In ordinary low-stress conditions, the Family-A braid is a fully 3D object with persistent binary indices, an ordered set of normals, and precession structure. At the event horizon, the same assembly is hypothesized to approach coplanarity and alignment. The question is whether `pro/anti` remains directly visible in that planar state or whether only a reduced exterior spin pattern survives.

The chapter is therefore a reduction map, not a new chirality doctrine. It keeps four labels from collapsing into one another: the deeper 3D pro/anti branch orientation, polarity conjugation at fixed worldlines, the planar clockwise/counterclockwise sign seen from an exterior normal, and any later helicity-like sign tied to a propagation or translation axis.

Source-Record Horizon Condition

The Family-A terminal-alignment target is inherited from singularity-resolution.md and black-holes.md. In the illustrative source record used here, the near-horizon speed rows are

$$v_2 = c_f, \qquad v_3 \to c_f$$

with binaries 2 and 3 becoming coplanar and collinear with binary 1 at alignment and precession ceasing in that limit.

The speed assignments to binaries 2 and 3 belong to this source record; the taxonomy does not assign field-speed roles to fixed indices. This chapter asks what chirality information can still be distinguished once the Family-A braid has been compressed into that planar boundary-like state.

Pro/Anti Before Planar Lock

Away from the horizon, the project treats `pro/anti` as an ordering property of the 3D Family-A braid scaffold rather than as polarity conjugation, matter/antimatter, or a net-charge distinction. The orientation basis is owned by Noether Sea Pro/Anti Coupling:

- `pro`: $1 \to 2 \to 3$ ordering in time;
- `anti`: $1 \to 3 \to 2$ ordering in time.

That distinction is natural in the ordinary Family-A braid because the three binaries occupy non-coplanar planes with an ordered set of normals and a genuine precession structure. In that regime, `pro/anti` is a 3D chirality datum.

The strongest mathematical candidate beneath that datum comes from causal-action-functional.md: the causal writhe

$$Wr_c(\mathfrak{B}) = \sum_{\alpha,\beta} \mathrm{sgn}(\alpha,\beta)\,\chi_{\mathrm{causal}}(\alpha,\beta)$$

records signed causal-locus crossings or linkages in the retained branch record $\mathfrak{B}$. The indices α and β label oriented retained causal-locus strands or strand segments in the declared projection; $\chi_{\mathrm{causal}}(\alpha,\beta)$ is 1 only for an admissible same-record crossing or linkage event, and 0 otherwise. The sign $\mathrm{sgn}(\alpha,\beta)$ is defined only relative to the declared branch framing and is not defined at a fold, framing slip, or unresolved collision row.

So the cleanest reading is:

- the surface convention for `pro/anti` remains the ordered `123/132` Family-A braid distinction;
- the best formalization candidate is a topological branch label carried by the retained causal-locus and framed-topology record, with Wr_c as a leading crossing statistic only when the same retained branch record also supplies D_t, D_r, and W^{acc}.
- polarity conjugation C leaves that order unchanged because it relabels polarities at fixed worldlines; parity P reverses the order.

The horizon state is different. Once the planes collapse into one planar lock and precession ceases, some of the ordinary 3D chirality data are suppressed. That makes it plausible that the horizon exposes only a reduced exterior signature of the deeper `pro/anti` distinction.

Broader Pro/Anti Balance in $\mathbb{AAA}$

This chapter should also be read against a broader guardrail from the project framing: $\mathbb{AAA}$ does **not** naturally suggest a large universal pro/anti imbalance in the substrate as a whole. The Noether sea picture is instead built around persistent local or mesoscopic balance between complementary Noether braid orientations.

Several standing examples point in that direction.

- **Noether sea / spacetime medium:** the ambient Noether sea is already framed as a coupled pro/anti population rather than a single-sign sea.
- **Photon channel:** the proposed photon assembly is a coaxial contra-rotating polarity-conjugate planar pair, or one record $\mathfrak{B}$ and its C-image $C(\mathfrak{B})$. It is not an example of pro/anti orientation balance, because the three-dimensional indexed-frame orientation carrier is no longer assigned in the planar limit.
- $2+2$ **pro/anti cluster hypothesis:** the standing cluster intuition remains a $2+2$ object, with two pro and two anti Noether braids in a three-dimensional coupled state rather than a single-sign configuration.

So when this note isolates `pro/anti`, it is **not** doing so because the larger ontology is expected to drift into a globally pro-dominant or anti-dominant universe. It is doing so because the horizon problem tests whether the ordered three-dimensional orientation has any surviving planar readout. The polarity-conjugate relation is a separate row.

Orientation-selective reaction channels then become the special case. Pro-Noether braid and anti-Noether braid orientations may meet as geometric complements and open fast reconfiguration channels, but that pairing is not automatically a particle-antiparticle reaction. A matter-antimatter event additionally requires polarity-conjugate retained branch records and conjugate charged-sector ledgers. In either case, the standard word “annihilation” is too blunt: the deeper process is a **reaction** or **reconfiguration event** in which coupled structures open, exchange, and re-express their content through new channels rather than vanishing into nothing.

That broader matter/reaction thesis belongs with reaction-channel provenance and fermion assembly structure. Inside this chapter, its role is narrower: it reminds us that horizon chirality should be developed inside a theory that is broadly pro/anti balanced, with the dramatic visible asymmetries appearing only in certain reaction channels or assembly sectors.

Working Dictionary

To keep terms from sliding into one another, use the following provisional dictionary throughout this chapter:

Label	Meaning in this note	Typical regime
`pro/anti`	the deeper 3D Noether braid ordered orientation, tracked by structure such as 123 versus 132; C-even and P-odd	pre-planar 3D braid
polarity-conjugate pair	one retained record $\mathfrak{B}$ and its fixed-worldline polarity-reversed image $C(\mathfrak{B})$	any regime, including the planar limit
`CW/CCW`	the exterior planar angular-momentum sign seen from one chosen viewing side of a planarized Noether braid	horizon / planar lock
`left/right`	a possible axial sign relative to translation, for example $\hat{J}_{\mathrm{net}} \parallel \pm\hat{\mathbf{V}}$, if that later proves to control forward exposure of the weak-active structure	high-velocity aligned regime

This chapter treats these as related but not yet identical labels. One of its main goals is to understand how they may collapse onto one another in the terminal high-velocity regime.

Comparison Across Sectors

The horizon question becomes clearer when compared against the main assembly sectors already present in the theory.

Sector	Pro/anti organization	Dimensional character	Why it matters here
Noether sea	broadly balanced pro/anti medium	mainly 3D distributed medium	background reminder that $\mathbb{AAA}$ does not predict a large universal imbalance
Photon channel	coaxial contra-rotating polarity-conjugate planar pair; pro/anti orientation unassigned	planar / propagating pair	shows that polarity-conjugate pairing remains meaningful after the 3D order has collapsed

Sector	Pro/anti organization	Dimensional character	Why it matters here
$2+2$ pro/anti cluster hypothesis	2+2 pro/anti cluster	3D coupled cluster	shows balanced multi-braid organization without collapsing to one sign
Orientation-selective reaction channels	pro/anti encounters can open rapid reconfiguration channels without thereby being matter/antimatter events	mixed 3D and reaction geometry	tests whether ordered orientation changes reaction accessibility

This comparison helps keep the horizon problem honest. The goal is not to prove that the universe is mostly pro or mostly anti. The goal is to understand how one compressed Family-A braid advertises its branch structure when driven into the strongest alignment regime.

The photon row is also an interface to the radiation and cosmology stack. Because the photon carrier is already a moving planar pro/anti pair, it is the ordinary transport channel most naturally comparable to the flat symmetry-breaking state. That does not make every photon a horizon fragment, but it does make horizon-adjacent photon processing a serious candidate mechanism: the same planar branch logic can appear as free photon propagation, horizon-interface compression, strong-field blueshift, outward redshift, or release-channel conversion depending on the surrounding Noether sea record.

Exterior Planar Angular-Momentum Basis

Fix one exterior viewing direction normal to the horizon disk. From that viewpoint, each planar binary appears to rotate either clockwise (`CW`) or counterclockwise (`CCW`). If the three binaries remain distinguishable by persistent indices `1`, `2`, and `3`, then the full planar angular-momentum sign space contains exactly $2^3 = 8$ possibilities.

Row	1	2	3	Class	Comment
1	`CW`	`CW`	`CW`	uniform	clean common-sign lock
2	`CW`	`CW`	`CCW`	mixed	
3	`CW`	`CCW`	`CW`	mixed	
4	`CW`	`CCW`	`CCW`	mixed	
5	`CCW`	`CW`	`CW`	mixed	
6	`CCW`	`CW`	`CCW`	mixed	
7	`CCW`	`CCW`	`CW`	mixed	
8	`CCW`	`CCW`	`CCW`	uniform	clean common-sign lock

This is the complete planar-sign table as viewed from one fixed exterior side of the black-hole horizon. Reversing the viewing side flips `CW` and `CCW`, so the table should always be read relative to a chosen exterior normal.

Observer Views

The planar angular-momentum table is viewpoint dependent in a controlled way.

- **Absolute-frame exterior observer:** fixes one normal to the planar disk and reads the visible planar circulation as `CW` or `CCW`.
- **Observer on the opposite side of the same disk:** reverses the normal and therefore swaps `CW` with `CCW`.
- **Co-moving or assembly-built observer:** may not have direct access to the absolute normal choice and instead infer only relative handedness, exposure, or wake asymmetry.

So the physically stronger datum is not the literal word `CW` or `CCW` by itself. It is the sign of the planar angular momentum relative to a chosen normal. In standard quantum language, helicity is an angular-momentum projection onto the momentum or propagation axis, usually the projection of spin for an elementary particle. The horizon quantity here is therefore a **boundary helicity proxy**: it becomes helicity-like only when the chosen exterior normal is dynamically tied to a propagation or translation axis.

This is also the right place to keep the substrate/effective split explicit: the substrate dynamics know about absolute path histories, delayed branch intersections, and topological branch labels. Observer-level helicity is a **dimensional reduction** of that deeper structure, not a primitive substrate variable, and boundary helicity should not be silently identified with weak-interaction chirality.

Boundary Helicity Versus Deeper Chirality

The table above does not by itself prove that all eight rows are equally meaningful as horizon identities.

The simplest exterior quantity is the sign of the common planar angular momentum when all three binaries share one rotation sense. That sign is a boundary-visible two-way distinction:

- all-`CW`;
- all-`CCW`.

This chapter will call that reduced exterior quantity **boundary helicity**: the horizon-local sign of common planar angular momentum relative to a chosen normal. The term is deliberately narrower than standard helicity until the normal is identified with the relevant propagation or translation direction.

The deeper `pro/anti` distinction is plausibly stronger than boundary helicity alone. In the 3D scaffold, `pro/anti` tracks ordered Family-A braid chirality, not merely the sign of one visible planar swirl. Once the horizon suppresses precession and forces coplanarity, two different 3D histories may collapse to the same exterior planar sign.

That motivates the following working distinction:

- **Boundary helicity:** the visible sign of the common planar angular momentum at the horizon, measured relative to a chosen normal.
- **Core chirality:** the deeper `pro/anti` distinction inherited from the ordered 3D Family-A braid before flattening.

If this distinction is correct, then the horizon does not necessarily erase `pro/anti`, but it may compress it so strongly that the exterior observer sees only a reduced proxy.

Translation-Axis Alignment at High Velocity

The next question is whether a rapidly translating Family-A braid should drive the three orbital angular-momentum vectors toward the translation axis itself.

The answer is dynamical rather than purely kinematic. Straight-line translation does **not** require that result merely from conservation laws. In the path-history dynamics, total linear momentum and total angular momentum are distinct conserved quantities, so an isolated translating assembly may in principle carry internal angular momentum whose axis is not parallel to the center-of-mass velocity.

The stronger argument comes from the high-velocity delay geometry. Use the primitive branch-chart channel here: $v_{\text{trans}} = \|\mathbf{V}_{\text{trans}}\|$ is the native center-drift speed, $\beta_f = v_{\text{trans}}/c_f$, and $\gamma_f = (1-\beta_f^2)^{-1/2}$. Let $(x_{\perp,1}, x_{\perp,2}, x_\parallel)$ be principal-frame coordinates for the oblate spheroidal envelope, with $x_\parallel$ along the translation direction. Then the geometry inherited from Braid Envelope Geometry and its dynamics treatment in A1 Dynamics is

$$\frac{x_{\perp,1}^2 + x_{\perp,2}^2}{R_\perp^2} + \frac{x_\parallel^2}{R_\parallel^2} = 1, \qquad R_\parallel = \frac{R_\perp}{\gamma_f}, \qquad \gamma_f = \frac{1}{\sqrt{1-\beta_f^2}}, \qquad \beta_f = \frac{v_{\text{trans}}}{c_f}$$

Now let one binary orbit in a plane whose unit normal $\hat{n}$ makes angle α with the translation axis $\hat{z}$. The central cross-section of the oblate spheroidal envelope cut by that orbital plane has area

$$A(\alpha) = \frac{\pi R_\perp^2 R_\parallel}{\sqrt{R_\perp^2 \sin^2\alpha + R_\parallel^2 \cos^2\alpha}} = \frac{\pi R_\perp^2}{\sqrt{\gamma_f^2 \sin^2\alpha + \cos^2\alpha}}$$

This area is maximal at $\alpha = 0$ or $\alpha = \pi$, meaning the orbital normal is parallel or antiparallel to the line of translation. It is minimal at $\alpha = \pi/2$, when the orbital normal is transverse to the motion.

So the delayed geometry creates a real high-speed bias:

- planes with normals parallel or antiparallel to the line of translation inherit the largest available cross-section;
- tilted planes suffer stronger anisotropic squeezing;
- the penalty for tilt grows with γ_f.

For small tilt,

$$A(\alpha) \approx \pi R_\perp^2 \left[1 - \frac{\gamma_f^2 - 1}{2}\alpha^2\right]$$

so the restoring pressure toward axial alignment strengthens as $v_{\text{trans}} \to c_f$.

This gives a precise version of the intuition: a high-velocity Family-A braid should be driven toward a state in which the three orbital angular-momentum vectors are **coaxial with the line of translation**, not because momentum conservation alone demands it, but because delayed closure becomes least frustrated there.

Exact Conservation Versus Dynamical Selection

This distinction is important enough to state plainly.

- **Exact conserved quantities:** the dynamics preserve total momentum and total angular momentum through substrate translation and rotation symmetry.
- **Topological branch data:** writhe and winding-class labels of the causal locus are not ordinary Noether charges, but they are robust branch labels that change only through reconnection or tearing events.

- **Dynamical selection:** alignment of the net orbital axis with the translation direction is neither a new conserved quantity nor a kinematic identity. It is a high-velocity attractor selected by the anisotropic delayed geometry.

In symmetry language, the ambient substrate begins with the full spatial isotropy of $SO(3)$. A fast translating assembly supplies a distinguished direction $\hat{\mathbf{V}}$ and therefore selects a reduced effective symmetry around that axis, schematically $SO(3) \to SO(2)$, with the remaining planar phase behaving in the aligned limit like a $U(1)$-type degree of freedom. The near-horizon planar lock should therefore be read as a **symmetry-broken dynamical branch** of the underlying theory, not as a new exact conservation law.

State-Transition Ladder

The emerging picture is easier to reason about if written as a shape-and-label ladder:

$$\text{3D precessing braid} \;\to\; \text{oblate translating braid} \;\to\; \text{axialized high-}v\text{ braid} \;\to\; \text{planar horizon lock} \;\to\; \text{post-lock reconfiguration or reopening}$$

The intended label flow along that ladder is:

1. In the ordinary 3D regime, `pro/anti` is carried by ordered Family-A braid chirality.
2. Under high translation speed, the orbital normals are biased toward the translation axis.
3. Near the terminal aligned state, the surviving branch data may reduce to the sign of the common axial orientation and then to the sign of the visible planar helicity.
4. After passage through the lock, the Noether braid may either preserve that branch, re-expand with the same handed history, or undergo a deeper reconfiguration if the planar degeneracy is strong enough.

This ladder is still a working map, not a completed derivation. Its value is organizational: it shows where the theory expects information to be compressed, preserved, or potentially switched.

Canonical Horizon Branch Hypothesis

The most conservative horizon hypothesis is that the stable terminal branches are the two uniform planar rows:

- Row 1: `1 = 2 = 3 = CW`;
- Row 8: `1 = 2 = 3 = CCW`.

These are the cleanest candidates for the two horizon-level branches that an exterior observer could identify. In that reading, the horizon presents a binary choice of common-sign planar lock.

The six mixed rows should be treated more cautiously. They are best read as candidate:

- transitional states during flattening;
- frustrated planar states that still carry unresolved internal shear;
- or short-lived reconfiguration states rather than canonical terminal locks.

This is only a working hypothesis. The theory does not yet derive that mixed-sign planar states are forbidden. It says only that the two uniform rows are the strongest candidates for stable horizon identities, while the mixed rows appear less natural as endpoint states.

Under the translation-axis argument above, those two rows can be restated more sharply: in the terminal branch the three orbital normals are expected to become coaxial with $\pm\hat{\mathbf{V}}$, where $\hat{\mathbf{V}}$ is the unit translation direction. The remaining binary choice is then the sign of the common axial spin.

Candidate Theories for Pro and Anti at the Horizon

Two main theories are available.

Theory A: direct planar identification

In the strongest reduction, `pro/anti` at the horizon is simply identified with the two uniform planar states:

- `pro` = all-`CW`,
- `anti` = all-`CCW`,

or the reverse, depending on the chosen sign convention.

This theory is attractive because it makes the horizon classification maximally simple and directly observable from outside.

Theory B: history-lifted horizon identification

In the more cautious reduction, the two uniform planar states are still the visible horizon branches, but `pro/anti` is not exhausted by the observed `CW/CCW` sign. Instead:

- the uniform planar sign is the **visible boundary marker**;

- the deeper `pro/anti` label still refers to the ordered 3D chirality from which the planar state was reached.

On this reading, the horizon preserves only a compressed image of the deeper Family-A braid chirality. The exterior observer sees the branch, but not necessarily the full internal ordering history.

Theory B is the stronger conceptual fit with the existing 3D `123/132` framing, because that framing is richer than a single planar spin sign.

The history-lifted reading also sets a guardrail for nearby labels. Horizon `pro/anti`, boundary helicity, `CW/CCW`, `123/132`, and weak left/right language should not be identified with one another by a visible planar sign alone. A stronger identification requires the same-record spinor-label pullback: a component row carrying the lifted history $\tilde{r}(s)$, the row-local parity checks $\Pi^{2\pi}_{W,r}$ and $\Pi^{4\pi}_{W,r}$, a quotient witness, doubled-path restoration, and gauge invariance. Without those rows, the horizon sign is a boundary-visible marker for a deeper branch history, not the whole chirality proof.

Possible Left/Right Spin Mapping

The translation-axis picture opens one further possibility. If the terminal high-velocity attractor really forces the common orbital axis onto the line of translation, then the two axial branches

$$\hat{J}_{\text{net}} \parallel +\hat{\mathbf{V}}, \qquad \hat{J}_{\text{net}} \parallel -\hat{\mathbf{V}}$$

are natural candidates for a left/right or helicity-like pair.

That does **not** automatically make them identical to weak-interaction chirality. The canon uses left/right language operationally in terms of whether the weak-coupling triad is exposed or hidden relative to motion and wake geometry. Still, the axial-lock picture suggests a possible underlying bridge:

- the high-velocity Noether braid first selects one of the two axial branches $\pm\hat{\mathbf{V}}$;
- that branch then influences which side of the axial structure is forward-exposed versus wake-hidden;
- the observer-level left/right distinction may therefore descend from the sign choice of the common axial angular momentum in the translating aligned state.

In that reading, the horizon or near-horizon limit does not merely present two boundary-helicity states. It may also reveal a candidate upstream axial-lock variable for later left/right spin mapping:

- `right-like`: net braid axis aligned with translation;
- `left-like`: net braid axis anti-aligned with translation;

or the reverse, depending on the eventual sign convention.

This should remain a live hypothesis rather than a settled identification. The safe claim is only that the high-velocity math strongly favors **axialization** of the Family-A braid angular-momentum vectors along the line of translation, and that the surviving sign choice is exactly the kind of binary datum that could later map onto a left/right spin label.

The explicit defer condition is that terminal axial sign,

$$\hat{J}_{\text{net}} \parallel \pm\hat{\mathbf{V}}$$

is not enough to identify weak left/right exposure. The same record must also pass the row-local parity and gauge-control checks used in Angular Momentum and Spin and the Δ_{WCT} exposure record used in Weak Mixing and CKM. Until then, axial sign remains a candidate bridge variable rather than a weak-chirality derivation.

Status Table

This chapter mixes canonical inputs with stronger and weaker hypotheses. The distinction should stay explicit.

Claim	Status
Family-A terminal alignment drives the braid toward coplanarity and suppresses precession	canonical target in project framing; retained-branch derivation remains open
`pro/anti` is a deeper 3D Noether braid chirality label rather than a net-charge label	canonical working convention
`Wr_c` and causal-locus topology supply the best formalization candidate for that chirality	strong structural candidate only on the same retained branch record that supplies D_t, D_r, and W^{acc}; not yet sole canonical definition
the planar exterior sign space has 8 rows for labeled `1/2/3` binaries	exact combinatorial statement
high translation speed biases orbital normals toward the translation axis	strong geometric argument in this chapter
the two uniform planar rows are the most likely stable terminal horizon branches	strong working hypothesis

Claim	Status
the six mixed rows are transitional or frustrated rather than stable endpoint states	plausible but still open
the axial sign $\hat{J}_{\rm net} \parallel \pm\hat{\mathbf{V}}$ supplies a candidate upstream variable for a later left/right spin distinction	live speculative hypothesis requiring the same retained spinor/gauge-control and weak-exposure record
`pro/anti`, `CW/CCW`, and `left/right` all become the same label in the terminal regime	not yet established

Mixed-Sign Planar States

If mixed-sign rows are admitted at all, then the horizon theory becomes more complicated than a simple two-branch picture. Rows 2 through 7 would imply that the three binaries can remain role-distinct in the planar lock while not sharing a common in-plane circulation.

That possibility raises three immediate questions:

1. Are mixed-sign rows dynamically stable, or do they relax toward a common-sign lock?
2. If they are stable, do they define additional horizon classes beyond `pro/anti`?
3. If they are unstable, are they the natural transition states through which a Noether braid passes while entering or leaving the horizon interface?

This note favors the third reading: mixed-sign planar states are more naturally interpreted as transition or frustration states than as clean final branches. But this remains an open dynamics question rather than a closed derivation.

One reason for that preference is action-geometric rather than merely visual. In a strictly flattened disk, mixed-sign configurations plausibly generate stronger phase-slip and more severe branch competition, because not all tangential drives can cooperate in closing the delayed loop on one clean planar branch family. That does not yet amount to a theorem, but it points to the right criterion: mixed rows should be judged by whether they force larger Jacobian stress, larger cycle-to-cycle action variance, or repeated failure of singularity-free phase closure.

Transition Rules for Pro/Anti Conversion

One of the biggest unresolved questions is whether a Noether braid can flip from `pro` to `anti` smoothly, or only through a more singular reconfiguration.

This chapter points toward the second option. The likely possibilities are:

1. **No flip in ordinary smooth evolution:** away from the planar degeneracy, the ordered 3D Noether braid chirality appears robust and should survive adiabatic deformations.
2. **Near-degenerate branch switch at planar lock:** when the three planes collapse into one planar state, some 3D chirality data are compressed strongly enough that a branch change may become dynamically accessible.
3. **Full reconfiguration / reaction channel:** a deeper split, exchange, or reconstruction of the constituent binaries could permit a true $pro \leftrightarrow anti$ conversion.

This is exactly where the language of “annihilation” starts to look too weak. If a pro/anti encounter opens the Noether braid and allows branch-changing reconfiguration, the physical process is better described as a structured reaction than as disappearance.

The strongest language from the dynamics stack is that true branch conversion should be associated with a **mode-lock event** or related non-perturbative reconfiguration, not with an adiabatic drift. If the branch label is indeed carried by the topology of the causal locus, then a smooth $pro \leftrightarrow anti$ conversion would require passage through a singular or near-singular reconnection stage rather than ordinary continuous motion.

Put differently: if branch-changing evolution forces an active delayed branch toward a Jacobian-null boundary, then the exact dynamics encounter the same kind of amplitude wall already familiar from the self-hit geometry. That is why smooth branch inversion should be treated as forbidden or at least highly non-generic in the exact theory. The expected route is instead a discrete mode-lock / reconnection event in which the old branch graph fails and a new one nucleates.

The safest working rule is:

- smooth motion should preserve the deeper branch label;
- planar degeneracy may permit branch ambiguity;
- true branch conversion likely requires a reconfiguration event rather than a mild perturbation.

Simulation Diagnostics

If this note is to become more than a conceptual sketch, the following diagnostics should be added to simulations of fast translating or horizon-adjacent Family-A braids:

- **Axis-alignment diagnostic:** track $\hat{J}_{\rm net} \cdot \hat{\mathbf{V}}$ and test whether it tends toward ±1 as $v_{\rm trans} \to c_f$.

- **Tilt decay diagnostic:** track each orbital-normal angle α_i to test whether non-axial states relax toward the translation axis with a rate that grows with γ_f.
- **Planar branch diagnostic:** once the planarity threshold is met, record which of the 8 planar sign rows the assembly occupies.
- **Mixed-row lifetime diagnostic:** test whether rows 2 through 7 are long-lived or short-lived compared with the two uniform rows.
- **Exposure diagnostic:** compare the sign of $\hat{J}_{\text{net}} \cdot \hat{\mathbf{V}}$ against forward exposure of the weak-active structure to test the left/right bridge hypothesis.
- **Branch persistence diagnostic:** drive a Noether braid into and back out of the planar regime and test whether the same deeper branch label is recovered after re-expansion.

Provisional Conclusion

The full planar spin-sign space at the horizon has eight rows because each of the three labeled binaries can appear as either `CW` or `CCW` from a fixed exterior viewpoint. But the strongest theory is that only two of those rows are good candidates for canonical horizon identities: the two uniform common-sign locks.

That yields a disciplined provisional picture:

- `pro/anti` in the ordinary Family-A braid is a 3D chirality or ordering property;
- the horizon compresses the Family-A braid into a planar state with a reduced exterior signature;
- the exterior planar state has eight logical spin permutations;
- the two uniform rows are the best candidates for stable horizon branches;
- the other six rows are most naturally read as transitional, frustrated, or unstable states unless future dynamics show otherwise.

Standard Model Assemblies

Standard Model

Gauge Structure Emergence

This chapter explains how gauge language enters $\mathbb{AAA}$. The short version is that gauge fields are not added to the Euclidean void as new primitive substances. They are observer-level bookkeeping for repeatable patterns in Noether sea state, assembly geometry, axial-layer exposure, and causal-wake response.

The target is the low-energy Standard Model gauge record, including $U(1)_Y$, $SU(2)_L$, $SU(3)_c$, electroweak mixing, charge bookkeeping, anomaly cancellation, running couplings, and null results for non-baseline channels. This chapter is a working emergence map, not the formal symmetry theorem chapter. Its job is to show what must be recovered and which substrate records are allowed to carry that recovery before exact closure is finished.

The reader should keep three layers separate. At the substrate layer there are architrinos, assemblies, causal wakes, and the Noether sea. At the effective layer there are potentials, fields, gauge connections, and symmetry labels. At the validation layer there are charge tables, scattering records, precision couplings, and absence-of-extra-channel constraints. The emergence claim is that one retained assembly and Noether sea record must project to the tested effective layer without turning the effective fields into final ontology.

Readers who want the particle dictionary before this emergence map can read Quantum Number Mapping and Particle Masses first.

Physical Medium: From Vacuum Language to Noether Sea

In standard QFT, the vacuum is represented by quantum fields and their ground-state structure. In $\mathbb{AAA}$, that language is retained only as an observer-level comparison. The physical medium is the Noether sea, while the fixed container remains the Euclidean void.

In this chapter, the Noether sea means the dense, permeating medium of coupled, neutral Noether braids occupying the Euclidean void; see Noether Sea Pro/Anti Coupling. It is not empty space and is not the Euclidean void itself.

- **Occupancy:** Nonzero occupancy of pro/anti Noether braid assemblies.
- **Net properties:** Balanced charge and angular-momentum bookkeeping at the medium scale, schematically $\sum q = 0$ and $\sum S = 0$ over neutral coarse windows, where S denotes spin/angular-momentum bookkeeping rather than the action.
- **Medium response:** The Noether sea is the working source for the effective local permeability μ_0 and permittivity ϵ_0 read by observer-level electrodynamics. The subscripted ϵ_0 is the standard effective permittivity symbol and is unrelated to the polarity unit $\epsilon = |e|/6$. These are not fundamental constants of the void but derived measures of Noether sea response, including resistance to polarization and density-like occupation.

One useful assembly-level picture is that long-lived Noether sea units arise when complementary pro/anti braids pair in antiparallel fashion so that local polar-site leakage is mutually suppressed. In that reading, Noether sea transparency is not emptiness but a successful cancellation strategy: the Noether sea remains quiet because its local polar-site leakage is internally routed and its large-scale moments stay near zero.

Field Language as Effective Bookkeeping

Standard Model fields are often treated as fundamental entities. Here, field language is an **effective bookkeeping tool** for Noether sea state and assembly state, not a second substrate ontology.

The relevant distinction is between the $\mathbb{U}_{\text{now}}$ universe-state perspective and the Physical Observer.

- **Complete-state view:** The $\mathbb{U}_{\text{now}}$ universe-state perspective records architrinos with polarity bookkeeping labels $q = \pm\epsilon$ and their causal-wake histories. There are no primitive continuous gauge fields, only effective potential summaries reconstructed from causal-wake contributions.

- **Physical Observer view:** A Physical Observer lacks direct resolution of individual architrinos and instead measures collective observables such as the effective potential gradient $\nabla\Phi$ at a point.
  - $\mathbf{E}$ **and** $\mathbf{B}$ **fields** are statistical averages of receiver-side causal-flux density and circulation/vorticity in the Noether sea.
  - **Gauge potentials (**A_μ**)** correspond to local twists, strains, or density gradients in the Noether braid assembly network.

Gauss-Law Source and Closure Benchmarks

The Faraday-to-Gauss field picture is a useful low-energy checkpoint for the effective electromagnetic map. Field lines are visualization aids, not literal strands in the substrate, and the test charge or compass needle is an apparatus probe of a coarse response. What must survive is the closed-surface bookkeeping. In ordinary electrostatics, the electric flux through a closed surface depends only on the net charge enclosed:

$$\oint_{\partial V} \mathbf{E}_{\text{eff}} \cdot d\mathbf{A} = \frac{Q_{\text{enc}}}{\epsilon_0}$$

In standard magnetostatics, the corresponding magnetic flux through a closed surface vanishes in the no-monopole regime:

$$\oint_{\partial V} \mathbf{B}_{\text{eff}} \cdot d\mathbf{A} = 0$$

For $\mathbb{AAA}$, these equations are recovery targets for one effective branch record. The electric relation says the retained polarity ledger, Noether sea response, and apparatus surface must project to the same enclosed-charge flux. The magnetic relation says the observer-level magnetic response must close through circulation/vorticity without requiring an untracked isolated magnetic source. If the electric source row, magnetic closure row, and measured force response require different medium records or independently tuned ϵ_0 and μ_0, the effective field description has not yet recovered the Maxwell-level limit.

Maxwell-Ampere Continuity Benchmark

The charging-capacitor case is a useful low-energy benchmark for this map. In standard electrodynamics, the same boundary loop can be spanned by a surface that cuts the conducting wire or by a bulging surface through the capacitor gap. The observer-level magnetic circulation cannot depend on that arbitrary surface choice, so the Maxwell-Ampere comparison must recover

$$\oint_{\partial S} \mathbf{B}_{\text{eff}} \cdot d\boldsymbol{\ell} = \mu_0 \left(I_{\text{cond}} + \epsilon_0 \frac{d\Phi_E}{dt_{\text{eff}}} \right)$$

in the validated regime. The useful lesson is not that displacement current is a new substrate current moving through empty space. It is that conduction-current bookkeeping in charged assemblies and changing effective electric flux in the Noether sea response must project to the same loop-circulation record. If the two surface choices require different branch records, different medium-response variables, or a hidden retuning of μ_0 and ϵ_0, then the effective electromagnetic map has not recovered Maxwell-level continuity.

Symmetry Groups as Geometric Deformations

We map the abstract gauge groups of the Standard Model to physical deformations of the Noether sea and its Noether braids:

1. **U(1) (Electromagnetism):**
   - *SM View:* Phase rotation of the complex field.
   - $\mathbb{AAA}$ *View:* A variation in the **potential density** or polarization alignment of the Noether sea. A particle moving through this gradient experiences a delayed line-of-action force whose transverse and velocity-dependent observer-level pieces arise from branch geometry, causal delay, and transmitter-side acceleration-weight modulation (the transmitter-side Jacobian entering only as transversality and root-density data).
2. **SU(2) (Weak Interaction):**
   - *SM View:* Non-Abelian rotation in isospin space.
   - $\mathbb{AAA}$ *View:* A **chiral twist** or structural strain in Noether braid assemblies. Because the assemblies have internal handedness, deformations can be order-dependent, mirroring the non-Abelian nature of $SU(2)$ at the effective level.
3. **SU(3) (Color):**
   - *SM View:* Non-Abelian color rotation among three quark color labels.

- $\mathbb{AAA}$ *View:* A color-sector recovery target for axis-exceptionality bookkeeping in the axial frame of the Noether braid assembly; see Color Charge SU(3).

The emergence claim in this chapter is therefore a mapping target with four required parts. The mechanism is delayed causal-wake coupling through Noether sea state and axial-layer deformation. The mapping is from closure labels, axial inventories, exposed weak-coupling triads, color axis-exceptionality records, and medium-response variables to the observer-level symbols $U(1)_Y$, $SU(2)_L$, $SU(3)_c$, g_1, g_2, g_3, θ_W, and the charge table. The regime is the low-energy observer sector where stable assemblies, weak gradients, and resolved apparatus records make the coarse variables meaningful. The breakdown occurs at root-ledger changes, unstable axial inventories, unresolved Noether sea updates, or any branch that predicts extra low-energy partners or transport modes.

A compact reader-facing residual for this map is

$$\mathcal{R}_{\text{EW-map}}(\theta) = d_Q(Q_\theta, Q_{\text{SM}}) + d_{\text{mix}}((g_1, g_2, \theta_W)_\theta, (g_1, g_2, \theta_W)_{\text{obs}}) + d_{\text{chiral}}(W_\theta, W_{\text{obs}}) + \mathcal{R}_{\text{null}}(\theta)$$

Here θ is the retained Noether sea state and assembly branch record, d_Q measures charge-table mismatch, d_{mix} measures electroweak-coupling and weak-mixing mismatch, d_{chiral} measures failure of the weak-coupling-triad exposure record to recover observed handedness, and $\mathcal{R}_{\text{null}}$ penalizes any added low-energy channel that is not observed. This residual is not a new ontology; it names the observer-level recovery burden.

Standard Model Recovery Discipline

This working map starts from the measured low-energy pattern, not from a larger symmetry that must later be hidden. The durable observer-level target is the Standard Model gauge record: $U(1)_Y \times SU(2)_L \times SU(3)_c$, the charge relation $Q = T_3 + Y/2$, the observed chiral weak couplings, the charge and generation tables, the running of g_1, g_2, g_3, and the absence of additional low-energy partners or transport modes above current bounds.

The hypercharge symbol must be read with its local convention. This chapter uses the weak-hypercharge convention $Q = T_3 + Y/2$. If a source instead uses the left-Weyl convention $Q = T_L^3 + Y_{\text{SM}}$, convert by $Y = 2Y_{\text{SM}}$ before comparing charge tables, anomaly sums, or electroweak mixing records.

The recovery target is hybrid rather than a single declared finite-cutoff path integral. Color-sector comparisons consume nonperturbative QCD matrix elements or color-singlet operator data; electroweak comparisons consume a renormalized perturbative chiral-gauge chart or a matched weak effective theory; reaction chapters consume the matching map that connects those records to a measured channel. A finite regulator, when present, is auxiliary evidence until its removal or matching map and systematic error budget are declared. It is not a physical Standard Model parameter in the observer-level recovery residual.

The familiar running-coupling plot is a useful bridge for this target. It says that the effective $SU(3)_c$, $SU(2)_L$, and $U(1)_Y$ interaction strengths change with observer-level probe scale, with approximate high-scale convergence in many normalizations. In $\mathbb{AAA}$ this is not treated as proof of grand-unified ontology. It is a pressure on the mapping: the same Noether sea response, axial-layer exposure, and color axis-exceptionality bookkeeping must generate the scale-dependent effective record discussed in Gauge Symmetries, while the same branch record keeps non-baseline channels absent.

The useful translation of “force unification” is therefore channel availability, not merger into a single primitive force:

Effective stage	Assembly channels present	What is shielded or unavailable	Observer-facing translation
Noether braid dominated	Neutral Noether braid binding and medium response	Axial charge exposure and free electromagnetic/weak channels	Gravity-like medium response can be active before electric or weak observability
Axial association	Stable axial architrino bookkeeping begins to lock to neutral cores	Most internal causal history remains shielded	Inertial response and electroweak differentiation become meaningful
Charged assembly regime	Electromagnetic, weak-corridor, and color-singlet hadronic channels can appear	Non-baseline channels remain suppressed by stability and null-result constraints	The Standard Model channel table is the recovery target
High-probe comparison	Running couplings and possible approximate convergence appear in observer charts	Larger symmetry groups are not substrate ontology by default	Unification claims must explain both recovered channels and absent channels

There is a second consistency pressure that is just as important as the charge table. The Standard Model is a chiral gauge theory, so the low-energy fermion collection must cancel gauge anomalies and the $SU(2)$ Witten obstruction as a set. In this working emergence map, anomaly cancellation is read as a recovery condition on the assembly dictionary:

$$\mathcal{A}^{\mathbb{AAA}}_{\rm SM} = \left(\mathcal{A}_{[SU(3)_c]^3}, N_{2,\rm Weyl} \bmod 2, \mathcal{A}_{[SU(3)_c]^2U(1)_Y}, \mathcal{A}_{[SU(2)_L]^2U(1)_Y}, \mathcal{A}_{[U(1)_Y]^3}, \mathcal{A}_{[\rm grav]^2U(1)_Y}\right) = (0,0,0,0,0,0)$$

This does not make the Standard Model variables substrate ontology. It says that any accepted Noether sea state and axial-layer branch must project to the same anomaly-free effective gauge record; otherwise the branch cannot be the observer-level Standard Model limit.

From the $\mathbb{AAA}$ side, that means the Noether sea state and assembly variables must first reproduce the known gauge bookkeeping. Larger group unification, supersymmetric partner bookkeeping, or extra-dimensional geometry may be useful comparison languages, but none of them is native ontology here. They become relevant only if a branch record derives the Standard Model pattern and also explains why every added observable channel is absent without using a separate suppression parameter for each failed prediction.

The local closure discipline is therefore:

1. recover the effective gauge group and representation table from assembly and axial-layer bookkeeping;
2. derive g_1, g_2, g_3 and θ_W as shared effective outputs rather than per-observable fit constants;
3. keep weak chirality, CKM/PMNS overlap, and weak-reaction provenance tied to the same exposed weak-coupling-triad domain;
4. pass the null-result residual in Failure Criteria for any predicted non-baseline channel.

Single-medium source-of-interactions models are useful here only as a mode-taxonomy warning. They show how one ground-state medium picture can try to generate scalar, vector, and tensor bosons as collective excitations, but they also show the closure burden this creates. For a candidate observer-level boson channel b, define the comparison record

$$\mathcal{M}^\theta_b = \left(J^\theta_b,\, P^\theta_b,\, m^\theta_b,\, \omega^\theta_b(k),\, \mathcal{C}^\theta_b\right)$$

where J^θ_b is the recovered spin label, P^θ_b the parity or transverse/longitudinal projector record when applicable, m^θ_b the mass or gap, $\omega^\theta_b(k)$ the dispersion, and $\mathcal{C}^\theta_b$ the coupling ledger to fermion, photon, weak, color, or gravitational channels. A collective-mode interpretation is admissible only when one Noether sea state and assembly branch supplies $\mathcal{M}^\theta_b$ while also suppressing unobserved scalar, vector, tensor, mirror, or hidden channels. Otherwise “boson as excitation” is an analogy, not gauge-structure emergence.

Gauge-Covariance Recovery Target

The Standard Model gauge equations are comparison constraints on the effective record, not evidence for primitive continuum gauge fields in the substrate. A successful emergence map must recover the covariance structure of a connection and curvature after coarse-graining causal wakes, axial-layer bookkeeping, and Noether sea response into observer-level variables. For a declared low-energy branch θ, write the effective comparison operators as

$$D^\theta_\mu = \partial_\mu - ig_\theta A^\theta_{\mathrm{eff},\mu}, \qquad F^\theta_{\mu\nu} = \frac{i}{g_\theta}[D^\theta_\mu, D^\theta_\nu]$$

If $U(x)$ is an allowed effective gauge relabeling, then the record should transform as

$$\Psi'_\theta = U\Psi_\theta, \qquad D^{\theta'}_\mu \Psi'_\theta = UD^\theta_\mu \Psi_\theta, \qquad F^{\theta'}_{\mu\nu} = UF^\theta_{\mu\nu}U^{-1}$$

This is a redundancy test. It asks whether different gauge charts describe the same observer-level channel, not whether the Noether sea itself has been changed.

The passive/active distinction is load-bearing here. A gauge relabeling is passive when it changes only the effective bookkeeping basis and leaves the retained assembly, causal-wake, axial-layer, and Noether sea record fixed. An active physical change belongs in the branch record θ itself: it may alter medium response, exposed axial inventory, apparatus coupling, or causal-wake provenance. Gauge covariance is recovered only when passive relabelings preserve the same record. It cannot be used to hide a changed physical branch behind a different chart.

A compact residual for the comparison is

$$\mathcal{R}_{\rm cov}(\theta;U) = \sup_{\Psi\in\mathcal{D}_\theta} \frac{\left\|D^{\theta'}(U\Psi) - UD^\theta\Psi\right\|}{\|D^\theta\Psi\| + \varepsilon_{\rm op}}$$

The electroweak or color branch passes only when this residual stays below its declared tolerance on the same record domain used for charge, chirality, mixing, and null-channel tests. If covariance appears only after changing the physical branch ledger, the construction has not recovered gauge redundancy; it has renamed a different physical state.

The same discipline applies to holonomy. For a closed observer-level loop γ, the non-Abelian comparison object is

$$W_\gamma^\theta = \mathrm{Tr}\ \mathcal{P} \exp\left(i g_\theta \oint_\gamma A^\theta_{\mathrm{eff},\mu}\, d\ell^\mu \right)$$

This Wilson-loop language is useful because it tests gauge-invariant loop content. In $\mathbb{AAA}$ terms, the loop value must be reconstructed from the closed causal-wake and axial-layer provenance sampled by the apparatus channel. It is not a claim that the loop integral is fundamental ontology.

Topological sectors supply a stronger global guardrail. In an effective non-Abelian chart, a standard comparison integer is

$$k_\theta = \frac{1}{8\pi^2} \int_{\mathcal{D}_\theta} \mathrm{tr}(F_{\mathrm{eff}} \wedge F_{\mathrm{eff}})\,, \qquad \mathcal{R}_{\mathrm{top}}(\theta) = \inf_{N \in \mathbb{Z}} |k_\theta - N|$$

This target belongs to the gauge recovery map only after $\mathcal{D}_\theta$, F_{eff}, and the apparatus-accessible sector have been declared. It passes when the integer sector is fixed by the same branch record that supplies the local gauge response. It fails if the winding number is imported as an external bundle label while the assembly and Noether sea provenance remain silent.

The same topological-sector map must recover the strong-CP null result. Let $\bar{\theta}_{\mathrm{eff}}(\theta)$ be the observer-level CP-odd strong-sector angle extracted from the declared assembly and Noether sea branch. The target is

$$\mathcal{R}_{\text{strong-}CP}(\theta) = \left|\bar{\theta}_{\mathrm{eff}}(\theta)\right| \lesssim 10^{-10},$$

at the neutron-electric-dipole comparison scale. This bound is an observer-level constraint, not a substrate premise. The extraction must also join the kaon twist-phase row in Mesons: the same CP-odd contribution cannot be counted once as a strong-sector angle and again as an independently fitted weak-sector phase.

Scattering-Amplitude Comparison Target

Gauge recovery also has a scattering side. Standard perturbative QFT packages interactions into amplitudes with physical poles, residues, color factors, and numerator identities. In this framework those amplitudes are comparison-layer summaries of finite event windows. The branch ledger must still carry the participating assemblies, causal wakes, transient channel, Noether sea exchange, recoil, and final records.

For a channel I with intermediate invariant P_I^2, the observer-level amplitude extracted from branch θ should factorize at a physical pole:

$$\mathcal{A}_{n,\theta} \xrightarrow{P_I^2 \to m_h^2} \sum_h \mathcal{A}^{(h)}_{L,\theta} \frac{i}{P_I^2 - m_h^2 + i0} \mathcal{A}^{(h)}_{R,\theta} + \mathcal{A}_{\mathrm{reg},\theta}$$

This equation is a locality-emergence test. It says that a boundary of the event-window description must reduce to two lower-channel records connected by the same accepted transient channel h. If the pole residue cannot be traced to a replayable branch-boundary decomposition, the amplitude has been fitted but not derived.

Color/kinematics duality supplies a sharper optional comparison. Whenever an oriented color triple satisfies a Jacobi relation, the corresponding kinematic numerators should satisfy the matched relation on a closed representation,

$$c_i + c_j + c_k = 0 \quad \Longrightarrow \quad n_i^\theta + n_j^\theta + n_k^\theta \to 0$$

The native value of this test is not the formal identity by itself. The value is whether the indexed color-exceptionality relation $Q_1 + Q_2 + Q_3 = 0$ and the scattering numerator ledger can be derived as two projections of the same branch geometry.

Positive-geometry amplitude work adds one more useful guardrail. If an amplitude is represented by a positive-coordinate auxiliary geometry, then physical boundaries should carry the factorization residues above, while spurious cell boundaries should cancel in the sum. In native terms, a positive-geometry chart is admissible only as a certificate for boundary factorization, spurious-pole cancellation, and record-domain consistency. It does not replace the causal-wake and assembly derivation.

Higgs Mechanism and VEV Reinterpretation

The popular particle-centered Higgs narrative is replaced by a Noether sea medium-response comparison.

The Standard Model recovery sequence is still important. In the effective field description, a massless comparison field has no minimum-frequency gap; a restoring term traced to potential curvature creates the same equation structure as a massive quantum. The Higgs mechanism then adds the critical step: a field that would be massless on its own acquires an effective mass term when it couples to a scalar background with nonzero vacuum expectation value. The Higgs boson itself is the small quantized fluctuation around that background, and its observed mass probes the curvature of the Higgs potential at the selected resting value. In $\mathbb{AAA}$, that whole packet is a recovery target for the electroweak comparison layer. It is not evidence that the Euclidean void has density, not a replacement for the mass-map derivation, and not a claim that all observed mass comes from the Higgs sector; composite hadron masses remain tied to color-corridor closure, binding, shielding, and Noether sea response.

- **VEV (vacuum expectation value):** The VEV is interpreted as an equilibrium density or order-parameter proxy for the Noether sea. It is nonzero because medium contents occupy the void, not because the void has its own density; the exact order parameter and conversion to observer-level electroweak normalization remain closure targets.
- **Symmetry breaking:** Electroweak phase transition language is treated as a phase-change closure target. The high-energy plasma record must relax into the stable, coupled Noether sea inferred today, but the order parameter and transition dynamics still have to be derived.
- **Mass as medium-dressed response:** A fermion assembly moving or accelerating through the Noether sea must relock its internal causal ledger against the surrounding Noether sea.
  - Photon channels propagate as coherent planar-mode transport through the sea rather than as massive bodies.
  - Massive assemblies expose more shielded internal causal history to external probes. The measured inertial response is not ordinary dissipative drag; see Particle Masses: Emergent Inertia in the Noether Sea.

Resolving the Unruh Ambiguity

Quantum field theory for uniformly accelerated, Rindler observers predicts that an accelerating detector sees a thermal bath of particles (Unruh radiation), while an inertial detector sees a vacuum. This flat-spacetime comparison is distinct from Hawking radiation in curved-spacetime settings. It creates an ontological paradox: do the particles exist or not?

The $\mathbb{AAA}$ resolution:

- **Objective existence:** To the $\mathbb{U}_{\text{now}}$ universe-state perspective, assemblies have a definite substrate status. Their existence is not frame-dependent.
- **Acceleration-conditioned detector response:** The warm bath detected by the accelerating Physical Observer is an effective response of the detector's assembly state to accelerated coupling with the Noether sea.
- **Mechanism (interpretation hypothesis):** Acceleration through the Noether sea ($\mathbf{a} \neq 0$) changes the rate and geometry of coupling with ambient neutral Noether braids. The altered coupling is hypothesized to manifest as thermal energy in the detector. The particles inferred by the detector are detector excitations, not frame-dependent ontic creation. No operator-checkable discriminator currently exists for this reading — Unruh radiation itself remains unobserved.

Quantization from Stability (Selection Rules)

Why do observer-level electric charges appear in units of $e/3$?

- The Standard Model asserts this; $\mathbb{AAA}$ treats it as a stability-selection closure target grounded first in a protected six-unit polarity inventory, with the six-site axial layer as the current charged-fermion working realization.
- **Stability Selection:** The $\mathbb{U}_{\text{now}}$ universe-state perspective sees that arbitrary clusters of ϵ polarity units are likely unstable. They either collapse into an unstable self-hit branch or disperse.
- **The Survivors:** Specific geometric configurations of six sign-carrying units are candidate stable resonances where attractive and repulsive accelerations balance through the assembly branch. In the axial-layer realization these appear as six-pole axial patterns supported by a candidate Noether braid; this construction does not assign a taxonomy member. The local combinatorics reproduce the observed charge set; dynamical exclusion of non-SM stable assemblies remains part of the closure burden.

SM Charge Quantization ($\mathbb{AAA}$: Six ϵ Polarity Slots)

split	Electrinos	Positrinos	net observer-level charge
polarity label	$-\epsilon$	$+\epsilon$	units of $\lvert e\rvert$
6:0	6	0	−1
5:1	5	1	−2/3
4:2	4	2	−1/3
3:3	3	3	0
2:4	2	4	+1/3
1:5	1	5	+2/3
0:6	0	6	+1

Under the six-unit polarity inventory target, sweeping all Electrino:Positrino splits across the six retained slots yields exactly the Standard Model charge values listed in the table above and no other total charge values within that fixed six-unit inventory. The six-site axial-layer hypothesis is one geometric realization of those slots. Dynamical exclusion of non-Standard-Model stable assemblies remains a separate closure burden.

Combinatorial Proof (Six $\pm\epsilon$ Slots)

Proposition. If a charged-fermion polarity carrier has exactly six retained slots, each occupied by either $+\epsilon$ or $-\epsilon$, then the observer-level charge can only be

$$\{-|e|, -2|e|/3, -|e|/3, 0, +|e|/3, +2|e|/3, +|e|\}$$

Proof. Let N_+ be the number of $+\epsilon$ slots and N_- the number of $-\epsilon$ slots. Then

$$N_+ + N_- = 6, \qquad N_+, N_- \in \{0, 1, \ldots, 6\}$$

The net observer-level charge carried by the six-slot inventory is

$$Q = \epsilon(N_+ - N_-)$$

Using $N_- = 6 - N_+$,

$$Q = \epsilon(2N_+ - 6) = \frac{|e|}{3}(N_+ - 3)$$

Since N_+ is an integer from 0 to 6, $(N_+ - 3) \in \{-3, -2, -1, 0, 1, 2, 3\}$, so

$$Q \in \left\{-|e|, -\frac{2|e|}{3}, -\frac{|e|}{3}, 0, \frac{|e|}{3}, \frac{2|e|}{3}, |e|\right\}$$

No other values are possible. Different permutations with the same (N_+, N_-) have identical total Q; they only change micro-geometry, not net charge.

Loop-Phase Quantization Target

Dirac's 1931 monopole argument is useful here as an observer-level gauge-potential lesson, not as a claim that magnetic poles are $\mathbb{AAA}$ ontology. The comparison target is the global phase condition: a local effective potential may be chart-dependent, but the phase accumulated around a closed loop must be single-valued modulo 2π. For any observer-level loop γ and spanning surface S in a declared gauge-topology benchmark, the effective connection reconstructed from the wake/action ledger should therefore obey

$$\Theta_\gamma(Q) = \frac{Q}{\hbar}\oint_\gamma A_{\text{eff}} \cdot d\ell = \frac{Q}{\hbar}\int_S F_{\text{eff}}$$

with the physical ambiguity only

$$\Theta_\gamma(Q) - 2\pi N_\gamma \to 0, \qquad N_\gamma \in \mathbb{Z}$$

The six-unit charge inventory, and in the axial-layer realization the axial bookkeeping, must make this a charge-compatibility condition, not a separately imposed monopole postulate. A compact residual for the allowed six-slot charge set is

$$\mathcal{R}_{\text{loop-}Q} = \max_{Q\in\{-|e|,-2|e|/3,-|e|/3,0,|e|/3,2|e|/3,|e|\}} \inf_{N_\gamma\in\mathbb{Z}} \left| \frac{Q}{\hbar}\int_S F_{\text{eff}} - 2\pi N_\gamma \right|$$

This residual belongs to the observer-level recovery map. It passes only when the same Noether sea state and axial-layer branch record that supplies local electromagnetic force and phase transport also yields $\mathcal{R}_{\text{loop-}Q} \le \varepsilon_{\text{loop-}Q}$ for the benchmark loop family. If a branch recovers the charge table locally but cannot make closed-loop phase globally consistent, the six-site quantization proof is only combinatorial and has not yet recovered the gauge-topological content of charge quantization.

A magnetic-charge comparison branch must also separate formation from capture. In observer-level language a magnetically charged compact object can form with charge or later capture charged defects. The $\mathbb{AAA}$ gauge map should not import either story as ontology, but it can retain the provenance distinction as a residual on the effective flux record:

$$Q^\theta_{m,\text{eff}}(t_{\text{eff}}) = Q^\theta_{m,\text{form}} + \int_{t_{\text{form}}}^{t_{\text{eff}}} \Gamma^\theta_{m,\text{cap}}(t'_{\text{eff}})\, dt'_{\text{eff}} - \int_{t_{\text{form}}}^{t_{\text{eff}}} \Gamma^\theta_{m,\text{loss}}(t'_{\text{eff}})\, dt'_{\text{eff}}$$

The loop-phase target above then requires the same branch record to support both the effective magnetic-flux label and the allowed electric axial-layer charge set. A compact object that solves a monopole-abundance problem by hiding charge in an untracked capture channel has not recovered gauge structure; it has moved the charge ledger outside the derivation.

Observer-Level Electroweak Closure Map (Working)

In this map, electroweak “breaking” means a stabilizer and mass-coordinate recovery problem for the effective gauge chart. It does not mean that gauge redundancy is a primitive substrate symmetry that literally breaks. The substrate task is to derive the observer-level photon, $W^\pm$, Z, charge, and weak-mixing records from one branch state while preserving the gauge-invariant record of measured reactions.

To connect microdynamics to observer-sector electroweak equations, start from the canonical acceleration-first Master Equation. For receiver r and transmitter t,

$$\mathbf{A}_{r\leftarrow t}(T_r;T_t) = \kappa\,\sigma_{tr}\,\frac{|q_t q_r|}{r^2(T_r;T_t)} W^{\text{acc}}_{r\leftarrow t}(T_r;T_t)\,\hat{\mathbf{r}}_t(T_r;T_t),$$

with

$$\mathbf{A}_r(T_r) = \sum_t \sum_{T_t\in\mathcal{C}_{r\leftarrow t}(T_r)} \mathbf{A}_{r\leftarrow t}(T_r;T_t), \qquad W^{\text{acc}}_{r\leftarrow t} = \frac{c_f}{|c_f - \mathbf{V}_t(T_t)\cdot\hat{\mathbf{r}}_t|}.$$

This preserves the receiver-side causal-root geometry and keeps substrate dynamics acceleration-first. A previous Fokker-type action scaffold is not a premise here: its variation retains an unresolved derivative-of-delta contribution and a future-reception boundary. Fast-mode averaging and coarse-graining must therefore be performed on retained Master Equation solutions, and the effective action below must be derived from those records rather than assumed.

After fast-mode averaging of the declared fast binary phases and coarse-graining to $q^2 \ll \omega^2_{\text{fast}}$, the target observer-level action is

$$\mathcal{L}_{\text{eff}} = \bar{\Psi}\,(i\gamma^\mu D_\mu - \mathcal{M})\,\Psi - \frac{1}{4}\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu} - \frac{1}{4}\mathcal{W}^a_{\mu\nu}\mathcal{W}^{a\mu\nu} + \mathcal{L}_{\text{comp}}$$

with

$$D_\mu = \partial_\mu - ig\frac{\tau^a}{2}W^a_\mu - ig'\frac{Y}{2}B_\mu$$

The leading composite correction is modeled as

$$\mathcal{L}_{\text{comp}} = \frac{R^2_{\text{comp}}}{2}\,\bar{\Psi}\gamma^\mu D^\nu \mathcal{F}_{\mu\nu}\Psi + O(R^4_{\text{comp}})$$

where R_{comp} is the declared composite scale extracted from the indexed binary record.

For the formal closure layer beneath this working map, see Gauge Symmetries and Effective Lagrangian.

Parameter Dictionary (Substrate -> Electroweak)

Use the charge-bookkeeping identity:

$$|e| = 6\epsilon$$

This is separate from the dimensionful electromagnetic coupling normalization used by the force-response map:

$$\mathcal{G}_{\text{em}} = 6\epsilon\sqrt{\kappa c_f}\,Z_e$$

where Z_e is the coarse-graining normalization factor ($Z_e = 1$ under canonical normalization choice). In dimensional units $\mathcal{G}_{\text{em}}$ scales as $[\epsilon]\sqrt{[\kappa][c_f]}$ rather than as electric charge, so it must not be identified with the charge label e.

Weak mixing is represented as a geometric overlap functional:

$$\sin^2\theta_W = \frac{g'^2}{g^2 + g'^2} = \mathcal{O}_{\text{shield}} + \Delta_{\text{wake}}$$

This dictionary entry carries branch-increment-hypothesis grade; the graded derivation, its conditionality, and the falsifier live in Weak Mixing Angle.

Mass channels are mapped by

$$m_W^2 = \frac{1}{4}g^2 v_{\text{eff}}^2, \qquad m_Z^2 = \frac{1}{4}(g^2 + g'^2)\,v_{\text{eff}}^2$$

so

$$\frac{m_W}{m_Z} = \cos\theta_W$$

Fermion masses are targeted as cycle-averaged attractor energies, conditional on a retained attractor branch — an open closure item:

$$m_f \approx \frac{\langle E_{\text{kin}} + U_{\text{pot}}\rangle_f}{c_{\text{eff}}^2}$$

in the weak homogeneous branch where the scalar mass-map roadmap applies. The sharper closure still belongs to the medium-response tensor and shielding map in Particle Masses: Emergent Inertia in the Noether Sea.

Precision Interface to Measured Quantities

The closure observables are:

$$\sin^2\theta_W(m_Z), \quad \frac{m_W}{m_Z}, \quad a_e, \quad a_\mu, \quad \sigma(e^+e^- \to \mu^+\mu^-; s)$$

Composite magnetic-moment shift:

$$a_\ell^{\text{model}} = a_\ell^{\text{SM,ref}} + \mathcal{C}_\ell\,(m_\ell R_{\text{comp}})^2 + O(R_{\text{comp}}^4)$$

In natural units ($\hbar = c = 1$), the leading form factor correction for lepton-pair production is

$$F(s) = 1 - \frac{sR_{\text{comp}}^2}{4}, \qquad \sigma_{\text{model}}(s) = \sigma_{\text{SM}}(s)\,|F(s)|^2$$

For $R_{\text{comp}} \sim 10^{-19}\,\text{m}$, this predicts negligible deviations at $\sqrt{s} = 10.58\,\text{GeV}$ but a deviation of order the explicit 10^{-3} first falsification tolerance below near the Z pole at $\sqrt{s} = 91.19\,\text{GeV}$. Calling the Z-pole shift negligible requires a substantially smaller composite scale, for example $R_{\text{comp}} \lesssim 3 \times 10^{-20}\,\text{m}$.

Falsification Gates for This Map

1. If the R_{comp} needed to fit Δa_μ implies $|\Delta\sigma/\sigma| > 10^{-3}$ near the LEP Z pole, the composite correction map is ruled out.

2. If the required hierarchy violates nonresonance and destabilizes closure in the kinematic sector, the electroweak map is not self-consistent with Lorentz closure.
3. If charge reconstruction from six-pole averaging acquires drift-dependent leakage (non-integer multiples of $e/3$), the quantization map fails.
4. If the map predicts additional stable charged fermions, unsuppressed partner channels, proton-instability corridors, extra gauge modes, or other non-baseline observables above null-result bounds, the added structure is not a closed unification result.

Gauge Symmetries

This chapter gives the compact theorem-facing version of the gauge bridge. Gauge symmetry is treated here as a tested structure of the observer-level record, not as a primitive substance in the Euclidean void. The bridge question is whether architrino assemblies, axial-layer bookkeeping, causal-wake history, and Noether sea response can reproduce the same effective redundancy, charge assignments, anomaly cancellations, and running couplings that the Standard Model uses.

The page is deliberately stricter than the emergence narrative. It does not ask whether a larger symmetry package sounds attractive. It asks whether the effective gauge record can be recovered from one retained branch and medium state while every non-baseline channel remains absent.

The reader-facing rule is direct: gauge symmetry is a recovery constraint on the record, not a new ontology for the void. The Standard Model gauge structure survives here only if it can be produced as effective bookkeeping over real assembly histories, with no extra observable channels introduced by the same move.

Interface chapters:

- Electroweak emergence narrative: Gauge Structure Emergence
- Color $SU(3)$ algebra closure: Color Charge SU(3)
- Variational substrate: Effective Lagrangian

Regularized Setting

Work in the $\eta > 0$ regularized regime, with coarse-grained fields obtained from the same kernel used in the master/effective-action chapters.

This section starts in the effective layer on purpose. The symbols look like field theory because the benchmark is field-theoretic. The substrate claim is weaker and harder: those effective fields must be recoverable from regularized assembly, wake, and Noether sea records.

Assume:

- **(G1)** Existence of coarse-grained matter field Ψ and finite-energy histories on bounded windows.
- **(G2)** Action density depends on Ψ only through Ψ, $\partial_\mu \Psi$, and symmetry-compatible contractions.
- **(G3)** Color axis-exceptionality space is $\mathcal{H}^{\text{color}} \cong \mathbb{C}^3$.
- **(G4)** Weak-coupling triad is a local two-state channel at each point (effective doublet sector).

The fields in this section are effective observer-level variables. They are admitted because they encode tested continuity, phase, and scattering records; they are not primitive contents of the Euclidean void.

Standard Model Recovery Gate

The gauge bridge is allowed to use the language of connections and covariant derivatives because those are the tested observer-level structures. It is not allowed to promote a larger symmetry, extra sector, or hidden channel merely because that larger package contains the Standard Model as a subcase. The first recovery target is the low-energy effective gauge record

$$\mathcal{G}_{\text{SM}}^{\text{eff}} = U(1)_Y \times SU(2)_L \times SU(3)_c, \qquad Q = T_3 + \frac{Y}{2}$$

together with the observed charge assignments, chiral weak couplings, anomaly cancellations, running couplings, and mixing data consumed by the fermion and reaction chapters.

This chapter uses the weak-hypercharge convention in the displayed relation. Sources that use $Q = T_L^3 + Y_{\rm SM}$ must be converted by $Y = 2Y_{\rm SM}$ before their charge tables or anomaly coefficients are compared to this residual. A compact residual for this chapter is

$$\mathcal{R}_{\rm gauge}(\theta) = d_{\rm rep}\big(\mathcal{G}_{\rm eff}(\theta), \mathcal{G}_{\rm SM}^{\rm eff}\big) + d_{\rm run}\big((g_1, g_2, g_3, \theta_W)_\theta, (g_1, g_2, g_3, \theta_W)_{\rm obs}\big) + d_{\rm chiral}\big(\mathcal{E}_{\rm weak}(\theta), \mathcal{E}_{\rm weak}^{\rm obs}\big)$$

where $d_{\rm rep}$ checks representation and charge bookkeeping, $d_{\rm run}$ checks the scale-dependent effective couplings, and $d_{\rm chiral}$ checks the weak-coupling-triad exposure record against observed charged-current handedness. This chapter's bridge is promotable only if

$$\mathcal{R}_{\rm gauge}(\theta) \le \epsilon_{\rm gauge} \qquad \text{and} \qquad \mathcal{R}_{\rm null}(\theta) = 0$$

with $\mathcal{R}_{\rm null}$ defined in Failure Criteria. Thus larger group unification, supersymmetry, Kaluza-Klein-style geometry, and similar constructions remain comparison frameworks unless an $\mathbb{AAA}$ branch record recovers the observed gauge sector while also suppressing every added observable channel from the same shared state variables.

The representation term is local gauge bookkeeping unless the branch also makes claims about global line or bundle sectors. The local product notation $U(1)_Y \times SU(2)_L \times SU(3)_c$ is enough for the charge and anomaly residual above, but it does not by itself decide the global quotient or the allowed line-operator spectrum. A branch that uses those global sectors must declare the additional bundle and line data as part of $d_{\rm rep}$ rather than hiding it inside the local Lie-algebra match.

Gauge Redundancy and Anomaly Ledger

The effective gauge variables are redundant coordinates on an observer-level record. In the bridge theory, a gauge transformation must move within one physical equivalence class rather than between two distinct substrate states:

$$A_\mu \sim A_\mu + \frac{1}{g_1}\partial_\mu \alpha, \qquad W_\mu \sim U W_\mu U^{-1} + \frac{i}{g_2} U \partial_\mu U^{-1}, \qquad G_\mu \sim V G_\mu V^{-1} + \frac{i}{g_3} V \partial_\mu V^{-1}$$

The $U(1)$ parameter is normalized consistently with the sector convention below, so g_1 remains explicit rather than being absorbed into α. This is why the chapter treats A_μ, W_μ, G_μ as effective connections. The substrate burden is not to find primitive gauge fields, but to recover one gauge-invariant record of forces, phases, holonomies, and charge ledgers from causal-wake and assembly histories.

Global symmetries and gauge redundancies have different tests. For a genuine global transformation $\delta\Psi = \epsilon X(\Psi)$, the regularized effective action gives a Noether current through

$$\delta S_{\rm eff} = -\int d^4x\, \epsilon(x)\, \partial_\mu J^\mu, \qquad \partial_\mu J^\mu = 0$$

on solutions. In the quantum/effective bridge this becomes a Ward-identity recovery target for the coarse-grained generating functional. A local gauge redundancy, by contrast, is acceptable only if the unphysical directions are quotiented out and no anomalous gauge variation remains.

The anomaly ledger for a candidate branch record θ is therefore

$$\mathcal{A}_{\rm gauge}(\theta) = \big(\mathcal{A}_{[SU(3)_c]^3}, N_{2,\rm Weyl} \bmod 2, \mathcal{A}_{[SU(3)_c]^2 U(1)_Y}, \mathcal{A}_{[SU(2)_L]^2 U(1)_Y}, \mathcal{A}_{[U(1)_Y]^3}, \mathcal{A}_{[\rm grav]^2 U(1)_Y}\big)_\theta$$

For the Standard Model recovery gate this vector must equal

$$\mathcal{A}_{\rm gauge}(\theta) = (0, 0, 0, 0, 0, 0)$$

The second entry is the non-perturbative $SU(2)$ Witten check: the number of left-handed $SU(2)$ doublets must be even. Global anomalies that are part of known physics, such as axial-current violation and pion-to-photon anomaly matching, may be retained as observer-level recovery targets, but a gauge anomaly is a consistency failure rather than an optional correction.

Chiral gauge structure also constrains how this bridge may be regulated. A finite lattice, cutoff, or discrete branch approximation is not automatically a physical explanation of the Standard Model because weak handedness and gauge anomaly cancellation must survive the regulator. In $\mathbb{AAA}$ terms, a cutoff is admissible only as an approximation to one retained branch and observer-level gauge record. It fails if left-handed weak exposure, charge bookkeeping, anomaly cancellation, locality, and unitarity can be made compatible only by changing the underlying Noether sea state, axial inventory, or reaction provenance from row to row.

When this vector is evaluated from a fermion table, all entries are counted generation-by-generation with the correct spectator multiplicities and left-handed conjugate fields. For example, color multiplicity contributes to weak-doublet counting and weak multiplicity contributes to color anomaly sums. A visually correct charge table that passes only after dropping these multiplicities has not passed the Standard Model recovery gate.

Running-Coupling Bridge

The standard high-energy plot of $U(1)_Y$, $SU(2)_L$, and $SU(3)_c$ interaction strengths is read here as a scale-dependent effective gauge record, not as evidence that three substrate fields literally merge. The $SU(3)_c$ curve tests how color axis-exceptionality transport is exposed at short causal-wake and assembly scales. The $SU(2)_L$ curve tests the exposed weak-coupling-triad channel. The $U(1)_Y$ curve tests the hypercharge/electromagnetic bookkeeping before electroweak mixing. A candidate branch record must therefore output the running vector

$$\mathbf{g}_{\mathbb{AAA}}(\mu;\theta) = \big(g_1(\mu;\theta), g_2(\mu;\theta), g_3(\mu;\theta), \theta_W(\mu;\theta)\big)$$

where μ is the observer-level probe scale and θ is the retained branch and constitutive record. The term d_{run} measures the distance between this output and the observed running record across a declared scale window; it is not permission to fit each sector independently at one reference energy.

Near-convergence at high scale may be tracked as a comparison diagnostic by

$$\Delta_{\mathrm{meet}}(\theta) = \inf_{\mu\in W_{\mathrm{run}}} \max_{i,j\in\{1,2,3\}} \left|\alpha_i^{\mathbb{AAA}}(\mu;\theta) - \alpha_j^{\mathbb{AAA}}(\mu;\theta)\right|, \qquad \alpha_i^{\mathbb{AAA}}(\mu;\theta) = \frac{g_i^2(\mu;\theta)}{4\pi}$$

This diagnostic is subordinate to d_{run} and $\mathcal{R}_{\mathrm{null}}$. A small Δ_{meet} does not promote a grand-unified container unless the same branch record recovers the observed low-energy gauge record, reproduces the scale dependence, and explains the absence of mirror matter, superpartners, proton-instability channels, extra gauge bosons, hidden transport modes, and other non-baseline outputs in the tested regime.

For a proposed symmetry container C, a compact audit form is

$$\mathcal{R}_{\mathrm{container}}(\theta;C) = w_g\mathcal{R}_{\mathrm{gauge}}(\theta) + w_f\mathcal{R}_{\mathrm{fact}}(\theta) + w_0\mathcal{R}_{\mathrm{null}}^{\mathrm{op}}(\theta)$$

where $\mathcal{R}_{\mathrm{fact}}$ measures failure of the recovered observer-level scattering and gauge sector to factor into the validated spacetime and internal-gauge records once those effective records exist. The container is only comparison language unless one shared θ drives all terms below tolerance; in particular, $\mathcal{R}_{\mathrm{null}}^{\mathrm{op}} = 0$ must follow from the accepted branch family rather than from sector-specific hiding parameters.

The same filter applies to especially elegant symmetry containers, including grand-unified and exceptional-group embeddings. It is not enough for a larger algebra to contain $U(1)_Y \times SU(2)_L \times SU(3)_c$ or to organize one generation of fermions. The promoted record must also explain why mirror matter, superpartners, proton-instability channels, extra gauge bosons, hidden transport modes, and other non-baseline outputs are absent in the tested regime. If those absences require separate masses, thresholds, compactification choices, or sector-specific suppressions, the construction remains a comparison framework rather than an $\mathbb{AAA}$ gauge closure.

U(1) Sector

Theorem 1 (Global phase invariance implies charge continuity).
If the effective action is invariant under

$$\Psi \mapsto e^{i\alpha}\Psi, \qquad \alpha \in \mathbb{R}$$

then there exists a conserved current j^μ such that

$$\partial_\mu j^\mu = 0$$

Proof sketch: Apply Noether's theorem in the regularized variational setting; invariance under constant phase shifts yields the continuity equation.

Corollary (Local phase covariance requires a connection).
For local $\alpha(x)$, invariance requires a compensating field A_μ and covariant derivative

$$D_\mu = \partial_\mu - ig_1 A_\mu$$

with $U(1)$ gauge transform

$$\Psi \mapsto e^{i\alpha(x)}\Psi, \qquad A_\mu \mapsto A_\mu + \frac{1}{g_1}\partial_\mu \alpha$$

Here A_μ is the generic $U(1)_Y$ connection before electroweak mixing, not the already-mixed photon connection.

Aharonov-Bohm Holonomy Benchmark

The Aharonov-Bohm effect is the sharp U(1) benchmark because it separates local force from phase transport. The validated observable is not merely that an effective connection can be written, but that two force-free arms can accumulate a relative phase fixed by enclosed flux. In this chapter the benchmark is therefore a closure target for the emergent connection, not evidence that A_μ is substrate ontology.

For two interferometer arms γ_1 and γ_2 whose local force channel vanishes along the arms,

$$\mathbf{F}_{\text{eff}}\big|_{\gamma_1} = \mathbf{F}_{\text{eff}}\big|_{\gamma_2} = \mathbf{0}$$

the coarse-grained wake/action ledger must still produce the observer-level phase shift

$$\Delta\phi_{\text{AB}}^{\mathbb{AAA}} = \frac{1}{\hbar_{\text{eff}}}\left(\mathcal{S}_{\text{wake}}[\gamma_1] - \mathcal{S}_{\text{wake}}[\gamma_2]\right) \stackrel{!}{=} \frac{q_{\text{eff}}}{\hbar}\Phi_B \pmod{2\pi}$$

Here $\mathcal{S}_{\text{wake}}[\gamma_a]$ is the effective action accumulated by the coarse-grained causal-wake history assigned to arm γ_a, and Φ_B is the standard enclosed magnetic-flux observable. The equality also carries a calibration burden: a validated branch must identify the emergent phase quantum with the measured one on this benchmark window, $\hbar_{\text{eff}} = \hbar$, rather than fitting two independent phase scales. A useful residual is

$$\Delta_{\text{AB}} = \sup_{\Phi_B}\left|\Delta\phi_{\text{AB}}^{\mathbb{AAA}}(\Phi_B) - \frac{q_{\text{eff}}}{\hbar}\Phi_B\right|$$

When the benchmark is evaluated as a concrete interferometer packet, the force-free and phase requirements should be checked together rather than fitted separately. For a branch record θ, one compact validation residual is

$$\mathcal{V}_{\text{AB}}(\theta) = w_F \sum_{a=1}^{2}\int_{\gamma_a} \left\|\mathbf{F}_{\text{eff}}(\theta)\right\|^2 \, ds + w_\phi \inf_{N\in\mathbb{Z}}\left|\Delta\phi_{\text{AB}}^{\mathbb{AAA}}(\theta) - \frac{q_{\text{eff}}}{\hbar}\Phi_B - 2\pi N\right|$$

with w_F and w_ϕ fixed by the declared interferometer tolerance. The benchmark passes only when $\mathcal{V}_{\text{AB}}(\theta) \le \varepsilon_{\text{AB}}$ for the same wake/action ledger, so a model cannot trade a hidden local force for phase recovery or tune the phase apart from the local electromagnetic-force record.

The U(1) closure passes this benchmark only if Δ_{AB} remains below the declared interferometric tolerance while the same effective connection also preserves charge continuity and ordinary electromagnetic force recovery. If the phase recovery requires a local force on the arms, a separate phase fit, or a literal promotion of A_μ to substrate ontology, this gauge bridge has failed at the AB gate.

Global Gauge-Topology Completion Target

The Aharonov-Bohm benchmark is local in the sense that it tests one enclosed-flux holonomy. A stronger gauge bridge must also recover the global content usually hidden by chartwise potential language: flux quantization, charge compatibility, and the way local effective potentials glue across overlapping regions. This remains an effective-connection target, not evidence that a gauge potential is substrate ontology.

Let Γ_{AB} be a benchmark family of closed observer-level loops γ and spanning surfaces S for which the local force channel vanishes on the loop. The shared wake/action and effective-connection record should satisfy

$$\Delta_{\text{gauge,glob}}(\theta) = \sup_{(\gamma,S)\in\Gamma_{\text{AB}}} \inf_{N\in\mathbb{Z}}\left|\Delta\phi_{\text{wake}}^{\mathbb{AAA}}(\gamma;\theta) - \frac{q_{\text{eff}}}{\hbar}\int_S F_{\text{eff}}(\theta) - 2\pi N\right|$$

Here F_{eff} is the observer-level curvature recovered from the same effective gauge record used for force and phase transport. The integer N records the allowed 2π ambiguity of the phase, not an independent hidden sector.

A compact sector check inside the same target is useful when the benchmark includes disconnected flux sectors or instanton-like sectors rather than a single loop. Let $\mathcal{C}_{\text{top}}$ be the declared family of observer-level gauge-topology sectors, and let $\mathcal{O}_{\text{SM}}(s)$ be the corresponding Standard Model comparison record for sector s. The same wake/action ledger may define

$$\Delta_{\text{sector}}(\theta) = \sup_{s \in \mathcal{C}_{\text{top}}} \left[\inf_{n_s \in \mathbb{Z}} \left| \mathcal{Q}^{\mathbb{AAA}}_{\text{wake}}(s;\theta) - n_s \right| + d_{\text{obs}}(\mathcal{O}_\theta(s), \mathcal{O}_{\text{SM}}(s)) \right]$$

Here $\mathcal{Q}^{\mathbb{AAA}}_{\text{wake}}$ is only the sector label extracted from the retained causal-wake/action record. It is not an independent topological charge assigned after the effective gauge description has already been fitted.

The global gauge-topology target passes only if $\Delta_{\text{gauge,glob}}$ and any declared Δ_{sector} stay below tolerance while charge continuity, local force recovery, AB holonomy, and flux/charge compatibility are all read from one shared record. It fails if a chart-dependent potential must be promoted to ontology, if the topological charge is inserted separately from the wake/action ledger, or if the same sector requires different Noether sea variables for force, phase, and charge recovery.

SU(2) Weak Sector

Let ψ_L denote the local left-handed weak doublet in the effective exposed weak-coupling-triad channel.

Proposition 2 (Local weak-basis rotations define an SU(2) connection).
If physics is invariant under

$$\psi_L(x) \mapsto U_2(x)\psi_L(x), \qquad U_2(x) \in SU(2)$$

then the derivative must be promoted to

$$D_\mu \psi_L = \left(\partial_\mu - i g_2 W^a_\mu \frac{\tau^a}{2} \right) \psi_L$$

with curvature

$$F^a_{\mu\nu} = \partial_\mu W^a_\nu - \partial_\nu W^a_\mu + g_2 \epsilon^{abc} W^b_\mu W^c_\nu$$

Here ϵ^{abc} is the $SU(2)$ Levi-Civita structure constant; it is unrelated to the polarity-unit magnitude ϵ used in axial-inventory bookkeeping.

Proof sketch: Standard principal-connection construction for local non-Abelian basis changes; the commutator term follows from non-commutativity of $SU(2)$ generators.

SU(3) Color Sector

Theorem 3 (Color algebra closure in axis-exceptionality basis).
In the persistently indexed basis $(1, 2, 3)$, the eight generators built from axis mixers and two diagonal traceless operators close a Lie algebra isomorphic to $\mathfrak{su}(3)$.

This is the rigorous closure result already proven in color-charge-su3. Therefore effective color transport acts through

$$U_3 \in SU(3), \qquad D_\mu = \partial_\mu - i g_3 G^a_\mu T^a$$

Minimal Effective Gauge Lagrangian

Under (G1)-(G4), the lowest-order local gauge-covariant continuum form is

$$\mathcal{L}_{\text{gauge,min}} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} - \frac{1}{4} W^a_{\mu\nu} W^{a\,\mu\nu} - \frac{1}{4} G^a_{\mu\nu} G^{a\,\mu\nu} + \bar{\Psi}\, i\gamma^\mu D_\mu \Psi + \cdots$$

where omitted terms are higher-order constitutive corrections from the Noether sea.

This is an emergent effective description, not a claim that gauge fields are ontologically fundamental.

Closure Interface: Gauge-Topology Compatibility

For integration with the topological and metric closure programs, impose compatibility between gauge-covariant effective dynamics and topology-derived sector separation.

Required consistency conditions:

1. **Topology respect:** effective gauge transport must preserve the admissible axis-exceptionality sector decomposition used in confinement/topology chapters.
2. **No leakage contradiction:** constitutive preferred-frame leakage terms (from spacetime closure) must not force leading-order gauge-breaking operators.
3. **Energy-side compatibility:** gauge sector must admit open-vs-closed braid scaling laws without violating local covariance of the effective Lagrangian.
4. **Global completion:** local effective connections must assemble into one gauge record whose holonomies, fluxes, and charge ledgers agree across chart boundaries.

Interface chapters:

- topology and action invariants: dynamics/causal-action-functional.md
- color structure and confinement geometry: assemblies/fermions/color-charge-su3.md
- preferred-frame closure: spacetime/ppn-parameters.md

Failure Conditions

This gauge-emergence spine fails if any of the following occur in the calibrated low-energy regime:

- Measured effective continuity violation: $\partial_\mu j^\mu \neq 0$ beyond numerical/experimental tolerance.
- Weak channel requires non-SU(2)-covariant terms at leading order.
- Color generator set fails closure or requires dimension other than 8 in the one-axis-exceptionality sector.
- The Standard Model representation, coupling-running, or chirality residual $\mathcal{R}_{\text{gauge}}$ cannot be kept below tolerance using one shared gauge record.
- Global holonomies, fluxes, and charge compatibility cannot be recovered from the same effective gauge record that supplies local force and phase transport.
- Added partner families, extra gauge modes, baryon-instability channels, or hidden transport channels produce $\mathcal{R}_{\text{null}}(\theta) > 0$.
- Preferred-frame leakage forces explicit gauge-breaking operators at leading order.

These are theory-level falsifiers for this chapter's bridge.

Particle Masses

Mass is where the reader first sees why assemblies matter. In $\mathbb{AAA}$, an architrino does not carry its own particle-specific mass tag. What a Physical Observer calls mass is the externally exposed response of a stable assembly whose internal causal history is partly shielded and partly coupled to the surrounding Noether sea.

This chapter gives the reader-facing statement of that mass thesis and outlines the path toward quantitative mass predictions. The active derivation of a numerical mass map remains open until the shielding, stability, internal-energy, and medium-response terms are computed from retained assembly branches rather than fitted particle by particle.

The Mass Hypothesis: Inertia as Medium Interaction

Core Thesis

In $\mathbb{AAA}$, **mass is not a fundamental property** of individual architrinos. There is no intrinsic particle-specific "mass parameter" m assigned at the substrate level. Instead, what we observe as mass, especially **inertial resistance to acceleration**, is treated as an emergent response of stable assemblies embedded in the surrounding Noether sea, the physical medium composed of neutral Noether braid assemblies.

The conservative thesis is:

$$\text{observed mass} \quad \leftrightarrow \quad \text{the externally exposed response of a closed internal causal-history ledger.}$$

That response is shaped by internal energy storage, shielding, and the medium-dressed way the Noether sea couples to a moving or accelerated assembly.

Assembly-Level Reduction

The compact mass-map roadmap formula is an expression over an assembly A:

$$m_{\text{inertial}}(A) \approx \alpha_{\mathrm{m}} \frac{\zeta(A) E_{\text{internal}}(A)}{c_{\text{eff}}^2}$$

This is the clean scalar form of the thesis. It says that the observer-facing inertial mass is controlled by the shielded part of the internal assembly ledger, with α_{m} fixed once by a reference assembly in the regime where the effective low-energy closure is being matched. Here α_{m} denotes the single mass-normalization constant for the declared weak homogeneous regime; it is not the fine-structure constant and not a per-particle fit parameter.

The scalar form is not the whole derivation. In a resolved Noether sea environment, the denominator c_{eff}^2 is the isotropic weak-field limit of a medium-response tensor:

$$p_{\text{int}}^a \approx \alpha_{\mathrm{m}}\, \zeta(A) E_{\text{internal}}(A)\, \mathcal{M}_{\text{sea}}^{ab} V_{\text{cm},b}, \qquad \mathcal{M}_{\text{sea}}^{ab} \to \frac{h^{ab}}{c_{\text{eff}}^2}$$

in a homogeneous isotropic Noether sea cell. Here h^{ab} is the inverse Euclidean spatial metric on the local substrate slice. The tensor version is the sharper target because it carries direction dependence, gradient response, and the distinction between primitive wake speed and observer-facing effective signal speed. Until the internal ledger, shielding coefficient, and medium-response tensor are derived from stable assembly closure, this remains a roadmap formula rather than a theorem.

Rest Energy and Moving Energy

The mass-energy relation is retained as an effective observer-level closure, but it is not a substrate axiom. At rest, the native object is not a bare particle mass. It is the accepted assembly branch together with its internal energy ledger, exposure quotient, and Noether sea response record:

$$\left(E_{\text{internal}}(A), \zeta(A), \mathcal{M}_{\text{sea}}^{ab}\right)$$

In a locally homogeneous isotropic Noether sea cell, the scalar rest/internal readout is the branch invariant

$$M_0(A) \equiv m_{\text{tr}}(A)\big|_{v_{\text{CM}}=0} \approx \alpha_{\mathrm{m}} \frac{\zeta(A) E_{\text{internal}}(A)}{c_{\text{eff}}^2}$$

Equivalently, the exposed rest-energy channel is

$$M_0(A) c_{\text{eff}}^2 \approx \alpha_{\mathrm{m}} \zeta(A) E_{\text{internal}}(A)$$

This equation is the $\mathbb{AAA}$ reading of $E_0 = m_0 c^2$: Physical Observers measure a scalar rest mass because they couple to the exposed part of the closed causal ledger, not because every unit of internal circulation is visible at long range. The rest/internal invariant is therefore downstream of branch stability, shielding extraction, and the same medium-response tensor used by the acceleration response.

For a moving assembly in the same weak homogeneous regime, the effective energy-momentum closure is instead

$$E_{\text{CM}}^2 = p_{\text{CM}}^2 c_{\text{eff}}^2 + M_0^2 c_{\text{eff}}^4, \qquad E_{\text{CM}} = \gamma_{\text{eff}} M_0 c_{\text{eff}}^2$$

Here M_0 remains the rest/internal invariant of the accepted branch, while γ_{eff} is the observer-level boost-response factor read from the moving center-of-mass energy, momentum, clock, and ruler channels. Thus the theory does not need a velocity-dependent rest mass. It needs a proof that translating assemblies retune their causal-root ledger, shielding, clock channel, and Noether sea response so that the same γ_{eff} controls all four channels. The detailed energy statement is the effective closure test in Energy, and the clock-side cross-check is in Proper Time and Time Dilation.

Exposed Inertial-Response Trace

The scalar shielding coefficient $\zeta(A)$ should be read as the isotropic trace part of a larger exposed response. For an accepted assembly branch A, let $\mathcal{L}_A(\hat{R})$ denote the mass-facing scalar angular far-field ledger over extraction direction $\hat{R}$, and let $\|\mathcal{L}_{\mathrm{naive}}\|$ denote the corresponding unshielded constituent-sum norm. The monopole extraction is

$$\zeta(A) = \frac{1}{4\pi\|\mathcal{L}_{\mathrm{naive}}\|} \int_{S^2} \mathcal{L}_A(\hat{R})\, d\Omega$$

The trace-free exposed leakage is

$$\mathcal{Z}^{ab}_{\mathrm{tf}}(A) = \frac{1}{4\pi\|\mathcal{L}_{\mathrm{naive}}\|} \int_{S^2} \left(3\hat{R}^a\hat{R}^b - h^{ab}\right) \mathcal{L}_A(\hat{R})\, d\Omega, \qquad h_{ab}\mathcal{Z}^{ab}_{\mathrm{tf}}(A) = 0$$

The exposed-response tensor is therefore

$$\mathcal{Z}^{ab}_A = \zeta(A)h^{ab} + \mathcal{Z}^{ab}_{\mathrm{tf}}(A)$$

A candidate mechanism, at hypothesis level, says that the geometry of an accessory record helps set the size of this exposure. An Accessory Configuration is six additional architrinos placed inside, across, or outside the braid envelope, with the polarity and position of every site declared. Its first nonvanishing polarity-signed moment may help order exposed response, but applying that ordering requires the actual six-site record, its strain on the braid core, and its retained far-field ledger. Thus the relationship between $\mathcal{Z}^{ab}_{\mathrm{tf}}(A)$, $\zeta(A)$, and Accessory Configuration geometry remains a routing hypothesis rather than a computed extraction.

For the scalar inertial readout, only the reversible symmetric part of the Noether sea response belongs in the mass trace. Define

$$\mathcal{M}^{ab}_{+} \equiv \frac{1}{2}\left(\mathcal{M}^{ab}_{\mathrm{sea}} + \mathcal{M}^{ba}_{\mathrm{sea}}\right)$$

and set

$$\mathsf{I}^{ab}_A = \frac{\alpha_{\mathrm{m}} E_{\mathrm{internal}}(A)}{2} \left(\mathcal{Z}^{a}_{A\,c}\mathcal{M}^{cb}_{+} + \mathcal{Z}^{b}_{A\,c}\mathcal{M}^{ca}_{+}\right)$$

The scalar mass readout is the rotational trace

$$m_{\mathrm{tr}}(A) \equiv \frac{1}{3} h_{ab}\mathsf{I}^{ab}_A$$

In the homogeneous isotropic limit this reduces to the roadmap scalar formula. Pure exposure anisotropy changes direction-dependent inertia without changing the scalar trace unless it contracts with a trace-free part of the medium response. Antisymmetric response residue belongs to orientation, transport, loss accounting, or branch transition, not to scalar rest mass.

Reference-Normalized Mass Ratio

Because α_{m} is a single normalization for a declared weak homogeneous regime, the first nontrivial mass-map prediction is not an absolute mass. It is a reference-normalized ratio in which α_{m} cancels.

For two accepted assemblies A and B in the same homogeneous isotropic Noether sea response record, if both assemblies are evaluated through the same scalar exposure quotient and share the same low-energy response limit

$$\mathcal{M}^{ab}_{\mathrm{sea}} \to \frac{h^{ab}}{c^2_{\mathrm{eff}}}$$

then the scalar roadmap implies

$$\frac{m_{\mathrm{inertial}}(A)}{m_{\mathrm{inertial}}(B)} \approx \frac{\zeta(A)E_{\mathrm{internal}}(A)}{\zeta(B)E_{\mathrm{internal}}(B)}$$

Equivalently, once a reference assembly A_{ref} fixes α_{m} in that regime, every later scalar mass prediction must factor through

$$m_{\mathrm{inertial}}(A) \approx m_{\mathrm{inertial}}(A_{\mathrm{ref}}) \frac{\zeta(A)E_{\mathrm{internal}}(A)}{\zeta(A_{\mathrm{ref}})E_{\mathrm{internal}}(A_{\mathrm{ref}})}$$

In anisotropic or pressure-dependent cells, the same anti-fitting principle must be stated directionally. Let I_A^{ab} be the exposed inertial-response tensor for A and let $\hat{v}$ be a declared probe direction. The directional mass readout is

$$m_{\hat{v}}(A) = \hat{v}_a \mathsf{I}_A^{ab} \hat{v}_b$$

so the tensor ratio target is

$$\frac{m_{\hat{v}}(A)}{m_{\hat{v}}(B)} = \frac{\hat{v}_a \mathsf{I}_A^{ab} \hat{v}_b}{\hat{v}_a \mathsf{I}_B^{ab} \hat{v}_b}$$

In the reversible below-threshold regime, I_A^{ab} is built from the same branch-derived exposure, internal energy, and symmetric medium-response tensor for every channel in the declared response record. Thus α_{m} still cancels from the ratio, but trace-free exposure and trace-free medium response no longer disappear unless the homogeneous isotropic limit has been proven.

This ratio form is a sharper anti-fitting invariant than the absolute scalar formula. Changing α_{m} cannot improve one particle without changing all particles in the same regime. Changing $\zeta(A)$ is admissible only when it is produced by the branch ledger and exposure quotient for A, not when it is selected from the observed mass table. Failure of the tensor replacement in anisotropic or pressure-dependent cells is evidence that the scalar mass map is being used outside its regime.

Composite Branch Mass Is Not Constituent Mass Addition

The mass-ratio formulas apply to accepted branches after their own closure, exposure quotient, and Noether sea response record have been evaluated. If a composite branch C is built from retained sub-branches A_i, its scalar mass trace is therefore not generally the sum of the scalar mass traces those sub-branches would have as isolated free branches:

$$m_{\mathrm{tr}}(C) = \frac{1}{3} h_{ab} \mathsf{I}_C^{ab}, \qquad m_{\mathrm{tr}}(C) \neq \sum_i m_{\mathrm{tr}}(A_i) \quad \text{in general.}$$

The composite branch has its own coupling ledger: color-corridor closure for hadrons, residual-strong and nuclear-binding terms for nuclei, shared shielding, multipole cancellation, recoil channels, and local Noether sea polarization. Those entries change I_C^{ab} before the scalar trace is taken. Apparent mass is additive only in the limiting case where the interaction ledger, binding energy, shared shielding, and medium-response cross terms are negligible on the declared comparison window.

This is the mass-map reading of the familiar nuclear and hadronic warning that a proton, neutron, or deuteron is not weighed by adding the observer-facing masses of the quark or nucleon records visible at a different resolution. Conservation is still enforced at the full event ledger: any decrease in the composite scalar mass appears as binding energy, radiation, recoil, neutrino rows when weak channels participate, or a changed Noether sea response record. The nuclear-side bookkeeping is stated in Nuclear Binding, while the nucleon-side source envelope is stated in Nucleon Structure.

Charge-Conjugate Mass Equality

The equality of a particle's rest mass with the rest mass of its antiparticle is a mass-map constraint, not a separate fitted fact. Let $\bar{A} = C(A)$ denote the polarity-conjugate branch obtained from an accepted assembly A by reversing every architrino polarity at fixed worldlines while carrying the shielding-coherence class, retained path-history rows, causal-root ledger, wake-history rows, branch geometry, action rows, and Noether sea response record through the conjugation. The pro/anti ordered orientation is unchanged. For a charged branch, the sector-visible polarity ledger also maps to the opposite charge row:

$$q_a(\bar{A}) = -q_a(A)$$

Here q_a is a polarity ledger entry in the charged-sector projection. Electrino/Positrino polarity is not the matter/antimatter label.

If the mass-facing ledger depends on polarity through even data such as $q_a q_b$, $|q_a|$, causal-root topology, shielding, and polarity-neutral medium response, then complete conjugation leaves the scalar mass trace invariant:

$$E_{\mathrm{internal}}(\bar{A}) = E_{\mathrm{internal}}(A), \qquad \zeta(\bar{A}) = \zeta(A), \qquad \mathsf{I}_{\bar{A}}^{ab} = \mathsf{I}_A^{ab}, \qquad m_{\mathrm{tr}}(\bar{A}) = m_{\mathrm{tr}}(A)$$

The odd channel is the exposed charge-like projection,

$$Q_{\mathrm{eff}}(\bar{A}) = -Q_{\mathrm{eff}}(A)$$

not the rest-mass response. This is why the electron and positron can have opposite electric bookkeeping while sharing the same mass-facing causal buildup: complete branch-record conjugation preserves every internal pair product, every polarity-even exposure term, and the identity-bearing history rows. The constraint does not permit arbitrary partial polarity replacement, and it does not identify Electrino versus Positrino with matter versus antimatter. Flipping only part of an axial inventory or only one internal component can change $q_a q_b$, branch stability, shielding leakage, the causal-root ledger, and the wake-history provenance, so it is generally a different assembly rather than the antiparticle of A.

Thus a candidate mass map fails if an accepted matter branch and its complete anti-branch receive different scalar rest masses in the same neutral Noether sea environment, unless the model explicitly supplies a conjugation-odd medium or branch-asymmetry term and keeps the resulting mass splitting within the declared particle-antiparticle bounds.

Superfluid-vacuum and Nambu-Jona-Lasinio-style comparisons add a useful caution: an excitation gap can look like a rest-energy term without being the ontology of mass. For an accepted assembly branch A, the native analogue would be a branch gap

$$\Delta_A^\theta = E^\theta_{\text{first exc}}(A) - E^\theta_{\text{branch}}(A)$$

computed from the same causal ledger, shielding, and Noether sea response record as the mass map. A compact comparison residual is

$$\mathcal{R}_{\text{gap}\to m}(A;\theta) = \frac{\left|\Delta_A^\theta - M_{\text{sh}}(A;\theta)c_{\text{eff}}^2\right|}{\epsilon_\Delta} + \frac{\left\|\partial_{\theta_{\text{sea}}}\Delta_A^\theta - \partial_{\theta_{\text{sea}}}\left[M_{\text{sh}}(A;\theta)c_{\text{eff}}^2\right]\right\|}{\epsilon_{\text{env}}}$$

If this residual is small, the gap comparison supports the mass-map thesis. If it is small only after choosing a separate gap for each particle species, the comparison has merely renamed the observed mass table.

Sector Exposure Quotient

The scalar shielding factor $\zeta(A)$ is the mass-facing specialization of a more general sector exposure map. A stable assembly can carry far more internal ledger structure than any one observer-level sector is allowed to see. The mass map therefore cannot promote a hidden internal energy, phase, polarity, or branch label as an external response until the sector projection and quotient have been declared.

Let $\mathcal{L}_A \in \mathfrak{L}_A$ be the emitted or retained ledger of an accepted assembly or branch family A. The ledger is derived from the accepted branch ledger, causal-wake history, cycle averages, energy entries, multipole entries, polarity/provenance labels, phase labels, and angular-momentum entries required by the sector under test. For a sector S, define a sector projection Π_S to the retained sector-visible ledger and a quotient Q_S that removes only declared gauge choices, branch-preserving relabelings, hidden internal rotations, canceled pro/anti structure, or unobservable frame choices that do not change the sector benchmark. The visible response is

$$\mathcal{E}_S(A) = Q_S[\Pi_S \mathcal{L}_A]$$

For the isotropic mass-facing scalar sector, $\zeta(A)$ is the scalar summary of $\mathcal{E}_0(A)$. If anisotropic leakage survives, the sector must report a tensor exposure instead of hiding that residue inside $\zeta(A)$.

The useful factorization is that the mass-map numerator should pass through the same quotient. Let $\overline{\mathcal{B}}_0$ be the mass-facing recovery map from the scalar exposure quotient to the exposed source. Then the scalar roadmap numerator is

$$M_0^{\text{src}}(A) = \overline{\mathcal{B}}_0(\mathcal{E}_0(A)) = \zeta(A)E_{\text{internal}}(A)$$

so the inertial-mass target becomes

$$m_{\text{inertial}}(A) \approx \alpha_{\text{m}} \frac{M_0^{\text{src}}(A)}{c_{\text{eff}}^2}$$

This is stronger than treating $\zeta(A)$ as an adjustable small coefficient. If two restored representatives d_1 and d_2 become the same scalar exposure after projection and quotient, then the exposed source must also agree up to the declared scalar-exposure tolerance:

$$Q_0\Pi_0\mathcal{L}_A[d_1] = Q_0\Pi_0\mathcal{L}_A[d_2] \quad \Longrightarrow \quad \left|M_{0,d_1}^{\text{src}} - M_{0,d_2}^{\text{src}}\right| \leq \epsilon_{0,\text{handle}} E_{\text{internal}}(A)$$

When this implication fails, the discarded label is not a hidden quotient label. It is a mass-visible branch selector, so the scalar exposure must retain that label, be promoted to an anisotropic or tensor exposure, or remain unpromoted.

An exposure map is admissible only when the source ledger has branch-ledger provenance, Π_S is idempotent on the retained sector data, Q_S does not identify benchmark-distinct ledgers, and the discarded residue is below the declared tolerance. A useful reader-facing error contract is

$$\epsilon_S = \epsilon_{S,\mathrm{leak}} + \epsilon_{S,Q} + \epsilon_{S,\mathrm{gauge}} + \epsilon_{S,\mathrm{rec}}$$

Any discarded channel above tolerance blocks promotion of the sector response. It cannot be absorbed into shielding, fitted by the benchmark, or left as an unnamed hidden variable.

Scalar Mass-Trace Composition

The mass map is a composition chain rather than a single shielding slogan. The scalar exposed source descends through the mass-facing quotient,

$$M_0^{\mathrm{src}}(A) = \overline{\mathcal{B}}_0(\mathcal{E}_0(A)) = \zeta(A) E_{\mathrm{internal}}(A)$$

and the same source is then inserted into the exposed inertial-response tensor through the reversible symmetric medium response. To first order around a weak homogeneous reference cell, the scalar trace has the form

$$m_{\mathrm{tr}}(A) = \alpha_{\mathrm{m}} \frac{1}{c_{\mathrm{eff},0}^2} \left[M_0^{\mathrm{src}}(A)(1+\delta\mathcal{M}_0) + \frac{1}{3} E_{\mathrm{internal}}(A) \mathcal{Z}_{\mathrm{tf},ab}(A) \delta\mathcal{M}_{\mathrm{tf}}^{ab} \right] + \mathcal{R}_{\mathrm{chain}}$$

Here $\delta\mathcal{M}_0$ is the trace part of the reversible medium-response perturbation, $\delta\mathcal{M}_{\mathrm{tf}}^{ab}$ is its trace-free part, and $\mathcal{R}_{\mathrm{chain}}$ holds terms that have not yet been derived from a branch record. This formula is stronger than the scalar roadmap relation because it names the only first-order places where scalar mass can change: the quotient-visible source, the trace medium response, and the trace-free exposure / trace-free medium contraction.

The quotient test must therefore apply to the whole composed trace, not only to $M_0^{\mathrm{src}}(A)$. If two restored representatives are identified by the scalar quotient, write $\Delta_d F = F[d_1] - F[d_2]$. The first-order trace defect is

$$\Delta_{\mathrm{tr}}(d_1, d_2) = (1+\delta\mathcal{M}_0)\Delta_d M_0^{\mathrm{src}} + \frac{1}{3}\delta\mathcal{M}_{\mathrm{tf}}^{ab} \Delta_d \left(E_{\mathrm{internal}} \mathcal{Z}_{\mathrm{tf},ab} \right)$$

For scalar mass to be quotient-visible, this defect must remain below the declared trace tolerance. A scalar source can pass its no-hidden-handle test while the composed tensor trace still fails; in that case the discarded label is invisible in the homogeneous scalar source but mass-visible in anisotropic or pressure-sensitive response.

The trace-free part of this test is limited by what the branch actually probes. If $\mathcal{V}_{\mathcal{M}}$ is the span of retained reversible trace-free response tensors, then scalar mass only sees the projection of $E_{\mathrm{internal}} \mathcal{Z}_{\mathrm{tf},ab}$ onto $\mathcal{V}_{\mathcal{M}}$. Full trace-free descent is required only when the retained response directions reconstruct the full trace-free tensor. Otherwise the scalar mass claim is a projected claim: labels that move response-visible components are mass handles, while labels that move only orthogonal unprobed components remain invisible to scalar mass at this order.

The pressure specialization has the same discipline. For a branch-preserving pressure perturbation,

$$\delta_P m_{\mathrm{tr}}(A) = \alpha_{\mathrm{m}} \frac{1}{c_{\mathrm{eff},0}^2} \left[\delta_P M_0^{\mathrm{src}}(A) + M_0^{\mathrm{src}}(A)\, \delta_P \delta\mathcal{M}_0 + \frac{1}{3} E_{\mathrm{internal}}(A) \mathcal{Z}_{\mathrm{tf},ab}(A) \delta_P \delta\mathcal{M}_{\mathrm{tf}}^{ab} \right] + \mathcal{R}_P$$

Thus pressure cannot improve a mass prediction by adding a hidden scalar row. It must either change the quotient-visible source, change the shared reversible medium-response tensor, or leave the scalar trace unchanged to first order. In a density-only pressure channel with packing headroom s_n and density modulus K_{pack}, the corresponding limit is

$$\left. \frac{\partial m_{\mathrm{tr}}}{\partial P} \right|_{n\text{-only}} \propto \frac{s_n}{K_{\mathrm{pack}}}, \qquad \lim_{s_n \to 0^+} \left. \frac{\partial m_{\mathrm{tr}}}{\partial P} \right|_{n\text{-only}} = 0$$

This does not mean dense matter stops responding to pressure. It means the scalar density channel stops carrying that response when packing headroom closes; any remaining response must appear in exposed-source drift, envelope ratios λ and ξ, trace-free strain, reversible wake/contact stiffness, tensor response, or a threshold/branch event.

The Noether Braid as Causal Ledger Closure

A Noether braid can be read as a stable closure of delayed path-history relations. The three indexed binaries continually exchange partner-hit, self-hit, and inter-binary wakes. When those returns close with stable phase and integer ledger structure, the assembly traps geometric history in a localized causal circuit.

When the braid moves or is placed under a gradient, the closure does not remain a static set of circular binaries. The planes of binaries $a \in \{1, 2, 3\}$ are drawn into a coupled spiral-helical pattern: pitch, radius, phase, and inter-binary timing retune together so delayed wakes still return to the correct partners and binary records. This spiral-helical relocking is the geometric carrier of inertia in the present thesis.

In this view, rest energy is the energy stored in the closed causal ledger, and mass is the externally exposed response of that ledger when the braid is accelerated, perturbed, or placed in a Noether sea gradient. Shielding determines how much of the internal closure couples to the far field.

The useful ledger split is:

Mass-facing factor	What it records	What it must not replace
$E_{\text{internal}}(A)$	Closed branch energy stored in retained causal history	Observed mass inserted as input
$\zeta(A)$	Far-field exposure after shielding and quotienting	A tunable small number chosen per particle
$\mathcal{M}^{ab}_{\text{sea}}$	Reversible Noether sea response that turns exposed source into inertia and gradient response	Ordinary dissipative drag
$M_{\text{sh}}(A;\theta)$	Observer-facing shielded mass prediction in a declared response record	A sum of isolated constituent masses

Mechanism Stack

Apparent inertial mass is expected to arise from a connected stack of effects:

Internal Energy Shielding (ζ-Factor)

- **Energy Storage:** Assemblies contain enormous internal energy in the form of high-speed Noether braid rotations. For a Noether braid, the total internal energy E_{internal} can be orders of magnitude larger than the observed rest-energy scale mc^2_{eff}.
- **Shielding:** The pro/anti structure of the Noether braid creates destructive interference in the far field. The external "handle" (the field observable at large distances) represents only a small fraction $\zeta \ll 1$ of the total internal energy.
- **Result:** When an external force attempts to accelerate the assembly, the effective far-field response couples only to the exposed, shielded part of the internal ledger:

$$m_{\text{apparent}} c^2_{\text{eff}} \sim \zeta(A)\, E_{\text{internal}}(A)$$

- **Generational Hierarchy:** Heavier generations (Gen II, Gen III) are hypothesized to have **reduced shielding** because one or two declared indexed supports are depleted on the branch lifetime window. With fewer coherent supports, more of the high-energy core is exposed, increasing ζ and thus the apparent mass. This is a shielding-coherence statement over the persistent binary indices, not a deletion of the axial frame that carries color and electroweak bookkeeping.

Medium-Dressed Inertial Response

- **The Medium:** The Noether sea is not empty space; it is a dynamic population of neutral Noether braid assemblies. Moving or accelerating an assembly changes how its internal causal ledger closes relative to the Noether sea.
- **The Response:** The assembly resists acceleration because its internal path-history exchange must relock under a biased causal geometry. This should be modeled as a medium-dressed response tensor, not as ordinary dissipative friction.
- **Velocity Dependence:** In the homogeneous weak-field limit, the same closure geometry should recover the effective relativistic response without changing the rest/internal invariant M_0:

$$E_{\text{CM}} = \gamma_{\text{eff}} M_0 c^2_{\text{eff}}, \qquad p_{\text{CM}} = \gamma_{\text{eff}} M_0 v_{\text{CM}}$$

Language about velocity-dependent inertia should therefore be read as the moving center-of-mass response of the dressed assembly ledger, not as a change in scalar rest mass.

- **Environment Dependence:** Local variations in Noether sea density, compliance, drift, and effective lapse can modulate the response. In dense or strongly graded regions, the effective inertial and gravitational response must be computed from the same medium-dressed closure map.

Equivalence-Principle Response Target

The mass thesis must recover not only an inertial response to imposed acceleration, but also the observed agreement between inertial and gravitational response. In $\mathbb{AAA}$ language, this is a same-map requirement: bulk acceleration of a stable assembly and a matched Noether sea gradient must perturb the same shielded internal causal ledger to tested accuracy.

For a clock or mass-bearing assembly A, write the assembly-dependent clock/response factor in a weak cell as

$$N_A(x^i_{\text{eff}}) = N(x^i_{\text{eff}})\,[1 + \delta_A(x^i_{\text{eff}})]$$

where $N(x^i_{\text{eff}})$ is the universal effective lapse reconstructed from the local Noether sea state and δ_A is the assembly-dependent residue after the shared response has been removed. The weak equivalence target is then

$$|\delta_A - \delta_B| \lesssim 10^{-13}$$

across tested material pairs after the corresponding inertial and gravitational response maps are compared. The exact bound belongs to the selected experimental class, but the structural point is fixed: if δ_A carries unsuppressed composition dependence, or if the acceleration contribution and gradient row use different Noether sea records, the scalar mass relation is only a fitted average rather than a branch consequence.

Equivalently, the tensor response that maps exposed internal energy into p^a_{int} must have the same homogeneous low-energy limit in acceleration and gradient probes:

$$\mathcal{M}^{ab}_{\text{sea,acc}}(A) - \mathcal{M}^{ab}_{\text{sea,grad}}(A) = O(\epsilon_{\text{EP}})$$

with any residual reported as direction-dependent inertia, composition dependence, transport loss, or branch failure instead of being hidden inside $\zeta(A)$.

Stability Constraint

A critical requirement: assemblies in **equilibrium** with the Noether sea (e.g., atoms in stable orbitals) must experience no dissipative drag in the ordinary sense. Otherwise, electron orbitals would lose stability, radiate energy, and collapse into the nucleus (the classical electron catastrophe).

Resolution Hypothesis:

- Stable configurations are phase-locked causal ledgers whose perturbations remain in an attracting basin.
- The relevant diagnostic is not a phenomenological friction coefficient but a stability test: nearby phase errors should decay under the return map or Floquet analysis of the closed assembly cycle.
- The Noether sea can still shape inertia, but a stable bound state must not leak energy through a dissipative drag channel.

The condensed-matter cross-check is the Noether sea transport residual in Condensed Matter. Stable inertial response belongs to $\mathcal{R}_{\text{tr}} < \mathcal{R}_{\text{tr},*}$, where the response is reversible retuning rather than ordinary drag. Crossing $\mathcal{R}_{\text{tr},*}$ is a transition or failure condition that must route into excitation, radiation-like transport, medium heating, action shedding, or branch transition; it is not the origin of mass itself.

Ontological Distinctions

It is crucial to clarify what is **fundamental** versus what is **emergent**:

Concept	Status in $\mathbb{AAA}$
Architrino Position/Velocity	Fundamental (substrate level)
Architrino polarity magnitude ϵ	Fundamental at the polarity layer; observer-level electric charge is assembly-level inventory recovered as $|e| = 6\epsilon$
Noether sea state	Emergent density, compliance, drift, and clock-response fields
Inertial Mass (m)	**Emergent** (shielded internal energy + medium-dressed response)
Gravitational Mass	**Emergent** (Noether sea gradient response)

Status of Mass Claims

Claim	Status
Architrinos do not carry a primitive particle-specific inertial mass.	Canonical framework assumption.
Stable assemblies have externally measured inertial response.	Operational definition.
The mass response is governed by shielded internal causal history.	Canonical thesis, still requiring quantitative derivation.
$M_0(A)c_{\mathrm{eff}}^2 \sim \zeta(A)E_{\mathrm{internal}}(A)$.	Roadmap formula, not yet a theorem.
$\zeta(A)$ explains the charged-lepton hierarchy.	Priority target.
Inertial and gravitational mass share one shielded-energy response map.	Priority target constrained by equivalence-principle tests.
The Higgs sector is recovered as an effective matching layer.	Open comparison target.

The Substrate Mass Unit and Size Anchor

Claim level: a dimensional anchor plus a native size measurement; the extraction of an actual particle mass from it is gated on a retained free object and remains open.

The substrate carries no mass dimension of its own: its three constants — the coupling κ, the polarity unit ϵ, and the field speed c_f — span only length, time, and charge. A mass scale enters only with the action quantum $\hbar_{\mathrm{act}}$ of the fold-crossing ledger, and dimensional analysis then fixes the natural mass unit uniquely:

$$M_\star \sim \frac{\hbar_{\mathrm{act}}\, c_f}{\kappa\, \epsilon^2}.$$

Here $M_\star$ is the universal dimensional mass unit, distinct from the branch-specific rest invariant $M_0(A)$. Every emergent inertial mass in this chapter is a pure number times $M_\star$; the roadmap formula $M_0(A)c_{\mathrm{eff}}^2 \sim \zeta(A)E_{\mathrm{internal}}(A)$ is the statement that the number is set by the shielded internal energy of the retained branch.

The same constants are expected to fix an absolute size: a self-supporting braid configuration, if one exists, would carry a native equilibrium radius of order $\kappa\epsilon^2/c_f^2$ — the coupling-scale unit — and that radius would be the length half of the mass map, fixing the scale at which a candidate braid sits. No verified equilibrium radius is currently carried in this chapter: an earlier single-instrument value was retired with the failed search campaign, and the derivation awaits the validated engine. What the length half must still be joined by is the energy half — a retained free object from which E_{internal}, and hence the pure number multiplying $M_\star$, can be extracted. Both halves are gated on the same open retained-object question, so the first-particle mass remains a target rather than a computed value.

The Action Ladder

Claim level: interpretation and derivation target; assigning specific rungs to specific particles is the open mass-map work, not asserted here.

Because the family is iso-frequency — one shared internal cadence — an added or removed quantum of action cannot land on one layer as a private frequency change; it must re-tune the whole common-frequency coordinate structure together. The hypothesis of this section is that the re-tuning is quantized into integer rungs: all three layer radii co-move and the three tilts re-tune together under one shared constraint, so the layers' shares are fixed by the same closure conditions that fix the rest geometry. No settling dynamics and no speed-holding mechanism are asserted — an earlier proposed rail-pinning mechanism was retired when its own condition was measured false — and the rung structure is a derivation target for the validated engine.

Read as a spectrum, this would be a substrate origin of energy quantization. Each rung is a discrete allowed state; the spacing is one action quantum; a rung-to-rung transition is the emission or absorption of a quantum. The ladder carries the form $E = n\,h\,f$, tying the level index, the action quantum, and the internal cadence in one relation. Through the cadence-radius coupling, a higher cadence forces a smaller envelope, so climbing the ladder makes the object smaller and its observed inertial response larger — the emergent-mass counterpart of the observed mass–Compton-length relation. One geometric family, climbable through a very large (near-Planck) number of integer rungs, thus spans a whole spectrum from the lightest retained states up to the Planck-scale top ($\xi \to 0$, the singularity-resolution limit). Which rung corresponds to which observed particle is the open extraction the mass map owns; the structure — an integer action ladder whose rungs are the allowed states — is the candidate statement targeted for promotion.

Mass-Channel Categories

The mass thesis must keep the particle categories separate. The photon channel is treated as a massless coaxial contra-rotating polarity-conjugate planar pair transport mode: it carries phase, momentum, source/event-ledger energy, and transverse helicity, but it does not have a rest-frame clock or a stable volumetric internal-energy ledger. This is a two-gate statement, and its base referent is still open: the declared planar-pair family does not bind, so photon-lock quantities remain referent-pending until an equilibrium branch is exhibited. Gate A must supply the null kinematic branch with no rest proper-time clock; Gate B must supply the transverse polarization/spin ledger, including helicity ± 1, analyzer coupling, Malus' law, and no physical longitudinal free photon mode. A longitudinal or mixed-axis vector component belongs to a different massive or medium-bound channel, not to the massless free photon branch. The W/Z channels are different massive vector corridors whose apparent masses come from localized recoupling, longitudinal or mixed-axis structure, and medium-dressed Noether sea response. The Higgs comparison is different again: it concerns a scalar medium mode rather than a directed vector corridor. This category split depends on the angular-momentum and vector-mode closure program; it is not itself a derivation of photon helicity or massive-vector spin. For the electroweak version of this split, see Electroweak Bosons, and for the spin ledger see Angular Momentum and Spin.

Comparison to Standard Model

In the Standard Model, mass arises via the **Higgs Mechanism**: particles acquire mass by coupling to a background Higgs field (a scalar condensate with vacuum expectation value $v \approx 246$ GeV).

In $\mathbb{AAA}$, the Higgs-sector comparison is an effective matching problem, not yet a derived replacement. The working expectation is that Standard Model mass parameters and Yukawa couplings would be reinterpreted as effective summaries of assembly geometry, shielding, and Noether sea response. The benchmark is a neutral scalar-compatible resonance near 125 GeV with signal-strength normalization near the Standard Model expectation. Exact date-stamped masses, uncertainties, and signal-strength entries belong in validation and parameter ledgers; modeling the resonance as a collective medium excitation is a theorem target, not an established result.

For the electroweak medium interpretation behind this replacement, see Gauge Structure Emergence.

Higgs and Yukawa Matching Residual

A mass fit alone does not recover the Higgs sector. The same record must also explain why the scalar channel couples to massive assemblies with strengths that, at the effective Standard Model level, are summarized by Yukawa parameters. Let φ be a normalized radial perturbation of the local Noether sea scalar mode, with $\varphi = 0$ on the weak homogeneous branch. The effective scalar coupling to an assembly A should be the response derivative of the same shielding map:

$$g^{\mathrm{eff}}_{H,A}(\theta) \equiv \left.\frac{\partial M_{\mathrm{sh}}(A;\theta,\varphi)}{\partial\varphi}\right|_{\varphi=0}, \qquad M_{\mathrm{sh}}(A;\theta,0) = M_{\mathrm{sh}}(A;\theta)$$

If $v^{\mathrm{eff}}_{\mathrm{EW}}(\theta)$ is the electroweak normalization extracted from the same Noether sea order-parameter proxy used in the gauge-sector bridge, the Standard Model Yukawa summary is recovered only as

$$y^{\mathrm{eff}}_f(\theta) = \sqrt{2}\,\frac{M_{\mathrm{sh}}(A_f;\theta)}{v^{\mathrm{eff}}_{\mathrm{EW}}(\theta)}$$

after M_{sh}, $v^{\mathrm{eff}}_{\mathrm{EW}}$, and the scalar coupling derivative are all fixed by one shared record. A compact benchmark residual is

$$\mathcal{R}_{\mathrm{Higgs\,match}}(\theta) = \mathcal{R}_{\mathrm{gen\,mass}}(\theta) + \sum_{f\in\mathfrak{F}_H}\left[\frac{g^{\mathrm{eff}}_{H,A_f}(\theta) - M_{\mathrm{sh}}(A_f;\theta)/v^{\mathrm{eff}}_{\mathrm{EW}}(\theta)}{\sigma_{Hf}}\right]^2 + \left[\frac{M_H^{\mathrm{breath}}(\theta) - M_H^{\mathrm{obs}}}{\sigma_H}\right]^2$$

Here $\mathfrak{F}_H$ is the set of fermion channels with measured Higgs-coupling information, M_H^{obs} is the observed scalar resonance near 125 GeV, and $M_H^{\mathrm{breath}}(\theta)$ is the predicted radial Noether sea breathing-mode mass on the same branch. The benchmark fails if Yukawa-like numbers are inserted as independent per-particle constants, if $v^{\mathrm{eff}}_{\mathrm{EW}}$ is fitted separately from the gauge-sector normalization, or if the 125 GeV scalar match uses a different Noether sea record than the inertial-mass map.

The date-stamped LHC scalar validation surface makes the residual sharper than a single mass entry. Let M_H^{ledger}, $\sigma_H^{\mathrm{ledger}}$, μ_H^{ledger}, and $\sigma_{\mu_H}^{\mathrm{ledger}}$ denote the parameter-ledger entries for the scalar mass and production-and-branching normalization, with ATLAS and CMS treated as independent benchmark rows; the mass entry is expected to remain near 125 GeV. A candidate scalar branch must recover the mass, rate normalization, channel pattern, and absence of broad additional scalar signals in the excluded windows:

$$\mathcal{R}_{\text{Higgs validation}}(\theta) = \left[\frac{M_H^{\text{breath}}(\theta) - M_H^{\text{ledger}}}{\sigma_H^{\text{ledger}}}\right]^2 + \left[\frac{\mu_H^{\text{eff}}(\theta) - \mu_H^{\text{ledger}}}{\sigma_{\mu_H}^{\text{ledger}}}\right]^2 + \sum_{c\in\{ZZ^{(*)}4\ell,\gamma\gamma,WW^{(*)}\ell\nu\ell\nu\}} \left[\frac{Z_c^{\mathbb{AAA}}(\theta) - Z_c^{\text{ledger}}}{\sigma_{Z_c}^{\text{ledger}}}\right]^2 + \mathcal{R}_{\text{excluded scalar}}(\theta)$$

Here μ_H^{eff} is the observer-level production-and-branching normalization, and Z_c records the channel significance or equivalent likelihood contribution for the high-resolution $ZZ^{(*)} \to 4\ell$, $\gamma\gamma$, and $WW^{(*)}$ channels. The $\gamma\gamma$ channel also protects the scalar-vs-vector distinction: it supports a spin-0-compatible comparison and rules against treating the Higgs benchmark as another photon or massive-vector corridor.

Naturalness Comparison: QCD Running

Quantum chromodynamics supplies a useful comparison standard for hierarchy claims. In QCD, a dimensionless coupling runs logarithmically with energy, and the hadronic mass scale appears when that coupling becomes strong. The large ratio between the Planck scale and the proton scale is therefore not explained by inserting a small mass parameter; it is generated by slow logarithmic flow and the threshold at which a bound-state regime turns on.

The mass program in $\mathbb{AAA}$ should meet an analogous naturalness standard without borrowing the QCD mechanism as its own. A successful shielding map should show that large internal energy ratios can become ordinary observer-level masses through stable causal ledgers, exposed far-field coupling, and the medium-response tensor, with no per-particle mass parameter inserted after the fact. In formula language, the target is not merely

$$m_{\text{inertial}}(A) \approx \alpha_{\text{m}} \frac{\zeta(A)E_{\text{internal}}(A)}{c_{\text{eff}}^2}$$

but a derivation in which $\zeta(A)$ is fixed by the same root ledger, shielding geometry, and Noether sea response that also preserves stability and equivalence-principle behavior. If $\zeta(A)$ has to be tuned independently for each particle family, the analogy to QCD naturalness fails and the hierarchy has only been renamed.

This is the hierarchy-problem version of the mass thesis. The small observer mass does not require that the accepted branch contain little internal energy; it requires that most of that internal energy be hidden from the scalar mass channel by branch geometry. The quantitative burden is therefore

$$\zeta(A) = \frac{\|\Pi_{\text{mass}}\mathcal{L}_A\|}{\|\mathcal{L}_{\text{naive}}(A)\|} + O(\epsilon_{\text{quot}})$$

with Π_{mass} fixed by the sector exposure quotient. A derivation of this ratio from the accepted branch would explain why large internal scales can coexist with small exposed masses without fine tuning.

Generation-Mass Fitting Packet

The immediate quantitative packet is a shared fit across charged leptons, up-type quarks, and down-type quarks. Let

$$f \in \{\ell, u, d\}, \qquad a \in \{0, 1, 2\}$$

where $a = 0, 1, 2$ label Generations I, II, and III through the shielding quotient in Quantum Number Mapping. For one family representative $A_{f,0}$, define

$$A_{f,a} = T_{\text{gen}}^a A_{f,0}$$

The fit target is one shielding response map, not nine particle-specific masses:

$$M_{\text{sh}}(A_{f,a};\theta) = \frac{\alpha_{\text{m}}}{c_{\text{eff}}^2}\left[\zeta_{\text{sh}}(\mathsf{s}_{\text{sh}}(A_{f,a});\theta)\, E_{\text{internal}}(A_{f,a};\theta) + E_{\text{sector}}(A_{f,a};\theta)\right]$$

Here ζ_{sh} depends on the shielding class, α_{m} is a single mass normalization for the declared weak homogeneous regime, and E_{sector} is zero for charged leptons while quark contributions must be derived from the same color/topology and strong-sector ledger used in the hadronic chapters. The allowed family dependence is therefore carried by axial inventory, color/topology, and internal-energy bookkeeping, not by changing the shielding law.

The first hierarchy residual should be ratio-first. It is evaluated only after the branch ledger, scalar exposure quotient, internal energy, sector term, and shared response record have emitted predicted values $M_{\text{sh}}(A_c;\theta)$ without using the observed mass table. Let $c = (f, a)$ range over the nine generation channels, write $A_c = A_{f,a}$ and $m_c^{\text{obs}} = m_{f,a}^{\text{obs}}$, and fix a reference channel c_{ref} before evaluating the benchmark rather than choosing it to improve the residual. For quark channels, m_c^{obs} denotes the predeclared scheme-and-scale benchmark row with its covariance, not a scheme-free constituent mass. The ratio residual is

$$\mathcal{R}_{\mathrm{gen\,ratio}}(\theta) = \sum_{c \neq c_{\mathrm{ref}}} \frac{\left[\log \frac{M_{\mathrm{sh}}(A_c;\theta)}{M_{\mathrm{sh}}(A_{c_{\mathrm{ref}}};\theta)} - \log \frac{m_c^{\mathrm{obs}}}{m_{c_{\mathrm{ref}}}^{\mathrm{obs}}}\right]^2}{\sigma_{c/c_{\mathrm{ref}}}^2}$$

The shared factor $\alpha_{\mathrm{m}}/c_{\mathrm{eff}}^2$ cancels inside each predicted ratio when the channels share one homogeneous weak-field response record. The displayed denominator is the diagonal approximation to the log-ratio covariance; a full comparison should replace it by the covariance matrix on the ratio vector when shared benchmark uncertainties matter. The absolute scale is therefore a separate reference calibration,

$$\mathcal{R}_{\mathrm{gen\,scale}}(\theta) = \frac{\left[\log\left(\frac{M_{\mathrm{sh}}(A_{c_{\mathrm{ref}}};\theta)}{m_{c_{\mathrm{ref}}}^{\mathrm{obs}}}\right)\right]^2}{\sigma_{c_{\mathrm{ref}}}^2}$$

and the combined benchmark residual is

$$\mathcal{R}_{\mathrm{gen\,mass}}(\theta) = \mathcal{R}_{\mathrm{gen\,ratio}}(\theta) + \mathcal{R}_{\mathrm{gen\,scale}}(\theta) + \lambda_{\mathrm{split}} \sum_f \mathrm{dist}_{\mathrm{map}}(\theta_f, \theta_{\mathrm{shared}})^2 + \mathcal{R}_{\mathrm{null}}^{\mathrm{op}}(\theta)$$

Here θ_f denotes the record that would be used if family f were fit separately, while θ_{shared} is the one promoted record. The split term is the no-retuning guard: it penalizes any attempt to fit charged leptons, up-type quarks, and down-type quarks with different shielding maps or different medium-response coefficients. The null-result term prevents the fit from improving the observed masses by adding partner branches, extra gauge modes, or proton-instability channels that are not independently suppressed.

The first benchmark is not exact mass prediction. It is monotone hierarchy and shared-map survival:

$$M_{\mathrm{sh}}(A_{f,0};\theta) < M_{\mathrm{sh}}(A_{f,1};\theta) < M_{\mathrm{sh}}(A_{f,2};\theta)$$

for $f = \ell, u, d$, while the same ζ_{sh}, α_{m}, and $\mathcal{M}_{\mathrm{sea}}^{ab}$ remain in force. If the charged-lepton hierarchy can be fit only by changing the map that fits quarks, or if quarks require independent per-generation shielding factors after color/topology terms are included, generation-by-shielding has not closed.

Speculative Charged-Lepton Benchmark: Koide

The charged-lepton mass triplet is unusual enough that it is worth recording one explicit benchmark, while keeping the status clear: this is **speculative** and should not be presented as a derivation.

Let

$$\mathbf{r} = \left(\sqrt{m_e}, \sqrt{m_\mu}, \sqrt{m_\tau}\right)$$

The empirical Koide relation can be written as

$$\frac{(r_e + r_\mu + r_\tau)^2}{r_e^2 + r_\mu^2 + r_\tau^2} = \frac{3}{2}$$

Within $\mathbb{AAA}$, the natural place to test this is the generation-by-shielding ladder. If the three charged leptons are the same candidate braid-scaffold-plus-axial-layer architecture viewed through three shielding-support vectors, then a mass-root relation may be an external clue that the exposure map from full, Generation-II, and Generation-III shielding branches is more constrained than a generic monotone hierarchy. This particle map does not assign a braid-taxonomy member.

The conservative use of Koide here is therefore:

- as a **charged-lepton benchmark** on the shielding/exposure mass map,
- not as proof that the architecture has derived lepton masses,
- and not as a license to tune free parameters until the ratio appears.

If a first-principles shielding model naturally lands near the Koide surface for (e, μ, τ), that is a meaningful success signal. If it does not, the framework is not automatically falsified, but the idea that generation lifting alone tightly fixes the lepton mass triplet becomes weaker.

Why Quarks Should Not Be Expected to Obey Koide

Even if the charged leptons approximately follow a simple shielding geometry, quarks should not be expected to do so.

The reason is that quark inertial mass is not just bare core exposure. Quarks carry axis-exceptional color structure, induce persistent flux-tube tension, and require continual axis-reconfiguration exchange through the strong sector. In that regime, the measured effective mass is contaminated by confinement energy and Noether sea response to the color disturbance.

So the working distinction is:

- **charged leptons:** closest available probe of the bare shielding ladder; see Electron,
- **quarks:** shielding ladder plus strong-sector contamination; see Quarks.

That means a Koide-like benchmark, if it is useful at all, belongs first to the charged leptons. Failure of quarks to lie on the same mass-root surface should be treated as expected in the present ontology, not as an immediate contradiction.

Quantitative Derivation Path

To advance from qualitative thesis to quantitative mass prediction, the active mass program must close five linked steps.

1. **Stable A1 attractor target:** derive one robust Noether braid attractor family whose three persistent binaries have independently assignable positive radii and frequencies, mutually orthogonal axes at the Family-A near-rest endpoint, and axes that converge toward the group-translation direction along the prescribed flattening coordinate; record the remaining binary coordinates, branch data, and stability diagnostics. The `A1` label fixes this prescribed chart but does not prejudge retention.
2. **Internal energy ledger:** compute the dimensionless internal energy stored in that attractor without assuming the particle mass being derived.
3. **Shielding extraction:** derive $\zeta(A)$ from far-field wake cancellation and exposed coupling geometry.
4. **Medium-dressed response:** derive the response tensor that turns shielded internal energy into inertial and gravitational response in the weak-field regime.
5. **Benchmark prediction:** use the derived quantities to target a baseline electron mass and at least one hierarchy check, such as m_μ/m_e.

Reference Attractor Gate

The first mass-side calculation should not begin by fitting the electron mass. It should begin with a calibration-free reference attractor, denoted A_0: a neutral rest-branch candidate constrained to the A1 prescribed coordinates in a weak homogeneous Noether sea cell. This gate turns the mass thesis from a symbolic relation into a concrete closure target that can be checked before particle labels, charged-lepton ratios, or measured constants enter the calculation. Failure to retain the A1 coordinate relations on the same evolved record rejects this candidate before any mass comparison.

This attractor should not be pictured as three independent circular binaries. Its source record assigns different causal-speed regimes to the persistent indices: binary 1 is self-hit and super-field-speed on the active branch, binary 2 sits near the $v = c_f$ fold, and binary 3 remains sub-field-speed as the shielding and boundary-coupling channel. These assignments define the A_0 candidate record; they are not taxonomy-assigned roles. Circular or elliptic pictures can still be useful as carrier charts, but only after the coupled root ledger, phase lock, and stability diagnostics are respected.

For the mass program, this distinction controls which internal corrections matter. Nonresonant fast structure in source-record binary 1 may average out of the leading far-field shielding estimate, especially when the binary scales differ strongly. Resonant corrections, near-separator corrections, and small leakage asymmetries cannot be discarded in the same way, because they can change the accepted branch, the Floquet gap, or the extracted $\zeta(A_0)$ itself. The fast role is measured on the record and is not a meaning of index 1.

The minimal A_0 output contract is:

Output class	Required content	Why it matters
Geometry and winding	R_1, R_2, R_3, binary-plane normals, handedness, phase offsets, binary windings, and inter-binary closure integers	fixes the attractor as an integer-labeled Noether braid state rather than a loose configuration sketch

Output class	Required content	Why it matters
Root ledger and stability	partner-hit counts, self-hit counts, inter-layer hit channels, closure residuals, return-map residuals, and the non-symmetry Floquet gap $\Delta_{\mathbf{k}}$	separates stable closed cycles from integer-looking but dynamically unstable candidates
Internal energy ledger	E_I, E_M, E_O, interaction and wake terms, total $E_{\text{internal}}(A_0)$, and action per closed cycle	supplies the unshielded reservoir in the mass-map roadmap formula
Group-velocity anisotropy	declared $\mathbf{V}_{\text{cm}}$, causal speed $c_\star$, $\beta_\star$, envelope ratio, forward/backward delay ratio, and anisotropy tensor $\mathcal{A}^{ij}_{\text{gv}}$	keeps motion-induced deformation separate from far-field shielding leakage
Shielding extraction	far-field wake coefficients, the naive constituent sum, preliminary $\zeta(A_0)$, and residual leakage $\mathcal{L}_{\text{aniso}}$	turns shielding from a symbolic term into an extracted geometric response
Medium response	the homogeneous baseline for $\mathcal{M}^{ab}_{\text{sea}}$, plus acceleration and gradient probes	connects inertial response, gravitational response, and equivalence-principle tests

The detailed simulation-facing schema is the A_0 branch certificate packet: `metadata`, `sea_cell`, `branch_label`, `z_lambda`, conditional `branch_chart_revision`, `state_vector`, `closure_system`, `root_ledger`, `term_classification`, `residuals`, `stability`, `group_velocity_anisotropy`, `energy_ledger`, `far_field_shielding`, `medium_response`, `mass_summary`, `certificate_gates`, and `failure_code`. The canonical chapter names this interface so the mass thesis has a concrete handoff; the detailed protocol belongs in A_0 Branch Certificate Protocol.

The accepted A_0 branch must have small closure residuals over at least one closed cycle, a positive non-symmetry Floquet gap, no secular drift after symmetry modes are removed, a group-velocity anisotropy diagnostic that remains separate from shielding leakage, and a shielding estimate stable under increasing far-field extraction radius and angular resolution. No observed particle mass, charged-lepton ratio, electron radius, or measured α value should be used as an input to this gate.

Compact-carrier diagnostics have reached a finite-coordinate no-go for the compact branch chart tested so far. That result is a branch-certificate status blocker, not a mass result: $E_{\text{internal}}(A_0)$, $\zeta(A_0)$, $\mathcal{M}^{ab}_{\text{sea}}$, and the baseline mass prediction remain unavailable until a predeclared branch-chart revision and an accepted branch packet pass the same gates above. Even if a branch-chart checker clears a revised coordinate, the clearance authorizes only a Tier 1 rerun candidate; it does not accept the branch, supply accepted A_0 history, or make the downstream mass-facing quantities available.

The canonical chapter should carry this interface but not the detailed simulation protocol. Its role is to state the mass thesis, define the terms, and make clear which derivations remain open; implementation details belong with the simulation and proof-program material once the A_0 state vector and output schema are formalized.

Open Questions & Failure Modes

Critical Unknowns

1. **What sets d_0?** A certified minimum-radius bound branch could supply the prototype length scale, but the circular simple-root calculation currently supplies only algebraic MCB candidates. Which retained stable binary or larger-assembly branch defines d_0, and can its scale be derived from ϵ, c_f, and κ rather than postulated?
2. **Is the reference Noether braid density fixed?** Is $\rho_{\text{NS},0}$ universal, or does $\rho_{\text{NS}}(\mathbf{X}, T)$ vary with cosmological epoch, gravitational field strength, or local matter density?
3. **Why do neutrinos have mass at all?** If a neutrino is a near-photon polarity-conjugate braid pair, which residual internal-binary exposure breaks exact photon-like cancellation? The magnitude of that exposure is referent-pending; it cannot be assigned before the base photon lock exists and the exposure map is extracted.

Potential Falsifications

- **If $\zeta(A)E_{\text{internal}}(A)$ cannot reproduce $m(A)c^2_{\text{eff}}$ after the response tensor is fixed:** The shielding-based mass map is wrong.
- **If the medium response behaves like dissipative drag in stable atoms:** The stability condition fails; the model is incompatible with chemistry.
- **If generational masses do not scale with shielding coherence:** The shielding-depletion explanation for the hierarchy is wrong.

Fermions

Color Charge SU(3)

This chapter gives a candidate assembly-level interpretation of color charge and effective `SU(3)` structure. Its purpose is to explain how quark color bookkeeping, confinement language, and a prescribed A1 scaffold are hypothesized to fit together before the particle assignment and full topological confinement derivation are closed. It is the fermion-side companion to Gluons and the Strong Force: Geometric Origins and Quarks.

The standard color label is extremely successful as algebra. The implementation question is different: what physical feature of a quark assembly can be counted in three ways, transformed by an octet of corridor modes, and hidden inside color-singlet hadrons? This chapter answers at the recovery-target level: color is axis exceptionality in the axial frame of a Noether braid assembly.

That means the word `color` should be read as a structured bookkeeping channel, not as a colored substance. The three color states are the three possible exceptional-axis records; `SU(3)` is the effective transformation algebra that must be recovered when those records are compressed into observer-level quark language.

Ontology, Notation, and Generations

A1 Scaffold

The working Gen-I fermion mapping uses a candidate **A1 scaffold**: three persistently indexed electrino:positrino binaries whose positive radii and frequencies are independently assignable, whose axes are mutually orthogonal at the Family-A near-rest endpoint, and whose axes converge toward the group-translation direction along the prescribed flattening coordinate. Phases, axial half-separations, transverse orbit radii, and circulation remain explicit binary coordinates. **Noether braid** remains the broader neutral six-architrino class; see Noether Braid. The taxonomy defines this prescribed geometry only; it does not establish a quark assignment, retention, stability, or color mechanism.

The scaffold supplies the stable reference triad. The axial layer supplies the visible polarity pattern. Color appears only when those two facts together leave one axis distinguishable from the other two.

The illustrative source record used in this chapter assigns the following dynamical regimes to the persistent binary indices:

- **Binary 1**
  - Smallest radius
  - Velocity $v_1 > c_f$
  - Self-hit regime (strong path memory, highest curvature/energy)
- **Binary 2**
  - Intermediate radius
  - Velocity $v_2 = c_f$
  - Symmetry-breaking “pivot” scale
- **Binary 3**
  - Largest radius
  - Velocity $v_3 < c_f$
  - Lowest curvature; exposed-envelope expansion/contraction behavior

These speed, radius, curvature, and shielding roles are hypotheses of this source record. They are not meanings of indices 1, 2, and 3, and another A1 branch may assign the derived roles differently.

Each binary defines one **axis** with two **polar sites**. We use $\epsilon = |e|/6$ for the polarity-unit magnitude, with $\epsilon_- \equiv -\epsilon$ and $\epsilon_+ \equiv +\epsilon$. Each polar site is occupied by either:

- Electrino (ϵ_-), or
- Positrino (ϵ_+).

So each Noether braid has 3 axes (1, 2, 3) × 2 poles = **6 polar sites**.

We distinguish:

- **Scaffold architrinos**: the three electrino:positrino pairs in the 1, 2, 3 binaries (2 per binary → 6 per quark).
- **Axial architrinos**: the six $\epsilon_{\pm}$ axial-inventory entries bound to the polar sites.

For a Gen-I quark:

- 6 scaffold architrinos (3 binaries × 2)
- 6 axial architrinos
- Total per quark: 12.

For a Gen-I baryon (3 quarks):

- 18 scaffold architrinos
- 18 axial architrinos
- **36 architrinos** total.

We use **A1** only for this prescribed indexed Family-A member and **Noether braid** for the broader neutral six-architrino class. Every color and particle assignment in this chapter remains a candidate mapping.

Generational excitation states

Standard Model "generations" are interpreted as candidate **excitation states** of the same A1-based architecture:

- **Gen-I (ground-state assembly)**
  - All three binaries assembled: [1, 2, 3].
  - Fully shielded 1 core.
- **Gen-II (first excitation)**
  - [1, 2] remain coherently assembled as shielding support.
  - 3-tier support is depleted, unassembled, or transient on the branch lifetime window, exposing more of the 1/2 structure.
- **Gen-III (second excitation)**
  - 1 remains coherently assembled as shielding support.
  - 2 and 3 support are depleted on the branch lifetime window; the 1 self-hit core is effectively naked.

We treat these as **different assembly states**, not ordinary dissociation products in time. Heavier generations require energy input to form and relax back via W/Z/γ/ν emission, but the depletion signal still has to propagate to the weakly bound axial layer through causal wakes and relocking cycles before the branch opens its reaction corridor.

In this section, color is defined on the ordered axial frame $\{D_1, D_2, D_3\}$, not on the count of shielding tiers that remain coherent. Here D_1, D_2, D_3 denote the three polar-dyad records carried by the 1, 2, and 3 axes. Higher generations inherit the same color triplet through this metastable 1/2/3 axial record even when one or more shielding tiers are depleted. This separation is required because top and bottom quarks must remain color triplets while carrying Generation-III mass and lifetime behavior.

Braid orientation and matter/antimatter conjugation

Beyond which binaries are present, the orientation of their persistent indexed frame defines a pro/anti braid orientation:

- **Pro orientation:** indexed-frame order $1 \to 2 \to 3$.
- **Anti orientation:** indexed-frame order $1 \to 3 \to 2$.

This is the fermion-sector consumer of the pro/anti orientation basis defined in Noether Sea Pro/Anti Coupling. The retained carrier is the indexed-frame orientation sign o_{PA}, not a frequency or precession ordering. The orientation is parity-facing: parity exchanges the two orders. It does not distinguish particles from antiparticles. Matter/antimatter instead follows whole-branch polarity conjugation at fixed worldlines, which preserves the pro/anti order. Color is independent of both binary labels.

Colorless Fermions: Axis Uniformity

Core rule:

Color charge appears only when the indexed A1 axes are **not equivalent**. If all three axes carry the same axial pattern, there is no "which axis is special?" degree of freedom → **no color**.

This is the entry point for the whole chapter. Leptons are colorless because their axial pattern does not single out axis 1, 2, or 3. Quarks are colored because their axial pattern does.

Stealth and color neutrality

The guiding physical picture is that long-lived assemblies must suppress time-dependent far-field leakage. A useful test state is the equal-phase triad

$$\phi \in \left\{0, \frac{2\pi}{3}, \frac{4\pi}{3}\right\}$$

for which

$$1 + e^{i2\pi/3} + e^{i4\pi/3} = 0$$

This does not derive the full color algebra by itself, but it gives a clean geometric reason why three-way closure is special: three balanced phase channels can hide the leading dipole signal. In that heuristic sense, color-singlet organization is not just algebraic neutrality but a **stealth condition** that helps the Noether braid survive without strong radiative leakage.

Electron and positron

- **Electron**:
  $(1, 2, 3) = (-/-,\ -/-,\ -/-)$
  - Each axis: net -2ϵ.
  - Total: $-6\epsilon = -e$.
  - All axes identical → SU(3)$_c$ singlet.
- **Positron**:
  $(+/+,\ +/+,\ +/+)$
  - Each axis: net $+2\epsilon$.
  - Total: $+6\epsilon = +e$.
  - All axes identical → singlet.

Neutrinos: near-photon colorless neutral pairs

Neutrinos are treated as near-photon neutral assemblies rather than ordinary six-site axial-layer fermions. The working picture is a near-planar polarity-conjugate Noether braid pairing close to the photon channel, but not fully locked into the photon mode.

The photon lock used as this comparison point has not been exhibited: the declared planar polarity-conjugate family fails its binding gate. Neutrino residual-mass and oscillation quantities defined as departures from that lock are therefore referent-pending. The color conclusion below does not depend on those residuals; it uses only the absence of a quark-like exceptional-axis inventory in the proposed neutral-pair construction.

This makes the color statement sharper:

- The neutrino has no stable quark-like axial layer on which one 1, 2, or 3 axis can become exceptional.
- Its polarity-conjugate pairing cancels charge-like exposure and leaves no color triplet degree of freedom.
- The balanced $3\epsilon_+, 3\epsilon_-$ notation used in weak bookkeeping is an interaction projection, not a constituent color pattern.

Older neutral-axis patterns such as

$$(-/+,\ -/+,\ -/+)$$

or

$$(+/+,\ -/+,\ -/-)$$

are therefore best read as effective exposure diagrams for weak-channel coupling, not as the canonical neutrino inventory. Residual internal-binary exposure inside the near-photon pair remains the natural place to seek neutrino mass eigenstates and oscillation structure.

A PMNS-level derivation remains a closure target in the neutrino section.

Quarks: Axis Exceptionality and Admissible Patterns

Quarks are color-charged because **one axis is in a different axial class than the other two**.

Charged-sector dyad-counting lemma

Let each axis pattern be coarse-classified as:

- **negative-polarity dyad**: two Electrinos, (ϵ_-, ϵ_-)
- **positive-polarity dyad**: two Positrinos, (ϵ_+, ϵ_+)
- **mixed dyad**: one Electrino and one Positrino, (ϵ_-, ϵ_+) or (ϵ_+, ϵ_-), net neutral and dipolar

For a six-site inventory, let n_+, n_-, and n_m count positive-polarity, negative-polarity, and mixed dyads. Then

$$2n_+ + n_m = N_+, \qquad 2n_- + n_m = N_-, \qquad n_+ + n_- + n_m = 3.$$

For the up-type inventory $(N_+, N_-) = (5, 1)$, the unique nonnegative solution is $(n_+, n_-, n_m) = (2, 0, 1)$. For the down-type inventory $(2, 4)$, the solutions are $(1, 2, 0)$ and $(0, 1, 2)$. Thus every charged quark inventory forces exactly two axes into one dyad class and one axis into a different class. The pattern is a counting consequence, not an added stability postulate.

An all-three-different pattern has $(n_+, n_-, n_m) = (1, 1, 1)$ and therefore $(N_+, N_-) = (3, 3)$: it belongs to the neutral inventory, not either charged quark row. Whether any neutral three-different assembly is dynamically retained remains a separate stability question.

Accordingly, the axis-class dictionary is:

- **Colorless**: 1,2,3 all same class, for example all negative-polarity dyads or all mixed dyads.
- **Colored quark**: 1,2,3 pattern is one of:
  - two background dyads and one exceptional dyad
    where the exceptional dyad class differs from the background dyad class.

Color degree of freedom is then:
which axis carries the exceptional dyad?

Up-type quarks ($5\epsilon_+, 1\epsilon_-$)

Up-type (u,c,t) Gen-I quarks have:

- 1 Electrino and 5 Positrinos among 6 polar sites.

At axis-class level:

- **Two axes**: positive-polarity dyads, (ϵ_+, ϵ_+)
- **One axis**: mixed dyad containing the single Electrino, for example (ϵ_-, ϵ_+)

Thus:

- Background class: positive-polarity dyad
- Exceptional class: mixed dyad

Define color basis:

- $|u_1\rangle$: 1 axis is mixed (exceptional), while 2 and 3 are positive-polarity dyads.
- $|u_2\rangle$: 2 exceptional.
- $|u_3\rangle$: 3 exceptional.

These span the color space:
$\mathcal{H}_u^{\text{color}} = \operatorname{span}\{|u_1\rangle, |u_2\rangle, |u_3\rangle\} \cong \mathbb{C}^3$.

Pole assignment inside the exceptional axis (which pole hosts the electrino) changes local dipole structure but not which axis is exceptional; at the level of color it's a **gauge-like internal redundancy**.

Anti-up quarks use the polarity-conjugate A1 branch with 5 electrinos and 1 positrino in the axial layer, forming the conjugate triplet **3̄** with basis $|\bar{u}_1\rangle, |\bar{u}_2\rangle, |\bar{u}_3\rangle$.

Down-type quarks ($4\epsilon_-, 2\epsilon_+$)

Down-type (d,s,b) Gen-I quarks have:

- 4 Electrinos and 2 Positrinos among 6 slots.

All admissible axis-class patterns consistent with $4\epsilon_-, 2\epsilon_+$ and the "two-same + one-different" rule group naturally into two **families**.

Family I - one positive-polarity dyad, two negative-polarity dyads

Written as (1,2,3):

- (A) negative, negative, positive
- (B) negative, positive, negative
- © positive, negative, negative

Here:

- Background: negative-polarity dyads on two axes.
- Exceptional: positive-polarity dyad on one axis.

Family II - one negative-polarity dyad, two mixed dyads

- (D) mixed, mixed, negative
- (E) mixed, negative, mixed
- (F) negative, mixed, mixed

Here:

- Background: mixed dyads on two axes.
- Exceptional: negative-polarity dyad on one axis.

In both families, the same structural pattern appears:

> Two axes share one class; one axis in the other class.

Thus for down-type d we again define:

- $|d_1\rangle$: 1 axis is exceptional, either a positive-polarity dyad among negative-polarity dyads or a negative-polarity dyad among mixed dyads.
- $|d_2\rangle$: 2 exceptional.
- $|d_3\rangle$: 3 exceptional.

and:
$\mathcal{H}_d^{\text{color}} = \operatorname{span}\{|d_1\rangle, |d_2\rangle, |d_3\rangle\} \cong \mathbb{C}^3$.

Family selection: dynamic, not arbitrary

The branch rule must avoid over-prediction.

- If **both** families were independently stable and long-lived for the same down-flavor, we'd have extra down-like quarks beyond d/s/b. That is not observed.

- Therefore, the dynamics must:

1. Select exactly one family for each realized down-type branch over a declared stability window, or
2. Make one family metastable/short-lived only at high energies, or
3. Contextually select families inside hadrons (baryon environment determines which pattern survives).

The shared branch-selection rule is therefore:

$$F_\star(q,\mathcal{B}) \in \{I, II\}, \qquad q \in \{d, s, b\}$$

where $\mathcal{B}$ denotes the local branch context: generation tier, hadron boundary conditions, effective forcing window, and Noether sea environment. Once $F_\star$ is selected, its three 1/2/3 permutations form the red/green/blue triplet for that down-type quark. The other family is a competing branch sector, not an additional observed species.

Rigorous low-energy branch-selection criterion

Fix one down flavor and let Ω_I, Ω_{II} be the Family I/II constrained sectors of the full 9-axis baryon network phase space (after quotienting axis-label gauge redundancy).

Define the reduced energy minima

$$E_F^\star \equiv \min_{X\in\Omega_F} \mathcal{E}(X), \qquad F \in \{I, II\}$$

and local Hessians

$$H_F \equiv D^2\mathcal{E}(X_F^\star)$$

For finite but low noise/temperature scale $T_{\mathcal{Q},W}$, with temperature understood as a same-record ensemble variable in the sense of Entropy, use the harmonic free-energy approximation

$$\mathcal{F}_F(T_{\mathcal{Q},W}) = E_F^\star + \frac{T_{\mathcal{Q},W}}{2}\log\det H_F + \mathcal{O}(T_{\mathcal{Q},W}^2)$$

Linearize the delay dynamics about each minimizer and let

$$\rho_F \equiv \max_{j\neq 1} |\mu_j^{(F)}|$$

be the Floquet spectral radius of nontrivial multipliers.

Theorem (Single-family low-energy survival).
Assume there exists $F_\star \in \{I, II\}$ such that:

1. **Local dynamical stability:** $\rho_{F_\star} < 1$.
2. **Competitor exclusion:** either $\rho_{\bar{F}} \geq 1$ (linearly unstable), or $\rho_{\bar{F}} < 1$ and

$$\Delta\mathcal{F} \equiv \mathcal{F}_{\bar{F}} - \mathcal{F}_{F_\star} > 0$$

3. **Low-energy regime:** $T_{\mathcal{Q},W} \ll \Delta\mathcal{F}$ and forcing amplitude is below the inter-family escape barrier.

Then stationary occupation satisfies

$$\frac{\pi_{\bar{F}}}{\pi_{F_\star}} \lesssim \exp\left(-\frac{\Delta\mathcal{F}}{T_{\mathcal{Q},W}}\right)$$

so $\pi_{\bar{F}} \to 0$ as $T_{\mathcal{Q},W} \to 0$. Hence exactly one down-family survives as the low-energy ambient family.

Proof sketch: stable branches are metastable wells of the same delay flow; occupation ratio follows from large-deviation/Kramers scaling with free-energy gap, and unstable branches have zero asymptotic weight. The harmonic free-energy and Kramers steps are part of the approximation burden: the reduced state-dependent delay record must admit this metastable-well reduction before the criterion becomes quantitative.

Concrete screening corollary (Family II preference test).
If the reduced minimum can be decomposed as

$$E_F^\star = E_{\text{core},F} + E_{\text{self-hit},F} + E_{\text{strain},F} - s\,N_{\text{mix}}^{(F)}$$

with $N_{\text{mix}}^{(I)} = 0$, $N_{\text{mix}}^{(II)} = 2$, then Family II is selected whenever

$$2s > \left(E_{\text{core},II} - E_{\text{core},I}\right) + \left(E_{\text{self-hit},II} - E_{\text{self-hit},I}\right) + \left(E_{\text{strain},II} - E_{\text{strain},I}\right)$$

and the stability condition $\rho_{II} < 1$ holds.

Failure condition (theory-level, explicit).
The model fails this selection requirement if, over the low-energy ambient window relevant to nucleons,

$$\rho_I < 1, \qquad \rho_{II} < 1, \qquad |\mathcal{F}_{II} - \mathcal{F}_I| \le \varepsilon_F$$

for tolerance ε_F set by simulation uncertainty and environmental broadening.
In that case both families are generically long-lived and comparably populated, which over-predicts down-type species and requires revision of the assembly-selection mechanism.

Color Hilbert Space and SU(3) Structure

For any quark flavor q, define the color state space

$$\mathcal{H}_q^{\text{color}} \equiv \text{span}\{|q_1\rangle, |q_2\rangle, |q_3\rangle\} \cong \mathbb{C}^3$$

where $|q_1\rangle, |q_2\rangle, |q_3\rangle$ mean "axis-exceptionality on 1/2/3", respectively.
Fix this ordered basis and identify it with the canonical triplet basis

$$|q_1\rangle \leftrightarrow e_1, \quad |q_2\rangle \leftrightarrow e_2, \quad |q_3\rangle \leftrightarrow e_3$$

Admissible color transformations

We model internal color reconfiguration by linear maps $U : \mathcal{H}_q^{\text{color}} \to \mathcal{H}_q^{\text{color}}$ satisfying:

- Preserve net electric charge and total axial inventory.
- Preserve the one-axis-exceptionality sector (map superpositions of $|q_1\rangle, |q_2\rangle, |q_3\rangle$ to itself).
- Preserve Born norm (probability conservation): $U^\dagger U = I$.
- Preserve oriented color volume (gauge-fixed convention): $\det U = 1$.

So the effective color action is represented by

$$U \in SU(3)$$

The usual global phase map $|q\rangle \to e^{i\theta}|q\rangle$ is treated as unobservable gauge redundancy (it does not change which axis is exceptional or relative axis phases).

Generator basis from axis operations

Let E_{ab} be matrix units in the ordered basis $(1, 2, 3)$, i.e.
$(E_{ab})_{cd} = \delta_{ac}\delta_{bd}$ for $a, b \in \{1, 2, 3\}$.
Define Hermitian generators:

$$T_{ab}^{(x)} \equiv \frac{1}{2}(E_{ab} + E_{ba}), \qquad T_{ab}^{(y)} \equiv -\frac{i}{2}(E_{ab} - E_{ba}) \quad (a < b)$$

giving six off-diagonal generators:
$(12), (13), (23)$ each with (x, y) components.
Define diagonal generators:

$$H_1 \equiv \frac{1}{2}(E_{11} - E_{22}), \qquad H_2 \equiv \frac{1}{2\sqrt{3}}(E_{11} + E_{22} - 2E_{33})$$

These eight matrices are exactly the standard $T^a = \lambda_a/2$ basis in the indexed-axis ordering.

Algebra closure (rigorous statement)

Proposition. The real span of

$$\mathcal{B} = \{T_{12}^{(x)}, T_{12}^{(y)}, T_{13}^{(x)}, T_{13}^{(y)}, T_{23}^{(x)}, T_{23}^{(y)}, H_1, H_2\}$$

is an 8-dimensional Lie algebra isomorphic to $\mathfrak{su}(3)$; equivalently,

$$[T^a, T^b] = if^{abc}T^c$$

for the standard SU(3) structure constants in this basis.

Proof. Each element of $\mathcal{B}$ is Hermitian and traceless, and there are eight linearly independent such matrices. Under the basis identification above, $\mathcal{B}$ maps one-to-one to the Gell-Mann basis $\{\lambda_a/2\}_{a=1}^{8}$, whose commutator algebra is $\mathfrak{su}(3)$. Therefore the axis-exceptionality generators close under commutator with the same structure constants.

Eightfold-way recovery residual

The historical Eightfold Way lesson is useful here only as an algebraic recovery target: $SU(3)$ first classified hadrons by triplet, conjugate-triplet, and adjoint/octet representations before supplying the underlying strong-sector dynamics. In $\mathbb{AAA}$ terms, that means the axis-exceptionality construction must recover the representation bookkeeping while keeping the Noether braid as the ontology.

The branch condition is:

$$\mathcal{H}_q^{\text{color}} \cong \mathbf{3}, \qquad \mathcal{H}_{\bar{q}}^{\text{color}} \cong \bar{\mathbf{3}}, \qquad \text{span}_{\mathbb{R}}\mathcal{B} \cong \mathbf{8}_{\text{adj}}$$

with the observable closed sectors assembled through the usual singlet-containing products

$$\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{1} \oplus \mathbf{8}, \qquad \mathbf{3} \otimes \mathbf{3} \otimes \mathbf{3} \supset \mathbf{1}$$

This does not identify the Eightfold Way flavor octets with color itself. It says that any successful color branch must reproduce the same algebraic fact that eight traceless generators organize an octet-class residual, while native confinement and color-singlet closure still come from axis exceptionality, braid closure, and Noether sea energetics.

Symmetry breaking is then tested as a residual, not promoted to a second color rule. Let M_{obs} be the observed hadron mass vector for a chosen baryon or meson octet, and let $M_{\mathbb{AAA}}(\theta)$ be the mass vector predicted after projecting a closed color-singlet assembly onto its flavor and axial-layer labels. The admissible branch must support a decomposition

$$M_{\mathbb{AAA}}(\theta) = m_0\mathbf{1} + \alpha T_8 + \beta D_8 + \Delta_{\text{axis}}(\theta)$$

where T_8 and D_8 denote the two octet-breaking directions available to the adjoint classification, and $\Delta_{\text{axis}}(\theta)$ is the native correction from indexed-axis response differences, axial-layer family selection, and braid energy. The recovery residual is

$$\mathcal{R}_8 = \min_{m_0,\alpha,\beta,\theta} \|M_{\text{obs}} - (m_0\mathbf{1} + \alpha T_8 + \beta D_8 + \Delta_{\text{axis}}(\theta))\|$$

A branch fails this Eightfold-way check if $\mathcal{R}_8$ can be made small only by fitting unrelated parameters separately for baryons, mesons, and color confinement, or if Δ_{axis} erases the triplet/conjugate-triplet and adjoint structure above. The source signal to preserve is therefore narrow: algebraic classification and Gell-Mann-Okubo-style mass splitting are recovery constraints on the emergent branch, not evidence that the classification algebra is the underlying medium.

Example: 1↔2 axis-swap generator

The infinitesimal 1↔2 mixer is

$$T_{12}^{(x)} = \frac{1}{2}\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} = \frac{\lambda_1}{2}$$

It continuously rotates exceptionality between 1 and 2 while leaving 3 unchanged at first order. Together with $T_{12}^{(y)} = \lambda_2/2$, it generates the embedded SU(2) subgroup acting on the $(1,2)$ color plane.

Baryons, Color Singlets, and the 9-Axis Braid

A Gen-I baryon (e.g., proton or neutron) consists of:

- 3 quarks → 3 Noether braids
- Each with 1, 2, 3 axes
- Total of **9 axes**: 1_1,2_1,3_1; 1_2,2_2,3_2; 1_3,2_3,3_3.
- 18 scaffold architrinos + 18 axial architrinos → **36 architrinos**.

Color singlet condition as closed braid

In SU(3):

- Baryon color state: $3 \otimes 3 \otimes 3 \supset 1$ (fully antisymmetric singlet).

In A1-based geometry:

- A color singlet baryon is a configuration where each of 1, 2, 3 is exceptional **once** across the three quarks, and the 9 axes form a **closed coupling network** (a closed braid).

- Example proton (uud, schematic):

    - Quark 1 (u): exceptional on 1 → $|u_1\rangle$
    - Quark 2 (u): exceptional on 2 → $|u_2\rangle$
    - Quark 3 (d): exceptional on 3 within the selected down-type family $F_\star \to |d_3; F_\star\rangle$

The displayed assignment is one component of the fully antisymmetrized color singlet; the physical SU(3) singlet sums the 1/2/3 assignments with the Levi-Civita color tensor.

At large distances, axis-dependent multipoles from each regime cancel:

- 1-exceptionality from one quark is compensated by 2 and 3 exceptionality from others in the composite singlet combination.
- Net color flux into the surrounding Noether sea is zero; only isotropic observer-level monopole readouts (charge, baryon number, effective mass) remain.

This closed 3-strand braid (in color space) is **topologically distinct** from 2-strand configurations (mesons). Breaking a baryon into pure leptons/mesons would require nonlocal rupture of the Noether braids: that is the topological underpinning for **baryon number conservation** in this model (proton stability).

Residual Strong Force and Nuclear Binding

Even for color-singlet nucleons:

- Internal 1, 2, 3 structures and down-quark family choices determine how perfectly the 9-axis braid is screened at distances $\lesssim$ 1–2 fm.

Heuristic:

- At inter-nucleon separations ~ a few fm, the source record's more exposed axis-3 channels (and to some degree axis-2 channels) from neighboring nucleons begin to overlap and couple through the Noether sea.
- These residual couplings act like **meson exchange** in standard nuclear physics, producing an attractive Yukawa-like force with a hard-core repulsion scale tied to the less exposed indexed channels.

The downstream nucleon-potential derivation must use:

- the selected down-quark Family-I or Family-II sector,
- Axis-overlap geometry (3-3, 3-2 interactions),

as its inputs for nucleon–nucleon potentials and binding energies in the nuclear section. The local interface is:

> Residual strong force emerges from the same axis/braid structure as color, via imperfect screening of 1/2/3 at finite nucleon separations.

Closure Interface: Confinement Energy Scaling
